Renal Physiology*

Updated by: Brian Chang • Jonathan Hastie

The kidneys play a central role in the maintenance of homeostasis of the body. The kidneys stabilize extracellular fluid electrolyte composition, maintain acid-base balance, regulate volume status and blood pressure, secrete erythropoietin and renin, and excrete toxins and metabolic waste. These functions involve complex interactions within the kidneys and with other organ systems and are frequently altered during anesthesia. Hence, a thorough understanding of kidney function is important for the anesthesiologist before, during, and after patients receive care in the operating room.

Kidney Structure and Function

Basic Anatomy of the Kidney

The kidneys are paired organs located below the diaphragm in the retroperitoneal space, weighing between 115 and 160 g each. Each kidney has an outer portion (cortex) and inner portion (medulla). The renal arteries arise from the abdominal aorta, and the renal veins direct blood flow into the inferior vena cava. The kidneys are prominently innervated by the sympathetic nervous system from T4 to T12.

The nephron is the functional unit of the kidney ([Figure 16.1](#)). A nephron is composed of a capillary bed called the **glomerulus** surrounded by epithelial cells called **Bowman capsule**. Bowman capsule, in turn, is continuous with a long tubule that drains into the renal pelvis. Fluid is filtered through the glomerular capillaries and is converted, along the length of the renal tubule, into urine.¹ There are two types of nephrons: Juxtamedullary nephrons are located near the corticomedullary border and have long tubules that descend deep into the renal medulla, whereas cortical nephrons are closer to the surface of the kidney and have shorter tubules that only penetrate the outer portion of the renal medulla.

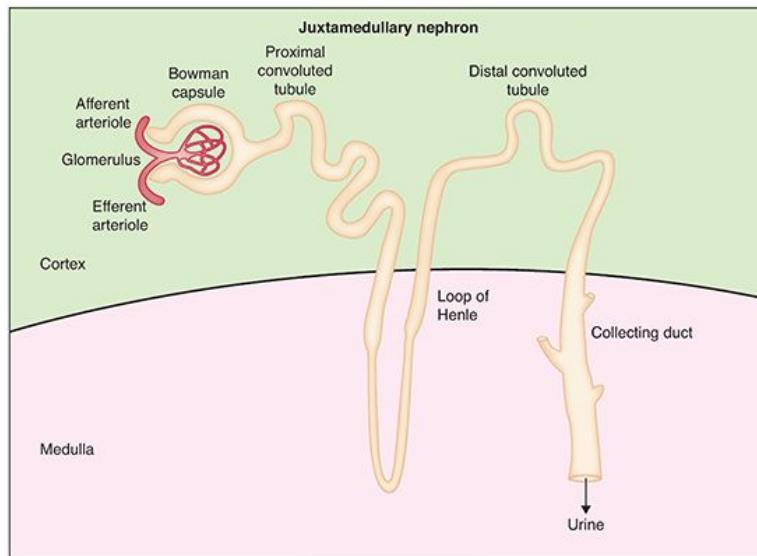

FIGURE 16.1 Schematic depiction of a juxtamedullary nephron.

The Glomerulus

Structure and Function of the Glomerulus

Glomeruli are found in the renal cortex and consist of a tuft of capillaries surrounded by Bowman capsule, the dilated blind end of the renal tubule. Glomerular capillaries are uniquely interposed between two sets of arterioles. Blood flows from the afferent arterioles through the glomerular capillaries and then on to the efferent arterioles. Hence, pressure in the glomerular capillaries is a function of the vascular activity of both the afferent and efferent arterioles ([Figure 16.2](#)): Afferent vasoconstriction lowers glomerular capillary pressure, whereas efferent arteriolar vasoconstriction raises glomerular capillary pressure. Glomerular capillary pressure causes water and low molecular weight substances to be filtered into Bowman capsule and the renal tubule system.

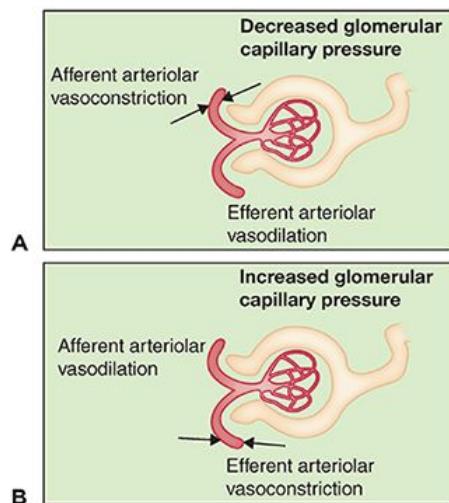

FIGURE 16.2 Glomerular filtration pressure. A, Afferent arteriolar vasoconstriction decreases glomerular capillary pressure and hence decreases glomerular filtration rate (GFR). B, Efferent arteriolar vasoconstriction increases glomerular capillary pressure and hence increases GFR.

Fluid that is filtered from the glomerular capillaries into the renal tubules is called **glomerular filtrate**. The permeability of the glomerular capillary membrane is much greater than that of the typical tissue capillary. Fluid, amino acids, and ions are rapidly filtered, whereas higher molecular weight proteins are retained within the capillary.

Glomerular Filtration Rate

The volume of collective glomerular filtrate formed over time is called the **glomerular filtration rate (GFR)**. In a normal person, the GFR is approximately 125 mL per minute or 180 L per day. Because 99% of this 180 L of glomerular filtrate is reabsorbed, daily urine output is 1 to 2 L. As described earlier, glomerular capillary pressure leads to filtration into the renal tubule. The normal filtration pressure of approximately 10 mm Hg is calculated as glomerular capillary pressure (60 mm Hg) minus colloid osmotic pressure (32 mm Hg) and pressure in Bowman capsule (18 mm Hg) ([Figure 16.3](#)). The filtration rate is influenced by several factors. Mean arterial pressure, cardiac output, and the sympathetic nervous system may each raise glomerular capillary pressure, thus increasing the GFR.

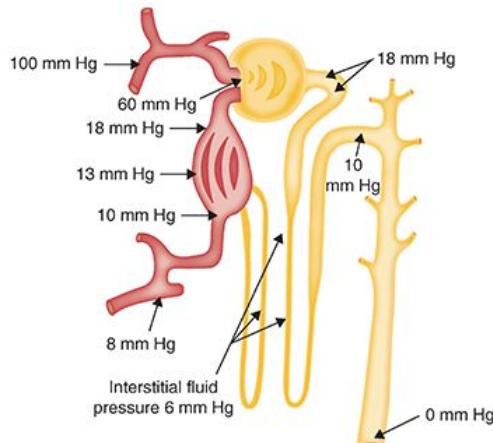

FIGURE 16.3 Intravascular pressures in the renal circulation. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

The kidneys have an autoregulatory mechanism to modulate the effect of mean arterial pressure on the GFR. This process of autoregulation involves feedback from the distal renal tubules to the glomerulus. Specialized epithelial cells in the distal renal tubules, called the **macula densa**, signal the afferent or efferent renal arterioles to either vasoconstrict or vasodilate. Through the consequent adjustment of glomerular capillary pressure, a nearly constant filtration pressure leads to a consistent GFR across a range of mean arterial pressure, remaining relatively constant between mean arterial pressures of 60 and 160 mm Hg. Because even a small change in GFR can lead to wide variations in urine output, it is clear that tubule-glomerular feedback serves an important role in homeostasis.

The Renal Tubule

Structure of the Renal Tubule

The renal tubule is composed of the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule (see [Figure 16.1](#)).¹ As described earlier, the loops of Henle in juxamedullary nephrons extend into the renal medulla before returning filtrate back to the renal cortex in the distal convoluted tubule. Glomerular filtrate, after passing along the length of the renal tubule, then enters the collecting duct, which is a confluence of filtrate from several nephrons into the renal pelvis.

Renal Tubular Function

Glomerular filtrate is converted into urine along the course of the renal tubule ([Table 16.1](#)).² The majority of water and various solutes that are filtered by glomerular capillaries are reabsorbed into peritubular capillaries. Metabolic waste products, also filtered by glomerular capillaries, are not reabsorbed. Other solutes are secreted by renal tubular epithelial cells into the lumen of the renal tubule. Thus, the urine found in the collecting duct is composed mainly of substances filtered through the glomerular capillaries and a small amount of secreted substances. The process of reabsorption determines the volume of urine formed, whereas secretion is particularly important in determining the nature of the urine, such as concentration of potassium and hydrogen ions. Various portions of the renal tubule have differing roles in reabsorption and secretion (see [Table 16.1](#)).² Approximately two-thirds of all reabsorption and secretion in the renal tubules occurs in the proximal renal tubules. The most important factors influencing the reabsorption of sodium and water are aldosterone, arginine vasopressin (AVP), renal prostaglandins, and atrial natriuretic peptide.

TABLE 16.1

Magnitude and site of solute reabsorption or secretion in the renal tubules

Filtered (24)	Reabsorbed (24)	Secreted (24)	Excreted (24)	%	Location
---------------	-----------------	---------------	---------------	---	----------

	hours)	hours)	hours)	hours)	Reabsorbed	
Water (L)	180	179	—	1	99.4	P, L, D, C
Sodium (mEq)	26,000	25,850	—	150	99.4	P, L, D, C
Potassium (mEq)	600	560	50	90	93.3	P, L, D, C
Chloride (mEq)	18,000	17,850	—	150	99.2	P, L, D, C
Bicarbonate (mEq)	4,900	4,900	—	0	10	P, D
Urea (mM)	870	460	—	410	53	P, L, D, C
Uric acid (mM)	50	49	4	5	98	P
Glucose (mM)	800	800	—	0	100	P

Abbreviations: C, convoluted tubule; D, distal tubule; L, loop of Henle; P, proximal tubule.

Reabsorption of sodium involves moving this ion against a concentration gradient from the lumen of the proximal tubule into peritubular capillaries. This process requires energy, supplied by the sodium-potassium adenosine triphosphatase (ATPase) system. Other transport processes along the tubule, including glucose reabsorption, amino acid reabsorption, and organic acid secretion, share a common carrier with sodium. Hence, the great majority of transport across renal tubular cells is dependent on sodium-potassium ATPase activity. Given this dependence on the sodium-potassium ATPase, the proximal convoluted renal tubules consume approximately 80% of renal oxygen consumption.³

More than 99% of the water in the glomerular filtrate is reabsorbed into peritubular capillaries as it passes through renal tubules. The variation in permeability of epithelial cells lining the tubules is important in renal function. Rapid osmosis of water through proximal renal tubules means that the concentration of solutes on the capillary side of cell membranes is almost never more than a few milliosmoles greater than in the tubular lumen. However, the distal tubules are almost completely impermeable to water, allowing for control of the specific gravity of the urine. The permeability of the collecting ducts is variable and determined by the action of AVP. When AVP activates adenylate cyclase in the epithelial cells lining the collecting duct, the resulting cyclic adenosine monophosphate increases permeability of cell membranes to water via aquaporins. Hence, increased AVP leads to reabsorption of water from the collecting ducts and small amounts of highly concentrated urine. Decreased AVP results in little water reabsorption and large amounts of dilute urine.

Countercurrent System

The ability of the kidneys to produce either dilute or concentrated urine depends on the osmolarity gradient between the renal cortex and renal medulla that is created by the loop of Henle. Whereas the renal cortex has a relatively low osmolarity (300 mOsm/L), the renal medulla contains highly concentrated interstitial fluid (1,400 mOsm/L near the renal pelvis) due to active reabsorption of solutes in the loop of Henle ([Figure 16.4](#)).³ The high medullary osmolarity is maintained in part by sluggish blood flow, preventing the removal of solutes.

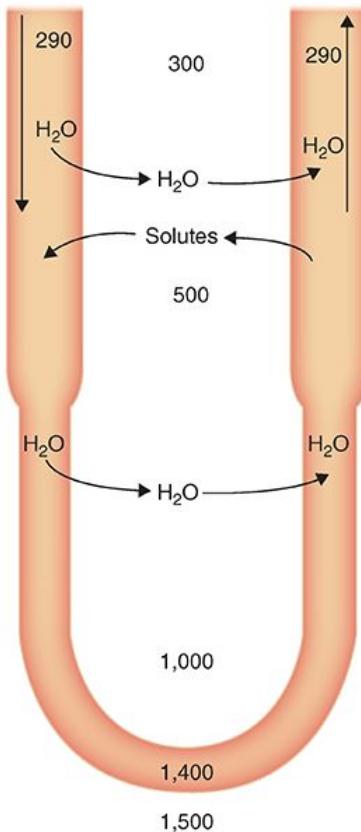

FIGURE 16.4 Countercurrent exchange of water and solutes in the vasa recta. Adapted from Lote CJ, Harper L, Savage CO. Mechanisms of acute renal failure. Br J Anaesth. 1996;77(1):82-89 and Lote CJ. Principles of Renal Physiology. 3rd ed. London: Chapman and Hall; 1994. Copyright © 1996 Elsevier. With permission.

Just as the juxamedullary loops of Henle carry glomerular filtrate from the cortex into the renal medulla and back to the cortex, the vascular supply has a similar structure. The U-shaped arrangement of peritubular capillaries, known as the **vasa recta**, parallels the loops of Henle. This forms a countercurrent system, in which capillary inflow runs parallel and in an opposite direction to capillary outflow.

Aquaporins

The high osmolarity in the renal medulla allows for the potential for quick reabsorption of water by osmosis as filtrate passes through the renal collecting ducts. This process is mediated by aquaporins, which are channels that facilitate rapid passage of water across lipid cell membranes at a velocity greater than possible by simple diffusion.⁴⁻⁶ They are tetramer protein structures and are found in the kidneys, brain, salivary and lacrimal glands, and respiratory tract. Five aquaporins in the kidney have a role in water balance.⁵ Aquaporin 1 is in the proximal renal tubules, whereas aquaporin 2 is found in the renal collecting ducts. In response to AVP, the channels in the tubular collecting duct epithelium are opened, leading to reabsorption of water and formation of concentrated urine. In the absence of AVP, dilute urine travels through the collecting ducts without being affected by medullary osmolarity.

Tubular Transport Maximum

Tubular transport maximum (T_{max} or T_{max}) is the maximum amount of a substance that can be actively reabsorbed from the lumens of renal tubules each minute. The T_{max} depends on the amounts of carrier substance and enzyme available to the specific active transport system in the lining epithelial cells of renal tubules.

For example, the T_{max} for glucose is approximately 220 mg per minute. When the amount of glucose that filters through the glomerular capillary exceeds this amount, the excess glucose cannot be reabsorbed and passes into urine ([Figure 16.5](#)). The usual amount of glucose in the glomerular filtrate entering proximal renal tubules is 125 mg per minute, and there is no detectable loss into urine. When the tubular load, however, exceeds approximately 220 mg per minute (threshold concentration), glucose begins to appear in urine. A blood glucose concentration of 180 mg/dL in the presence of a normal GFR results in delivery of 220 mg per minute of glucose into the renal tubular fluid. Loss of glucose in urine occurs at concentrations above the T_{max} for glucose. The presence of large amounts of unreabsorbed solutes in the urine such as glucose (or mannitol) produces osmotic diuresis by retaining water in the collecting duct system.

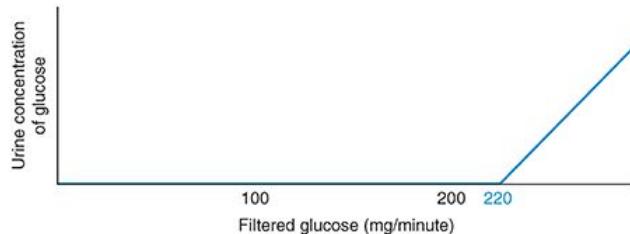

FIGURE 16.5 Transport maximum for glucose. Urinary concentration of glucose is negligible until the amount of filtered glucose exceeds the transport maximum.

Transport of Urine to the Bladder

From the collecting ducts, urine travels into the renal pelvis. A ureter arises from the pelvis of each kidney. At its distal end, the ureter penetrates the bladder obliquely such that pressure in the bladder compresses the ureter, thereby preventing reflux of urine into the ureter when bladder pressure increases during micturition.

Each ureter is innervated by the sympathetic and parasympathetic nervous system. As urine collects in the renal pelvis, the pressure in the pelvis increases and initiates a peristaltic contraction that travels downward along the ureter to force urine toward the bladder. Parasympathetic nervous system stimulation increases the frequency of peristalsis, whereas sympathetic nervous system stimulation decreases peristalsis.

Obstruction of a ureter by a stone causes intense reflex constriction and pain. This pain elicits a sympathetic nervous system reflex (ureterorenal reflex) that causes vasoconstriction of the renal arterioles and a concomitant decrease in urine formation in the kidney.

As the bladder fills with urine, stretch receptors in the bladder wall initiate micturition contractions. Sensory signals are conducted to the sacral segments of the spinal cord through the pelvic nerves and then back again to the bladder through parasympathetic nervous system fibers. The micturition reflex is a completely automatic spinal cord reflex that can be inhibited (tonic contraction of the external urinary sphincter) or facilitated by centers in the brain. Spinal cord damage above the sacral region leaves the micturition reflex intact but severs the connection to the brain.

Renal Blood Flow

Although the kidneys represent about 0.5% of total body weight, their blood flow is disproportionately large at 20% to 25% of the cardiac output.³ Renal blood flow is approximately 400 mL/100 g per minute, compared with 70 mL/100 g per minute for the heart and liver. Autoregulation keeps renal blood flow relatively constant across a range of systemic mean arterial pressures. Because renal blood flow is large, the fraction of oxygen extraction is low despite high oxygen consumption. The PO_2 decreases from 95 mm Hg in the renal artery to about 70 mm Hg in the renal vein.

Approximately 90% of the renal blood flow is distributed to the renal cortex, with less than 10% of renal blood flow going to the medulla. The generous delivery of blood to the cortex supports flow-dependent functions such as glomerular filtration and tubular reabsorption processes of the cortex. By contrast, low blood flow in the medulla maintains a high interstitial fluid osmolarity, which in turn permits concentration of the urine.⁷ Low blood flow also makes the medulla more susceptible to ischemia than the cortex.

Renal Cortex Blood Flow: Glomerular and Peritubular Capillaries

Blood enters the renal artery, whose branches ultimately supply the afferent arterioles of the glomeruli. As described earlier, afferent arterioles feed the glomerular capillary bed (see [Figure 16.1](#)).¹ The pressure in the glomerular capillary bed can be raised by an increase in the vascular resistance of the efferent arterioles. Increased glomerular capillary pressure increases filtration of fluid into Bowman capsule. Blood also flows from the arterioles into a second capillary network called **peritubular capillaries**. These capillaries have substantially lower pressure (see [Figure 16.3](#)),⁸ promoting reabsorption of fluid from the tubules into the peritubular capillaries.

Renal Medulla Blood Flow: The Vasa Recta

The **vasa recta**, described earlier in the countercurrent system, receive only 1% to 2% of renal blood flow. These capillaries, after descending into the renal medulla, return to the renal cortex and empty into veins. As described earlier, this countercurrent system minimizes the washout of solutes from the interstitial fluid of the medulla creating a high osmolarity that promotes the absorption of water from the collecting ducts and the formation of concentrated urine.

Autoregulation of Renal Blood Flow

As noted previously, autoregulation keeps renal blood flow and GFR relatively constant within a range of mean arterial pressure between approximately 60 and 160 mm Hg ([Figure 16.6](#)).⁸ Because the GFR parallels renal blood flow, cardiac output has an important effect on the GFR. The mechanism for autoregulation is controversial.⁹ One theory is a myogenic response, whereby increased perfusion pressure leads to an increased wall tension in the afferent arterioles, resulting in automatic contraction of the smooth muscle fibers in the vessel wall. This increases resistance, keeping flow constant despite the increase in perfusion pressure.³ An alternative hypothesis is that a tubuloglomerular feedback mechanism is responsible for autoregulation, whereby increased perfusion pressure will increase filtration, increasing the tubular fluid delivery to the macula densa, which then releases a factor or factors that cause vasoconstriction.

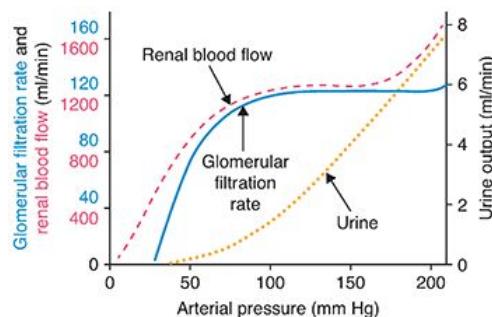

FIGURE 16.6 Autoregulation. Renal blood flow and glomerular filtration rate, but not urine output, are autoregulated between a mean arterial pressure of approximately 60 and 160 mm Hg. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

In the setting of decreased effective circulating volume, however, renal blood flow may be decreased despite adequate perfusion pressure. Activation of the sympathetic nervous system shunts cardiac output away from the kidneys. Hence, adequate systemic blood pressure does not necessarily indicate adequate renal perfusion in the presence of hypovolemia.

Juxtaglomerular Apparatus

The juxtaglomerular apparatus is where the distal renal tubule passes between the afferent and efferent arterioles and is composed of the macula densa and juxtaglomerular cells. In response to decreased renal blood flow, juxtaglomerular cells release renin into the circulation ([Figure 16.7](#)).³ Renin converts angiotensinogen to angiotensin I, which is then converted to angiotensin II by angiotensin-converting

enzyme. Effects of angiotensin II include thirst, vasoconstriction, and salt and water reabsorption by the kidneys to maintain circulating volume and increase renal blood flow. Whether the initial cause of decreased renal blood flow is the result of hypovolemia, systemic hypotension, or sympathetic nervous system stimulation, the effect of renin is to maintain renal blood flow and GFR.

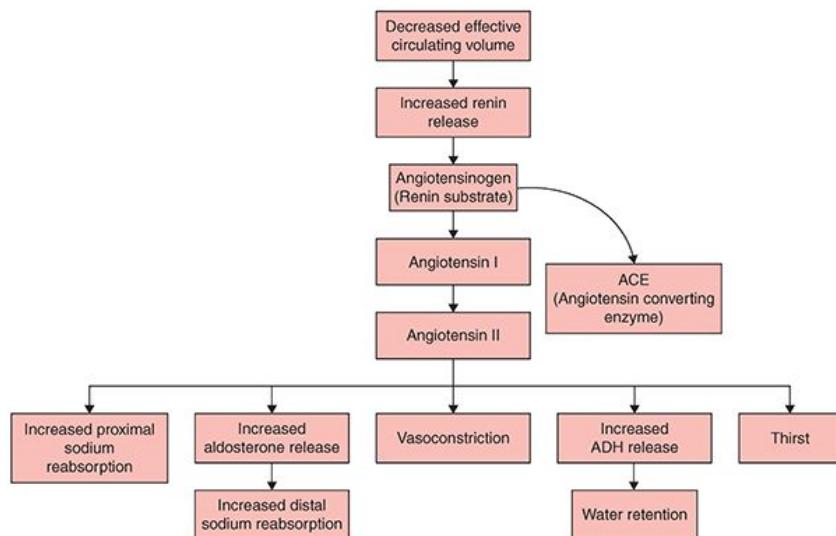

FIGURE 16.7 The role of the renin-angiotensin system in the maintenance of effective circulating volume. Abbreviation: ADH, antidiuretic hormone. Reprinted from Lote CJ, Harper L, Savage CO. Mechanisms of acute renal failure. Br J Anaesth. 1996;77(1):82-89; Copyright © 1996 Elsevier. With permission.

Regulation of Body Fluid

The kidneys have a primary role in the regulation of the amount and nature of body fluids. They control the following characteristics:

- Blood and extracellular fluid volume
- Osmolarity of body fluids
- Plasma concentration of ions and urea

Blood and Extracellular Fluid Volume

Blood volume is maintained over a narrow range despite large daily variations in fluid and solute intake or loss. The mechanism for control of blood volume also affects systemic blood pressure and cardiac output. An increase in blood volume increases the cardiac output, which usually increases the systemic blood pressure. Increased cardiac output and systemic arterial pressure will increase renal blood flow and GFR, resulting in an increase in urine output. The negative feedback loop is completed by a consequent decrease in circulating blood volume.

This basic regulatory mechanism is augmented by other factors. In the setting of decreased blood volume, an increased circulating concentration of AVP will increase water reabsorption, whereas an increase in aldosterone will promote sodium reabsorption and thus an osmotic reabsorption of water. This decreases urine volume and restores blood volume. Another factor is mediated through atrial stretch receptors and atrial natriuretic peptide to be described in the next section.

Regulation of normal circulating blood volume is impaired by factors directly affecting vascular capacitance. Persistent vasoconstriction associated with essential hypertension or sympathetic nervous system stimulation (eg, pheochromocytoma) results in a decrease in blood volume. Conversely, blood volume may be increased by chronic drug-induced vasodilation or the effects of severe varicose veins.

The regulation of extracellular fluid volume is controlled indirectly through the maintenance of circulating blood volume. An increase in blood volume leads to an increase in extracellular fluid volume,

whereas decreased extracellular fluid volume accompanies reduced blood volume. Although these volumes move in the same direction, their proportional change is affected by capillary permeability, which is commonly influenced by perioperative factors. Oxidative injury, ischemia/reperfusion injury, hypervolemia, and significant blood loss, damage the endothelial glycocalyx, which plays an important role in regulating vascular permeability.¹⁰ The extracellular fluid space may be considered as a reservoir for excess intravenous fluid administered during the perioperative period.

Atrial and Renal Natriuretic Factors

Cardiac atrial muscle synthesizes and secretes a peptide hormone known as **atrial natriuretic peptide** (ANP), which is released in response to increased right and left atrial pressure and volume. The ANP binds to receptors in the renal collecting ducts and, acting via transcellular second messenger systems, inhibits sodium reabsorption. Hence, atrial “stretch” promotes elimination of sodium and water, and a subsequent decrease in circulating volume. The ANP additionally has vasodilatory properties, thereby lowering systemic blood pressure and eliciting renal artery vasodilation.

The renal analogue of ANP is renal natriuretic peptide (urodilatin), which is synthesized in renal cortical nephrons. It is likely that ANP is primarily a cardiovascular regulator and relatively unimportant for sodium excretion, whereas renal natriuretic peptide participates in the intrarenal regulation of sodium excretion.^{3,11} In mechanical ventilation, positive end-expiratory pressure reduces atrial distension and atrial transmural pressure, by decreasing venous return. This reduces ANP release, which may contribute to sodium and water retention by the kidneys in patients who are mechanically ventilated.

Osmolarity of Body Fluids

The primary determinant of body fluid osmolarity is the concentration of sodium in the extracellular fluid. Sodium ion concentration is largely controlled by two mechanisms: the osmoreceptor-AVP response and the thirst reflex. Aldosterone, by contrast, has a minimal role in the maintenance of sodium concentration and plasma osmolarity ([Figure 16.8](#)).⁸ Aldosterone-induced reabsorption of sodium is accompanied by reabsorption of water. For this reason, patients with primary hyperaldosteronism typically have increased extracellular fluid volume but nearly normal serum sodium levels.

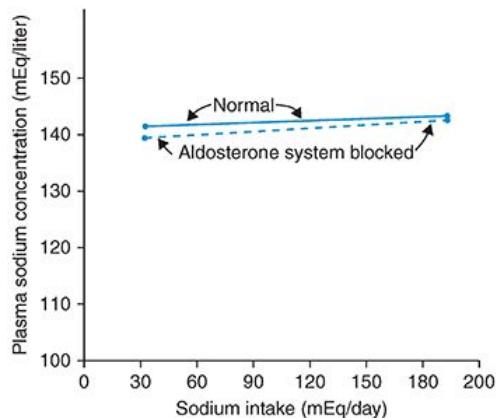

FIGURE 16.8 In the absence of aldosterone, the plasma concentration of sodium varies less than 2% over a sixfold range in sodium intake. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Osmoreceptor–Arginine Vasopressin Hormone

In response to increased extracellular fluid osmolarity, osmoreceptors in the hypothalamus signal the posterior pituitary to increase the release of AVP. The AVP is also secreted in the setting of water deprivation and hemorrhage. Circulating AVP causes collecting ducts to reabsorb water, thus decreasing serum sodium levels. Decreased sodium levels result in a decrease in serum osmolarity. The inverse is also true. Abnormally low

extracellular fluid osmolality will lead to a decrease in the release of AVP, thereby increasing the production of dilute urine. This increases serum sodium and osmolarity toward normal. A small change in osmolarity (as little as 1%) can produce a large change in circulating AVP concentration, producing tight regulation of serum osmolality.

Thirst Reflex

The thirst reflex is primarily elicited by an increase in sodium concentration in the extracellular fluid. An increase in sodium as small as 2 mEq/L above normal (or an increase in osmolarity of approximately 4 mOsm/L) will stimulate thirst, and water consumption decreases sodium concentration toward normal. In this way, extracellular fluid osmolarity is maintained within a narrow range. In addition, angiotensin II promotes a thirst response, so circulatory changes that increase the production of angiotensin II, such as acute hemorrhage or congestive heart failure, will increase thirst.

Plasma Concentration of Ions and Urea

Sodium

The kidneys control the concentration of sodium through the process of reabsorption. As described earlier, active transport moves sodium ions from the tubular lumen into the peritubular capillaries. Two-thirds of the sodium in glomerular filtrate is reabsorbed in the proximal renal tubule, and less than 10% of sodium is expected to reach the distal renal tubule. The renin-angiotensin-aldosterone system (RAAS) modulates the sodium reabsorption via the renal tubules. Hypotension or decreased circulating blood volume activates the RAAS, increasing levels of angiotensin II, which ultimately results in increased sodium reabsorption.

Angiotensin II leads to efferent arteriole vasoconstriction, increasing glomerular capillary pressure and GFR. It also increases secretion of aldosterone, which exerts its effect in the distal renal tubule. When aldosterone levels are increased, nearly all the remaining sodium is reabsorbed from the distal tubule, and urinary excretion of sodium is negligible. Typically, only 1% of the filtered sodium is excreted in the urine (see [Table 16.1](#)).²

Potassium

Potassium, after being filtered through the glomerulus, is then reabsorbed by the proximal tubule and loop of Henle. Potassium is either reabsorbed or secreted in the distal tubule and collecting duct, depending on the level of aldosterone. An increase in aldosterone increases potassium ion secretion into the renal tubules and consequently increases urinary potassium. The feedback mechanism allows for close regulation: Small changes in potassium concentration will lead to a substantial change in the concentration of aldosterone ([Figure 16.9](#)).⁸ When aldosterone activity is inhibited by certain diuretics (ie, spironolactone and eplerenone), plasma potassium concentration depends more on dietary intake of potassium, making hypokalemia or hyperkalemia more likely ([Figure 16.10](#)).⁸

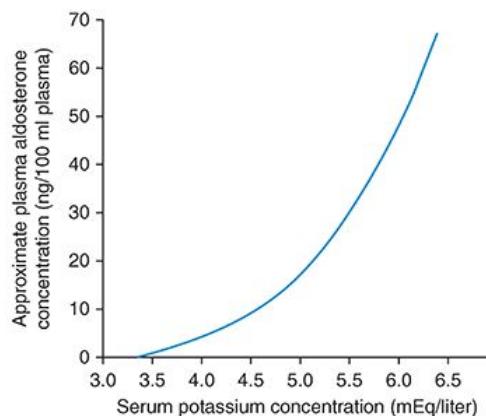

FIGURE 16.9 Small changes in the plasma concentrations of potassium evoke large changes in the plasma concentration of aldosterone. *Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed.*

Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

The regulation of sodium and hydrogen ion concentrations also has an effect on urinary excretion of potassium. Hydrogen ions compete with potassium for secretion into the renal tubules. In the presence of alkalosis (eg, vomiting and loss of gastric acid), potassium is excreted in the urine in order to maintain acid-base balance. Conversely, a metabolic acidosis will lead to the secretion of hydrogen ions and retention of potassium, and plasma potassium concentration will increase. Sodium intake may influence plasma concentrations of potassium because sodium is transported through renal tubular epithelial cells in exchange for potassium.

Acid-Base Balance

The kidneys secrete excess hydrogen ions by exchanging a hydrogen ion for a sodium ion, thus acidifying the urine, and by the synthesis of ammonia, which combines with hydrogen to form ammonium. In the presence of hypovolemia, bicarbonate reabsorption by the kidneys will lead to acidification of the urine and a metabolic alkalosis.

Calcium and Magnesium

Calcium ion concentration is controlled principally by the effect of parathyroid hormone on bone reabsorption, which releases calcium. Additionally, parathyroid hormone increases the reabsorption of calcium from the distal renal tubules and collecting ducts. Magnesium is reabsorbed by all portions of the renal tubules. Urinary excretion of magnesium parallels the plasma concentration of this ion.

Urea

Urea is the most abundant metabolic waste product. Without adequate clearance of urea, excessive accumulation in body fluids prevents normal function of multiple systems. Urea elimination depends on the plasma concentration of urea (blood urea nitrogen or BUN) and the GFR. Approximately 50% of the urea that is filtered into the renal tubules is eliminated in the urine; the remainder is reabsorbed. When the GFR is low, tubular filtrate flow is relatively slow, thus increasing the proportion of urea that is reabsorbed. This effectively increases the BUN by decreasing urinary elimination of urea. Conversely, when GFR increases, less urea is reabsorbed in the tubules, increasing its elimination in the urine, and BUN decreases.

Measuring Kidney Function

Formal measurement of kidney function requires labor-intensive studies such as collection of urine over time and measurement of blood and urine components. For clinical decision making, estimates of GFR are accessible and inexpensive, requiring only basic laboratory work. Serum creatinine (SCr), commonly used to measure changes in kidney function, is insensitive to small changes in GFR; GFR needs to decrease by about 50% before a rise in SCr is seen. For many years, the Cockcroft-Gault formula has been used to estimate GFR.¹²

$$\text{GFR}_{\text{men}} = (140 - \text{age}) \times \text{weight (kg)} / \text{serum creatinine (mg/dL)} \times 72$$

$$\text{GFR}_{\text{women}} = (140 - \text{age}) \times \text{weight (kg)} \times 0.85 / \text{serum creatinine (mg/dL)} \times 72$$

The difference in the formula between men and women accounts for the expected difference in muscle mass and creatinine production. The formula also takes into account the effect of age on GFR. Given an age-related decrease in muscle mass, GFR in an elderly person will typically be less than a younger person with the same weight and SCr.

The Modification of Diet in Renal Disease formula uses four variables to estimate GFR: age, SCr, ethnicity, and gender, and is independent of body weight.¹³ Developed in a population of patients with chronic kidney disease in the United States, it has been widely adopted as a useful estimate of GFR, although questions remain concerning its applicability to other populations. Both Cockcroft-Gault and Modification of Diet in Renal Disease assume steady-state conditions: balanced production and clearance of SCr leading to a consistent concentration. Because an acute reduction in GFR will result in a rise in SCr over many hours or days, these formulas are poor measures of GFR in acute kidney injury (AKI).

Acute Kidney Injury

The AKI results in an abrupt reduction in the kidney's ability to eliminate nitrogenous waste products and maintain fluid and electrolyte homeostasis.^{3,14} Despite the kidney's generous blood supply and large oxygen delivery, it remains at risk for ischemia in the perioperative period. The AKI may be classified by either the site of instigating pathology or the degree of injury sustained, as measured by changes in GFR and reduction in urine output. In light of the heterogeneous causes of AKI and the difficulty in comparing literature using disparate definitions,¹⁴ there has been a great deal of recent interest in standardizing and streamlining the classification of AKI.

Classification

The AKI has traditionally been classified by dividing the primary pathophysiology into prerenal, intrarenal, or postrenal causes ([Figure 16.11](#)).¹⁴

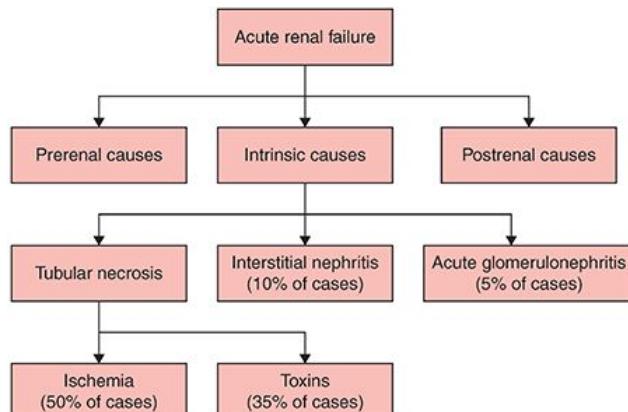

FIGURE 16.11 Classification of acute renal failure. From Thadhani R, Pascual M, Bonventre JV. Acute renal failure. N Engl J Med. 1996;334(22):1448-1460. Copyright © 1996 Massachusetts Medical Society.

Prerenal Azotemia

The term **azotemia** refers to any condition characterized by abnormally high levels of nitrogen-containing compounds, such as urea, creatinine, and other nitrogen-rich compounds, in the blood. Prerenal azotemia refers to decreases in renal function due to hypoperfusion in the setting of intact glomeruli and tubules. Correcting the underlying problems in circulation will improve renal function. Common causes of prerenal azotemia in hospitalized patients include septic shock, heart failure, liver failure, and perioperative hemodynamic changes that lead to decreased renal perfusion.¹⁴ Medications may also be implicated in at-risk patients. Nonsteroidal anti-inflammatory drugs (NSAIDs) are known to precipitate prerenal azotemia in hypovolemic patients or in patients with congestive heart failure.¹⁵ Calcineurin inhibitors (eg, cyclosporine and tacrolimus) also reduce GFR and lead to prerenal azotemia by causing vasoconstriction of afferent renal arteries.^{15,16}

Intrinsic Causes of Acute Kidney Injury

The most common cause of intrinsic renal failure is acute tubular necrosis (ATN), caused by either ischemia or nephrotoxic agents. Less common causes seen perioperatively include acute glomerulonephritis and interstitial nephritis from such agents as β -lactam antibiotics and NSAIDs (see [Figure 16.11](#)).⁸ In cases of ATN secondary to ischemia, prolonged decreases in renal blood flow stimulate epithelial cells to reabsorb sodium to restore renal blood flow. This increase in active transport in the renal medullary tubules exacerbates the mismatch of oxygen supply and demand, leading to injury and the expression of proteins that regulate the response to hypoxia.^{17,18} Thus, prerenal azotemia leads to ATN, and both entities may be considered to be on the continuum of ischemic renal disease.

Renal tubule cells are particularly susceptible to ischemia because of their transport-related oxygen requirements and the low baseline blood flow to the renal medulla. Injury is worsened both by hypoxemia and by endothelial cell swelling, which further decreases perfusion. Nephrotoxic agents such as aminoglycosides and iodinated radiocontrast media may also lead to ATN, either by direct injury to tubules or by processes mediated by free radicals.^{14,19}

The ATN secondary to renal medullary ischemia is the most common perioperative cause of AKI. In this setting, adequate urine output may be falsely reassuring. Ischemic ATN leads to failure of the sodium-potassium ATPase pump in the renal tubules, impairing their ability to concentrate urine. Thus, urine output does not correspond to the degree of cell damage or GFR in patients exposed to trauma, shock, or cardiovascular surgery.²⁰

Postrenal Obstructive Nephropathy

Perioperative patients with AKI should also be evaluated for postrenal etiologies, particularly those with acute oliguria. Because the pathophysiology underlying this AKI involves hindrance to urine flow, this is also called **obstructive nephropathy**. Causes include renal stones, prostatic hypertrophy, and mechanical obstruction of urinary catheters.

Acute Kidney Injury Diagnosis

Diagnostic Criteria

As recently as 2004, there was no widespread consensus definition of acute renal failure (ARF). Comparison of the literature was challenging as definitions and categories varied between studies. In 2004, the Acute Dialysis Quality Initiative group conducted a systematic review and consensus conference, which produced a five-tiered classification scheme for ARF, called **RIFLE** (risk, injury, failure, loss of kidney function, and end-stage kidney disease) ([Figure 16.12](#)).²¹ This scheme is based on easily measurable clinical variables and includes in its definition an accommodation for acute or chronic kidney disease.

RIFLE criteria		
	GFR criteria	Urine output criteria
Risk	Increased SCr by 1.5× or GFR decrease by 25%	UO < 0.5 mL/kg/h for six hours
Injury	Increased SCr by 2× or GFR decrease by 50%	UO < 0.5 mL/kg/h for twelve hours
Failure	Increased SCr by 3× or GFR decrease by 75% or SCr > 4 mg/dL	UO < 0.3 mL/kg/h for 24 hours or Anuria for 12 hours
Loss	Persistent acute renal failure (four weeks duration)	
ESKD	End stage kidney disease (greater than three months)	

FIGURE 16.12 The RIFLE criteria. Abbreviations: ESKD, end-stage kidney disease; GFR, glomerular filtration rate; SCr, serum creatinine; UO, urine output. Adapted by permission from Springer: Bellomo R, Ronco C, Kellum JA, et al; Acute Dialysis Quality Initiative Workgroup. Acute renal failure—definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. Crit Care. 2004;8(4):R204-R212.

The RIFLE classification includes three levels of renal dysfunction and two clinical outcomes. The degrees of renal dysfunction are defined either by changes in (1) SCr or estimated GFR or (2) oliguria. A patient may be categorized by meeting one criterion, the other, or both. The criterion that leads to the worst classification should be used.²¹

- R—risk of renal dysfunction: increased SCr by 1.5-fold (GFR decrease by 25%) or urine output less than 0.5 mL/kg per hour for 6 hours
- I—injury to the kidney: increased SCr by twofold (GFR decrease by 50%) or urine output less than 0.5 mL/kg per hour for 12 hours
- F—failure of kidney function: increased SCr by threefold (GFR decrease by 75%), SCr greater than 4 mg/dL, or urine output less than either 0.3 mL/kg per hour for 24 hours or anuria for 12 hours

Clinical outcomes include the following:

- L—Loss of kidney function is equivalent to persistent ARF, needing renal replacement therapy for more than 4 weeks.
- E—end-stage kidney disease: need for dialysis for more than 3 months

Proposed modifications to the RIFLE criteria were made by the Acute Kidney Injury Network (AKIN) in 2007 (Figure 16.13).²² The first three stages of RIFLE (risk, injury, and failure) correspond to the first three stages of injury in AKIN definitions. In addition, stage 1 AKI includes patients with a rise in SCr as little as 0.3 mg/dL, as even small increases in SCr are associated with worse outcomes.^{22,23} The AKIN further tightens the window to diagnosis of AKI by lab criteria or urine output to 48 hours as opposed to 7 days. Any patient with renal replacement therapy is included in stage 3, regardless of duration of therapy or concurrent urine output. Finally, “loss” and “end-stage kidney disease” have been removed, as they describe long-term outcomes rather than short-term categories. The RIFLE and AKIN definitions have been compared and are in general concordance. It has been suggested that the AKIN definitions do not provide significant advantages despite the increased sensitivity of stage 1 AKI.^{24,25}

RIFLE criteria			Acute Kidney Injury Network criteria		
	GFR criteria	Urine output criteria	Stage	Creatinine	Urine output criteria
Risk	Increased SCr by 1.5x or GFR decrease by 25%	UO < 0.5 mL/kg/h for six hours	1	1.5 to 2 times baseline or increase of 0.3 mg/dL	UO < 0.5 mL/kg/h for six hours
Injury	Increased SCr by 2x or GFR decrease by 50%	UO < 0.5 mL/kg/h for twelve hours	2	Increased 2 to 3 times baseline	UO < 0.5 mL/kg/h for twelve hours
Failure	Increased SCr by 3x or GFR decrease by 75% or SCr > 4 mg/dL	UO < 0.3 mL/kg/h for 24 hours or Anuria for 12 hours	3	>3 times baseline or SCr > 4.0 mg/dL with an acute increase of 0.5 mg/dL	UO < 0.3 mL/kg/h for 24 hours or Anuria for 12 hours
Loss	Persistent acute renal failure (four weeks duration)				
ESKD	End stage kidney disease (greater than three months)				

FIGURE 16.13 The RIFLE criteria compared to Acute Kidney Injury Network criteria. Abbreviations: ESKD, end-stage kidney disease; GFR, glomerular filtration rate; SCr, serum creatinine; UO, urine output. Adapted by permission from Springer: Mehta RL, Kellum JA, Shah SV, et al; Acute Kidney Injury Network. Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury. Crit Care. 2007;11(2):R31.

In 2012, the Kidney Disease: Improving Global Outcomes (KDIGO) work group developed a classification meant to improve use in clinical practice. This classification scheme combines RIFLE and AKIN classifications (**Table 16.2**). In KDIGO classification, stage 1 AKI is defined as an increase in SCr of at least 0.3 mg/dL within 48 hours, or an increase in SCr to more than 1.5 times baseline, or a decrease in urine output to less than 0.5 mL/kg per hour for 6 hours.²⁶

TABLE 16.2		
Kidney Disease: Improving Global Outcomes classification of acute kidney injury		
Stage	SCr/GFR criteria	Urine output criteria
1	Increase SCr \geq 0.3 mg/dL or increase SCr \geq 1.5–2x	<0.5 mL/kg per hour for >6 hours
2	Increase SCr >2–3x	<0.5 mL/kg per hour for >12 hours
3	Increase SCr >3 or increase SCr \geq 4 mg/dL or initiation of renal replacement therapy	<0.3 mL/kg per hour for 24 hours or anuria for 12 hours, or GFR <35 mL/minute/1.73 m ²

Abbreviations: GFR, glomerular filtration rate; SCr, serum creatinine.

Recent studies have examined the differences in the classification schemes to assess their diagnostic and prognostic abilities in various context. Studies have shown similar incidence of AKI, regardless of classification scheme, in critically ill patients,²⁷ heart failure patients,²⁸ and cardiac surgical patients.²⁹ In patients with myocardial infarction, KDIGO may be superior to RIFLE in diagnosing AKI and predicting mortality.³⁰

Biomarkers

As discussed earlier, the SCr and urine output are the most widely used diagnostic criteria to detect AKI. The use of SCr to estimate the GFR assumes steady-state conditions: Production of creatinine is equal to its clearance. It is therefore problematic to use SCr to estimate GFR in dynamic settings. Simply put, the rise in SCr lags an acute reduction in GFR. Furthermore, because even small changes in the GFR have significant impact on mortality and hospital length of stay,²³ the need for early detection of AKI has led to the pursuit for biomarkers that may give real-time information. The ideal biomarker should be specific to AKI, allow for early diagnosis, identify the cause, and allow for characterization of degree of injury. The hope is that earlier detection of AKI could lead to therapeutic interventions that improve outcomes, and research in this area has been very active for some time.

Neutrophil gelatinase-associated lipocalin (NGAL) has been identified as an early marker of AKI.^{31–33} Its expression is induced in renal tubular cells following ischemia-reperfusion injury, and it can be measured

either in serum or urine soon after injury. Significant research has investigated this promising biomarker, although its clinical use has been slowed by conflicting reports on its predictive value. An early meta-analysis suggested that NGAL is a useful predictor of early AKI across an array of clinical settings.²⁵ When using standardized assays, a generally agreed upon cutoff upper value of 150 ng/mL may be suggestive of AKI. Despite questions regarding appropriate cutoff values and assay technique, more recent reviews have reaffirmed NGAL's use in both the prediction of the presence and severity of AKI after cardiac surgery and to predict delayed graft function after kidney transplantation.³⁴

Other biomarkers of AKI are under ongoing investigation.³⁵ Cystatin C, a cysteine proteinase inhibitor produced by all nucleated cells, is small in size and easily filtered in the glomerulus. Because it is metabolized in the proximal renal tubules, urinary concentrations are insignificant. Furthermore, its short half-life means serum levels will reflect GFR. Interleukin-18 is synthesized both in the proximal tubular cells and in cells that mediate inflammatory response. Elevated levels are seen in patients with ATN, although its role as a biomarker of AKI is confounded by evidence indicating it may represent more closely the presence of general inflammatory processes. Lastly, kidney injury molecule-1 is a membrane protein expressed in injured proximal tubular epithelial cells. Although associated with ATN, its predictive value is still being defined.³⁵ Because AKI is a complex clinical phenomenon, biomarkers may be most useful when combined as a panel that covers different phases of the injury pattern. This approach may yield better insight into mechanism, prediction, and treatment strategies. Further research will also determine whether interventions in early AKI will affect clinical outcomes.

Anesthesia and the Kidneys

An understanding of kidney function is important for the anesthesiologist, as fundamental concepts of perioperative management include the maintenance of normal circulating volume, the regulation of electrolytes and acid-base status, and the clearance of metabolites and drugs. The perioperative time period is unique in that multiple potential insults, often concurrent or in rapid succession, challenge the kidney's functional ability. Perioperative AKI has an estimated overall incidence of 1% and is associated with an increase in hospital costs, postoperative complications, and ultimately risk of mortality.³⁶

Anesthesia and Renal Blood Flow

Several perioperative factors affect renal blood flow either directly by hemodynamic effects or indirectly through actions of the sympathetic nervous system or AVP. Regardless of the immediate cause, a fall in renal blood flow tends to decrease the GFR by diminishing blood flow to the renal cortex. Likewise, decreased renal blood flow puts the renal medulla at risk for ischemia because the blood supply to this region is already low at baseline. The sum effect of these changes is conservation of sodium and water and, consequently, a decrease in urine output.

Many perioperative factors influence renal blood flow through changes in cardiac output or systemic arterial pressure. Anesthetic drugs commonly have significant direct hemodynamic effects, either by reducing systemic vascular resistance, depressing myocardial function, or decreasing effective preload. Likewise, perioperative hypovolemia (from preoperative fasting, bowel preparation, fluid shifts, acute hemorrhage, or any combination of factors) will decrease cardiac output and systemic arterial pressure, ultimately leading to a decrease in renal blood flow.

Because the kidney has rich autonomic innervation, renal blood flow is also highly sensitive to the action of the sympathetic nervous system. Sympathetic stimulation leads to increased renal vascular resistance, which has two significant effects. First, blood is shunted away from the kidneys to other organs, preserving perfusion of critical organs such as the brain and heart. Second, constriction of the afferent renal arterioles lowers glomerular capillary pressure and decreases the GFR. Whether the root cause is pain, surgical stimulation, or exogenous catecholamines, excessive sympathetic stimulation can decrease glomerular blood flow to the point that urine output drops to nearly zero. Furthermore, painful stimuli elicit the release of AVP, which increases water absorption from the collecting ducts, resulting in concentrated urine. Retention of sodium and water caused by positive end-expiratory pressure is not associated with changes in the circulating plasma concentrations of AVP.³⁷

These direct and indirect mechanisms altering renal blood flow are not mutually exclusive. A decrease in cardiac output will also lead to a release of AVP and an increase in the activity of the sympathetic nervous system and the RAAS. The AVP and aldosterone tend to restore both normal circulating volume and normal renal blood flow by retaining sodium and water. Hypovolemia from acute hemorrhage also increases sympathetic tone, further reducing renal blood flow.

The autoregulation of renal blood flow may also be affected by perioperative factors. Although most anesthetic drugs do not abolish autoregulation, it is impaired in the following circumstances: severe sepsis, acute kidney failure, and cardiopulmonary bypass (CPB). Sustained changes in mean arterial pressure (greater than 10 minutes) are associated with a decreased ability to autoregulate renal blood flow. Autoregulation of GFR, by contrast, is sustained over longer periods of time. Thus, the GFR may remain near-normal despite a marked reduction in renal blood flow.

It is important to remember that normal systemic arterial pressure does not ensure adequate renal blood flow and that renal ischemia may occur even in the absence of hypotension. Also, intraoperative urine output is a poor predictor of postoperative changes in renal function ([Figure 16.14](#)).³⁸ Hence, factors that commonly emerge in the perioperative setting including anesthetic agents, fluid shifts, stress response, changes in hemodynamics, and administration of catecholamines all have the potential to decrease renal blood flow and affect kidney function.

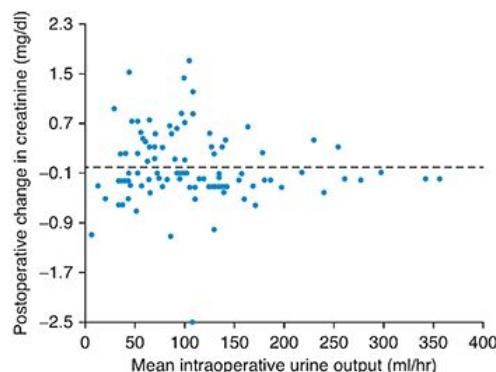

FIGURE 16.14 Intraoperative urine output. Mean intraoperative urine output does not correlate with postoperative changes in the plasma concentrations of creatinine. *From Alpert RA, Roizen MF, Hamilton WK, et al. Intraoperative urinary output does not predict postoperative renal function in patients undergoing abdominal aortic revascularization. Surgery. 1984;95:707-711. Perioperative Risk Assessment

An assessment of perioperative risk allows perioperative physicians to address this concern with patients and consultants as well as to plan the anesthetic with the aim of avoiding AKI. In the patient population undergoing general surgery, the risk of AKI is believed to be about 1%. Patient risk factors include age older than 56 years, male gender, active congestive heart failure, ascites, diabetes, and hypertension ([Table 16.3](#)).

TABLE 16.3

Risk factors for perioperative acute kidney injury	
Patient risk factors	Surgical risk factors
Age >56 years	Intraperitoneal surgery
Male gender	Emergent operation
Active congestive heart failure	
Ascites	
Diabetes	

Hypertension

Development and validation of an acute kidney injury risk index for patients undergoing general surgery: results from a national data set. *Anesthesiology*. 2009;110(3):505-515. Copyright © 2009 American Society of Anesthesiologists, Inc.

Special considerations should be taken in patients who are taking antihypertensives perioperatively, particularly angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and diuretics. Both ACEIs and ARBs inhibit the RAAS by decreasing the activity of angiotensin II, with ACEIs preventing the production of angiotensin II and ARBs preventing the binding of angiotensin II to its receptors. This results in vasodilation and in the perioperative setting can result in significant hypotension, potentially precipitating AKI. Additionally, when administered with NSAIDs, the concomitant vasoconstriction of the afferent arteriole caused by NSAIDs and vasodilation of the efferent arteriole caused by ACEIs can lead to significant renal dysfunction. Diuretics (ie, loop diuretics and thiazides) prevent the absorption of key electrolytes along different portions of the renal tubule, ultimately resulting in decreased water reabsorption and diuresis. Use of diuretics in the perioperative setting has the potential for causing significant dehydration and possible AKI and metabolic abnormalities.³⁹

Surgical factors associated with an increased likelihood of AKI include intraperitoneal surgery and emergent operations. Additional risk factors include requiring blood transfusions and sepsis.³⁶ The risk of perioperative AKI is of particular concern among patients undergoing cardiac surgery, vascular surgery, liver transplantation, or laparoscopic surgery.⁴⁰⁻⁴⁴

Cardiac Surgery

The rate of AKI in patients undergoing cardiac surgery ranges between 20% and 30%. Patients undergoing procedures that require CPB are at particular risk. Alterations in renal blood flow due to hypovolemia or direct sympathetic stimulation, hemolysis, inflammatory response, microemboli, and direct toxicity are several mechanisms for kidney injury in these patients. Furthermore, clamping or cannulation of the aorta in cardiac surgery is associated with atheromatous emboli to the kidneys.⁴⁵ Increased baseline SCr is the most significant risk factor for perioperative AKI after CPB. In patients with a baseline SCr between 2.0 and 4.0 mg/dL, the risk of AKI requiring dialysis is 10% to 20%. Other risk factors include ejection fraction less than 40% and preoperative use of an intra-aortic balloon pump.⁴⁶ Patients undergoing valve surgery are at higher risk than those undergoing coronary artery bypass grafting alone.⁴⁷

Vascular Surgery

The incidence of AKI among patients undergoing vascular surgery depends on the type of procedure being performed. Those undergoing open thoracic or abdominal aorta procedures have higher rates of AKI (26%-76%) when compared to their counterparts undergoing peripheral vascular operations (4%-19%). This patient population is at increased risk for AKI for many of the same reasons as patients undergoing cardiac surgery (eg, impaired renal blood flow, microemboli, and significant exposure to nephrotoxic contrast). Additionally, many of these patients have risk factors predisposing them to development of chronic kidney disease (ie, hypertension, diabetes, and hyperlipidemia).⁴⁸

Liver Transplantation

The risk of AKI in patients undergoing liver transplantation has been shown to be greater than 50%, and this injury has been associated with worse patient outcomes including decreased graft survival, prolonged intensive care unit length of stay, and overall mortality.⁴³ The increased rate of AKI in these patients is thought to be influenced by prolonged hypotension secondary to reperfusion and significant blood loss, increased risk of reoperation, and the use of nephrotoxic medications for immunosuppression. Patient-specific risk factors include severe preoperative liver disease (ie, decompensated cirrhosis), nonalcoholic steatohepatitis, female sex, poorly controlled diabetes, and obesity.^{43,49}

Laparoscopic Surgery

Insufflation of the abdomen with carbon dioxide during laparoscopic surgery increases in intra-abdominal pressure and activates the RAAS. These alterations have been shown to negatively impact renal blood flow and renal function.⁴⁴ However, the association between laparoscopy and an increased risk of perioperative AKI is inconsistent. Several case studies have reported the development of AKI after laparoscopic surgery⁵⁰⁻⁵²; however, there are relatively few large cohort studies that report on the overall rate of AKI after laparoscopic surgery. Reported rates of AKI following laparoscopic surgery have ranged between 5% to 35%.⁵³⁻⁵⁴ Moreover, there is data that suggest that laparoscopy is not associated with higher risk rates of AKI among patients undergoing major abdominal procedures.⁵⁵⁻⁵⁶ It is thought that the incidence and degree of kidney injury may relate to variations in the patients' volume status, positioning, insufflation pressure, and duration of pneumoperitoneum. Additional studies are needed to further clarify this relationship.

Intraoperative Management

Although the ability of the anesthesiologist to prevent AKI remains limited, general management principles include identifying potential causes of kidney injury (and mitigating their impact), minimizing exposure to nephrotoxic agents (NSAIDs and radiographic contrast), and maintaining renal blood flow. This can be accomplished by prompt correction of intravascular volume depletion and the maintenance of adequate systemic arterial pressure. Preoperative optimization of congestive heart failure, as well as maintaining normal cardiac output perioperatively, will help maintain renal blood flow. The judicious use of positive end-expiratory pressure and the avoidance of unnecessary increases in mean airway pressure will help maintain cardiac output and adequate renal blood flow. In laparoscopic surgery, using the lowest possible abdominal insufflation pressure and minimizing duration of insufflation will promote renal blood flow, although this must be balanced with operative needs. Adequate analgesia will minimize sympathetic nervous system-mediated decreases in renal blood flow. This may be a potential benefit of regional anesthesia. Agents used to promote afferent arteriolar dilation have not been shown to improve perioperative renal outcomes. Low-dose dopamine does not prevent AKI or improve mortality.⁵⁷ Fenoldopam mesylate, a selective dopamine agonist, may reduce the risk of AKI in selected patient populations,⁵⁸⁻⁵⁹ but further studies are needed to confirm this potential benefit.

Intravenous Fluids and Electrolytes*

Updated by: Emily P. Wang • Jessica Spellman

Total body water and electrolytes are divided between the intracellular and extracellular compartments. The major electrolytes in the intracellular compartment are potassium, magnesium, calcium, and phosphate. The extracellular compartment consists of the interstitial, plasma, and transcellular fluid components, where sodium and chloride are the major electrolytes. Fluid movement between these spaces, and thus the effect of fluid therapies, depends on the levels of water, electrolytes, and colloid proteins among them and the composition and permeability of the membranes that separate them.

Total Body Fluid Composition

The adult body is composed of approximately 60% water, with some variation with age and gender as well as significant variation among different tissues. For example, muscle is about 75% water, whereas adipose tissue only 10%. About two-thirds of total body fluid is intracellular and one-third extracellular ([Figure 17.1](#)). The intracellular compartment is rich in potassium (the major cation), magnesium, calcium, phosphate (the major anion), and proteins. Extracellular volume (ECV) includes interstitial fluids (about 80% of the ECV), plasma (about 20%), and transcellular fluids, which are anatomically separate fluid spaces, such as the intraocular, gastrointestinal, and cerebrospinal fluids, and are not available for water and solute exchange with the remainder of the ECV. Extracellular fluids are rich in sodium (the major cation) and chloride (the major anion). These and other small ions move freely between plasma and interstitium in the extracellular compartment. The plasma also contains proteins, such as albumin and globulins, which create the colloid oncotic pressure. Plasma proteins are prevented from freely moving from vascular to interstitial space by the interplay of the vascular endothelial cells and the endothelial glycocalyx layer (EGL) coating the inside of the vascular space. Macromolecule movement out of the vascular space is dependent on the type of EGL pores and endothelial cell junctions, which have four phenotypes throughout the body. In the liver, spleen, and marrow, sinusoidal capillaries have large EGL pores and open fenestrations allowing macromolecules to pass between plasma and the interstitial space. The glomeruli have open capillary fenestrations with the effective pore size reduced by overlying EGL. Endocrine, choroid plexus, and gut mucosa vascular endothelial cells have inducible fenestrations. Nerve, muscle, connective tissue, and lung have nonfenestrated or continuous capillaries so that little transvascular filtration into the interstitium occurs in these tissues. In states of inflammation, changes in the endothelial cells and an increase in the number of large pores in the capillaries increase the amount of protein passing from vascular into interstitial spaces. The transcapillary escape rate of albumin to tissues is normally 5% per hour but can double during surgery and increase to 20% in sepsis.¹ Fluid in the interstitial space is returned to the circulation as lymph.² The cell membrane prevents sodium, the primary extracellular cation, from moving into the cell, except for a small amount by active pump transport, but isotonic fluids containing sodium added to the vascular space are distributed throughout the ECV so that only 20% of the volume infused remains in the plasma.³

Intravenous Fluid Types

Crystalloids

Crystalloids are fluid solutions containing ion salts and other low-molecular-weight substances. Crystalloids can be categorized based on their tonicity or osmotic pressure of the solution with respect to that of plasma. Examples are listed in **Table 17.1**. Administering large volumes of normal saline (NS) can result in hyperchloremic metabolic acidosis.⁴ “Balanced” or “physiologic” crystalloid solutions contain a composition approximating that of extracellular fluid but are usually slightly hypotonic because of lower sodium concentration. Administering large volumes of balanced salt solutions can result in hyperlactatemia, metabolic alkalosis, and hypotonicity. Calcium-containing balanced salt solution may cause formation of microthrombi when infused with citrate-containing blood products.

TABLE 17.1

Common crystalloid solutions^a

Solution	Osmolarity (mOsm/L)	Tonicity	pH	Calories (kcal/L)	Na ⁺ (mEq/L)	Cl ⁻ (mEq/L)	K ⁺ (mEq/L)
NS	308	Iso	5		154	154	
D5NS	560	Hyper	4	170	154	154	
D5 1/2NS	406	Hyper	4	170	77	77	
LR	273	Iso	6.5	9	130	109	4

Plasma- Lyte	294	Iso	7.4	21	140	98	5
Solution	Ca ⁺⁺ (mEq/L)	Mg ⁺⁺ (mEq/L)	Glucose (g/L)	Lactate (mEq/L)	Acetate (mEq/L)	Gluconate (mEq/L)	

NS						
D5NS			50			
D5 1/2NS			50			
LR	3			28		
D5LR	3		50	28		
Plasma-Lyte		3			27	23

Abbreviations: D5LR, 5% dextrose in lactated Ringer; D5NS, 5% dextrose in normal saline; D5 1/2NS, 5% dextrose in 1/2 normal saline; LR, lactated Ringer; NS, normal saline.

^aData from Warren BB, Durieux ME. Hydroxyethyl starch: safe or not? *Anesth Analg*. 1997;84:206-212.

Perioperative fluid management is often discussed in the literature. Historically, fluid regimens were liberal, particularly for abdominal surgery, with patients receiving up to 7 L of intravenous (IV) hydration. Newer enhanced recovery after surgery pathways aim for a more restrictive IV fluid policy to promote faster recovery. Recently, the restrictive versus liberal fluid therapy in major abdominal surgery looked at disability-free survival up to 1 year after surgery in 3,000 patients receiving either liberal fluid management (10 mL/kg bolus at induction followed by 8 mL/kg per hour until the end of the surgery) or restrictive fluid management (5 mL/kg bolus at induction and 5 mL/kg per hour until the end of surgery). The study found no difference in the rate of disability-free survival at 1 year between the two groups ($P = .61$).⁵ Of the secondary outcomes, they found rate of acute kidney injury was higher in patients receiving restrictive fluid therapy ($P < .0001$). Current guidelines by the American Society of Anesthesiologists recommend a moderately liberal approach with overall positive fluid balance of 1 to 2 L at the end of surgery, with minimized preoperative fasting times and close consideration of hemodynamic monitoring to guide volume resuscitation.⁶

Furthermore, the best type of IV fluids used for fluid resuscitation is often debated. Recent studies have focused on comparing NS to balanced crystalloid solutions and their effects on the kidney and mortality. In a double-blind, cluster randomized, double-crossover trial of 2,278 patients in the intensive care unit (ICU) in New Zealand, patients received NS (0.9% sodium chloride) or a buffered crystalloid (Plasma-Lyte 148). The primary outcome was acute kidney injury based on five-category scoring system evaluating risk, injury, failure, loss, and end-stage renal failure criteria within 90 days after enrollment with secondary outcomes looking at incidence of renal replacement therapy (RRT) and in-hospital mortality. There was no significant difference between the two groups when assessing acute kidney injury ($P = .77$), the need for RRT ($P = .91$), or in-hospital deaths ($P = .4$).⁷ However, a newer study, the Isotonic Solutions and Major Adverse Renal Events Trial, looked at 15,802 critically ill adults using a cluster randomized, multiple-crossover, multicenter design and assigned patients to either receive saline or balanced crystalloids (lactated Ringer or Plasma-Lyte A). The primary outcome was major adverse kidney event, including death, initiation of RRT, or persistent renal dysfunction as defined as final creatinine value $\geq 200\%$ of baseline, within 30 days or hospital discharge. The balanced crystalloid group was found to have a decreased incidence of a major adverse kidney event as compared to the saline group ($P = .04$).⁸ In a related study, 13,347 noncritically ill patients in the emergency department were enrolled in a single-center, pragmatic, multiple-crossover trial comparing balanced crystalloids (lactated Ringer or Plasma-Lyte A) with saline. The primary outcome was hospital-free days, and secondary outcomes included major adverse kidney events as defined in the Isotonic Solutions and Major Adverse Renal Events Trial study. There was no difference between saline and balanced crystalloids in hospital-free days ($P = .41$); however, patients receiving balanced crystalloids had a lower incidence of death, requirement of new-onset RRT, and persistent renal dysfunction ($P = .01$). Thus, in critically ill patients and noncritically ill emergency department patients, treatment with balanced crystalloid solutions may offer the advantage of less adverse kidney events than treatment with NS.⁹

Colloids

Colloid solutions contain macromolecules suspended in electrolyte solutions. These macromolecules, such as plant or animal polysaccharides or polypeptides, remain in the plasma compartment longer than crystalloid solutions; however, their distribution has been shown to be context sensitive, with larger percentages of the

volume administered remaining intravascular in hypovolemic patients as compared to normovolemic patients.³ Semisynthetic colloid solutions are metabolized and excreted and thus have a shorter duration of effect than human albumin solutions.² Examples are listed in [Table 17.2](#).

TABLE 17.2

Common colloid solutions^a

Fluid	Trade Name	Source	Osmolarity (mOsm/L)	Na ⁺ (mmol/L)	Cl ⁻ (mmol/L)	K ⁺ (mmol/L)

Albumin (4%-5%)

Albumin solution is produced from human blood and suspended in saline. It is heat pasteurized at 60°C for 10 hours to reduce viral transmission. It is expensive to produce and distribute as compared to semisynthetic colloids and crystalloid solutions. The incidence of anaphylactoid reactions to albumin is 0.011%.¹⁰

The comparative effectiveness of fluid resuscitation with colloid versus crystalloid has been a long-standing controversy, which has been the subject of much recent clinical research. In the Saline versus Albumin Fluid Evaluation study, a multicenter, randomized, double-blind trial of 6,997 ICU patients, the effect of fluid resuscitation with albumin 4% or NS was evaluated. The primary outcome was death within 28 days. There was no significant increase in mortality ($P = .87$). The two groups also had similar rates of new single organ and multiple organ failure ($P = .85$), days spent in ICU ($P = .44$), days spent in hospital ($P = .3$), days of mechanical ventilation ($P = .74$), and days of RRT ($P = .41$).¹¹ In a post hoc analysis of the Saline versus Albumin Fluid Evaluation study of 460 patients with traumatic brain injury, the primary outcome of mortality was increased in the albumin-treated group (33.2%) versus the NS group (20.4%, $P = .03$).¹² In an additional subgroup analysis of 1,218 patients with severe sepsis, albumin administration was associated with a decreased risk of death as compared to NS with an adjusted odds ratio of 0.71 (95% confidence interval [CI], 0.52-0.97; $P = .03$).¹³ A more recent multicenter, open-label, randomized trial of 1,818 ICU patients with severe sepsis, the Albumin Italian Outcome Sepsis study, of 20% albumin and crystalloid versus crystalloid alone with primary outcome measure of death found no difference in survival at 28 or 90 days ($P = .29$).¹⁴ With many evaluations finding no significant clinical difference in ICU patients treated with albumin or saline, and increased mortality in the traumatic brain injury subset, providers must consider the costs of continuing to use such solutions.

Semisynthetic Colloid Solutions

Solutions include hydroxyethyl starch (HES) solutions, succinylated gelatin, urea-linked gelatin-polygeline preparations, and dextran solutions. The HES, the most commonly used semisynthetic colloid solutions, are created by attaching hydroxyethyl groups to carbons 2, 3, or 6 of the glucose moieties of starches of sorghum, maize, or potatoes. The HES solutions vary with respect to HES concentrations (6%-10%), molecular weights (70-670 kDa), molar substitution ratios (0.3-0.75), and crystalloid carrier solutions. The concentration influences the initial volume effect with 6% solutions being iso-oncotic and 10% solutions hyperoncotic. The HES is polydisperse with particles in a wide range of molecular mass (dispersity is a measure of the heterogeneity of sizes of molecules or particles in a mixture); thus, the molecular weight is averaged by either weight or number. The substitution ratio indicates the average fraction of glucose moieties bearing a hydroxyethyl group.¹⁵ The HES can also be named hexa- (0.6), penta- (0.5), or tetra- (0.4) starches for this level of substitution. Substitution increases the solubility of the starch in water and inhibits the destruction of the starch by amylase, thus prolonging intravascular retention. The HES can also be categorized with respect to the pattern of hydroxyethylation of the C₂ and C₆ carbon atoms. Hydroxyethyl groups in the C₂ position inhibit amylase access to the starch more effectively than hydroxyethyl groups at the C₆ position; thus, high C₂/C₆ ratios would be expected to hydrolyze more slowly. The maximum daily dose of HES is limited to 20 to 50 mL/kg of body weight per day but varies by solution.¹⁵

The HES is removed from the circulation by redistribution and renal excretion. Redistribution of HES results in temporary storage in the skin, liver, and kidneys. Skin deposition results in non-histamine-associated pruritus. After 24 hours, 23% of the total dose is interstitial, and at 26 weeks, trace amounts of HES are still detectable.¹¹ The HES molecules with greater molecular weights and increased substitution ratios tend to be stored more than those with more rapid clearance and deposition appears to be dose dependent.¹⁵

Renal excretion of HES occurs in two phases: immediate glomerular filtration of HES polymers less than 59 kDa and delayed glomerular filtration after HES metabolism by plasma α -amylase. This amylase functions as an endoamylase cleaving within the polyglucose chain instead of acting at the ends of the molecule, resulting in polydispersity and varying molecular weights of the remaining HES molecules in the plasma. Thus, pharmacokinetic parameters of plasma clearance and half-life will change over time, cannot be rigorously defined, and must not be interpreted as efficacy half-lives or contributing to the pharmacodynamics of volume effect of HES solutions.¹⁶ Additionally, the hydroxyethyl groups retard hydrolysis of the compound by amylases, allowing longer presence in the plasma. Plasma levels of amylase are elevated after HES administration for 72 hours, without evidence of increased pancreatic production, owing to decreased

renal elimination of amylase as it remains complexed to HES.¹⁰ The pharmacokinetic profile of some HES solutions after single dose and multiple infusions in healthy volunteers is described in [Tables 17.3](#) and [17.4](#),¹⁶ and in impaired renal function in [Table 17.5](#).¹⁷

^bDefined according to measurements of creatinine clearance (mL/min/1.73 m²).

The HES compounds have effects on coagulation with reductions in factor VIII, von Willebrand factor, and platelet function, although the exact mechanisms are unclear. Coagulation effects are noted even when used below recommended maximum doses. Solutions with more rapid degradation are associated with less effects on coagulation.¹⁵ The incidence of anaphylactoid reactions with HES use is 0.085%.¹¹

The HES solutions carry a US Food and Drug Administration black box warning with the following recommendations: Do not use HES solutions in critically ill adult patients including those with sepsis and those admitted to the ICU; avoid use in patients with preexisting renal dysfunction; discontinue use of HES at the first sign of renal injury; need for RRT has been reported up to 90 days after HES administration; continue to monitor renal function for at least 90 days in all patients; avoid use in patients undergoing open heart surgery in association with cardiopulmonary bypass due to excess bleeding; and discontinue use of HES at first sign of coagulopathy.¹⁸

The Crystalloid versus Hydroxyethyl Starch Trial evaluated HES versus NS in a multicenter, prospective, blinded, parallel-group, randomized controlled trial of over 7,000 adult ICU patients. Patients were randomized to receive either HES (6% [130/0.4] Voluven, Fresenius Kabi Norge AS, Halden, Norway) solution or NS until ICU discharge, death, or 90 days following randomization. The primary outcome was death 90 days after randomization, and secondary outcomes were acute kidney injury, failure, and treatment with RRT. There was no significant difference in mortality during the study period (18% in the HES group and 17% in the NS group, $P = .26$) or renal failure (HES group 10.4% and 9.2% NS group, $P = .12$); however, significant differences in renal injury (34.6% HES group and 38% NS group, $P = .005$) and RRT use (7% HES group, 5.8% NS group, $P = .04$) were found. Additionally, HES was associated with significantly more adverse events (0.3% vs 2.8%, $P < .001$).¹⁹

The HES (6% [130/0.42] Tetraspan, B. Braun Melsungen AG, Melsungen, Germany) has also been evaluated in a multicenter, parallel-group, blinded, randomized trial of 798 adult ICU patients with severe sepsis versus Ringer acetate in the Scandinavian Starch for Severe Sepsis/Septic Shock Trial. Primary outcomes measured were death or end-stage kidney failure at 90 days. Death was greater at 90 days in the HES group (51% vs 43%, $P = .03$). One patient in each group had end-stage kidney failure; however, in the 90-day period, 22% of HES patients were treated with RRT versus 16% in the Ringer acetate group ($P = .04$).²⁰

In the Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis multicenter, randomized trial evaluating adult ICU patients with severe sepsis, patients were randomized to receive either intensive insulin therapy or conventional insulin therapy in addition to either HES 10% pentastarch, HES 200/0.5, or lactated Ringer for fluid resuscitation. The primary end points were death and mean score for organ failure. There were 537 patients who were evaluated, and the trial was stopped early due to increased severe hypoglycemia events in the intensive insulin therapy group, but the comparison between HES and lactated Ringer was continued with all patients receiving conventional insulin therapy. The HES therapy was associated with higher rates of acute renal failure (34.9%, 22.8% in the lactated Ringer group, $P = .002$) and RRT than lactated Ringer (18.3%, 9.2% lactated Ringer group).²¹ Thus, use of HES is currently limited due to concerns for coagulopathy and impairment of renal function.

Assessing Fluid Responsiveness

Fluid responsiveness may be defined as a 15% increase in cardiac output following a 500-mL IV fluid bolus, indicating that the patient is still on the ascending limb of the cardiac output/end diastolic volume curve, also

referred to as the **cardiac function curve** ([Figure 17.2](#)).²² Fluid administration to a patient on the plateau part of the curve may be of little benefit and result in adverse effects. Filling pressure measures, particularly central venous pressure, correlate poorly with blood volume, and changes in central venous pressure have been shown to poorly predict hemodynamic response to fluid challenge.²³ Stroke volume changes due to increases or decreases in right ventricular preload may be used to assess fluid responsiveness. Positive pressure ventilation decreases right ventricular stroke volume by decreasing venous return to the right heart and increasing right ventricular afterload. The decrease in right ventricular stroke volume is passed on to the left ventricle over subsequent cardiac cycles, and if the left ventricle is preload dependent, decreases in the left ventricle stroke volume will cause a decrease in the arterial pulse pressure. These cyclic changes associated with positive airway pressure are greater when the ventricles are functioning on the steep, ascending portion of the cardiac function curve. Variation in the arterial pulse pressure can be derived from analysis of the arterial pressure waveform and variation greater than 12% to 13% is predictive of volume responsiveness.²⁴ Other measures of these positive pressure–associated stroke volume changes include systolic pressure variation of the arterial waveform, stroke volume variation derived from arterial pulse contour analysis, Pleth Variability Index derived from pulse oximeter waveform analysis, inferior vena cava diameter variation measured by echocardiography, and descending aortic blood velocity measured by esophageal Doppler. Measures dependent on variations caused by positive pressure ventilation are limited by the presence of arrhythmia, spontaneous breathing, tidal volume settings (8 mL/kg ideal body weight minimum required for pulse pressure variation and stroke volume variation),²⁴ low lung compliance (<30 mL/cm H₂O), increased abdominal pressure, and open chest surgery.²⁵

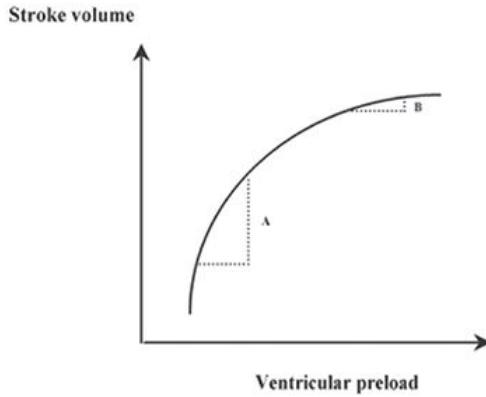

FIGURE 17.2 Schematic representation of Frank-Starling relationship between ventricular preload and stroke volume. A given change in preload induces a larger change in stroke volume when the ventricle operates on the ascending portion of the relationship (A, condition of preload dependence) than when it operates on the flat portion of the curve (B, condition of preload independence). *Reprinted by permission from Springer: Michard F, Teboul JL. Using heart-lung interactions to assess fluid responsiveness during mechanical ventilation. Crit Care. 2000;4(5):282-289. Copyright © 2000 Springer Nature.*

The end-expiratory occlusion test is useful in ventilated patients with cardiac arrhythmias, mild amplitude spontaneous breathing activity, or low tidal volume positive pressure ventilation. The test assesses the effect of a 15-second interruption in the ventilation on cardiac preload. A 5% increase in pulse contour cardiac output (sensitivity 91%, specificity 100%) or pulse pressure (sensitivity 87%, specificity 100%) is suggestive of volume responsiveness.²⁶ Passive leg raising maneuvers can be used to assess preload responsiveness in spontaneously breathing patients with arrhythmias but is limited in patients with intra-abdominal hypertension. The test is performed in a supine patient by elevating the legs to 45 degrees while assessing cardiac output or stroke volume over 30 to 90 seconds. Cardiac output measures during passive leg raising maneuvers are more accurate in predicting fluid responsiveness than arterial pressure measurements during the maneuver.²⁷

Important Fluid Constituents

Magnesium

Magnesium is almost all intracellular in bone (53%), muscle (27%), and soft tissues (19%), with less than 1% of total body magnesium in the extracellular fluid and only 0.3% in the plasma.²⁸ Most intracellular magnesium is bound to adenosine 5'-triphosphate and DNA, with less than 3% being in solution and ionized immediately available for intracellular magnesium homeostasis.²⁹ Plasma magnesium level is normally 1.7 to 2.4 mg/dL, where it is found in three states: ionized (62%), protein bound (33%), and complexed to anions (5%).²⁸ Given these distributions, plasma magnesium measurements may not be representative of total body magnesium stores. Also, magnesium measurements can be falsely elevated with hemolysis of the blood sample, which releases the intracellular electrolytes. Ingested magnesium is absorbed in the small intestines, primarily the ileum (75%),²⁹ via passive concentration effects and in the colon by active transcellular absorption.²⁵ Excretion occurs via the kidney with more than 95% of the filtered magnesium being reabsorbed in the renal tubules, with this mechanism effectively regulating the plasma level. Reabsorption occurs primarily (70%) in the ascending loop of Henle via passive mechanisms with a small amount occurring in both the proximal tubule via passive mechanisms and distal convoluted tubules via active mechanisms.²⁹ Bone, as the primary store of total body magnesium, provides a buffer for plasma magnesium levels through poorly understood mechanisms controlling magnesium incorporation into bone by osteoblasts and removal by osteoclasts.³⁰ Genetic mutations in colon transport channels³⁰ and loop of Henle junction proteins²⁹ can both result in hypomagnesemia.

Role of Magnesium

Magnesium plays a key role in many biologic processes including protein synthesis, neuromuscular function, and nucleic acid stability. It is involved in adenosine 5'-triphosphatase function, antagonizes *N*-methyl-D-aspartate (NMDA) glutamate receptors, inhibits catecholamine release, and is involved in the regulation of other electrolytes. For instance, magnesium antagonizes the uptake and distribution of calcium and modulates sodium and potassium currents through nicotinic acetylcholine receptors, NMDA receptors, and ion pumps, thus affecting membrane potentials. Magnesium has antiarrhythmic properties related to calcium channel antagonism.²⁹ The IV magnesium administration can exert muscle-relaxing effects, enhance nondepolarizing neuromuscular blockers, attenuate muscle fasciculations and potassium release with administration of succinylcholine, and precipitate skeletal muscle weakness in patients with Lambert-Eaton syndrome and myasthenia gravis. It has been used to reduce anesthetic requirements and attenuate cardiovascular effects of laryngoscopy and intubation. Magnesium has been shown to vasodilate blood vessels in many vascular beds (mesenteric, skeletal muscle, uterine, cerebral, coronary, and the aorta). It also decreases blood-brain barrier disruption and limits cerebral edema formation after brain injury.³¹ Side effects of IV administration include burning or pain on injection, drowsiness, nausea, headache, flushing, dizziness, muscle weakness, hypotension, and bradycardia.

Hypomagnesemia

Hypomagnesemia may result from dietary deficiency (as seen in chronic alcoholism), gastrointestinal malabsorption or secretion (diarrhea, vomiting, laxative use), renal losses (medication effects, nephrotoxic agents, endocrine disease, diabetic nephropathy), and chelation (citrate binding in the case of massive transfusion).²⁹ It is seen in as many as 11% of hospitalized patients and 65% of patients in the ICU. Clinical manifestations of hypomagnesemia result in cardiac and neuromuscular disorders and include symptoms of nausea, vomiting, weakness, convulsions, tetany, fasciculations, as well as electrocardiogram (ECG) abnormalities (prolonged PR and QT intervals, diminished T-wave morphology, torsades de pointes, and others) and accompanying hypokalemia and hypocalcemia.

Hypermagnesemia

Hypermagnesemia is rare and most commonly occurs with excessive administration of magnesium for therapeutic purposes. Clinical manifestations include QRS widening, hypotension, narcosis, diminution of deep tendon reflexes, respiratory depression from paralysis of muscles of ventilation, heart block, and cardiac arrest. Immediate treatment of life-threatening hypermagnesemia is with calcium gluconate, 10 to 15 mg/kg IV, followed by diuretics or dialysis, along with appropriate respiratory and circulatory support.

Preeclampsia

Magnesium appears to improve the clinical symptoms of preeclampsia by causing systemic, vertebral, and uterine vasodilation via direct effects on vessels as well as by increasing concentrations of endogenous vasodilators (endothelium-derived relaxing factor and calcitonin gene-related peptide) and attenuating endogenous vasoconstrictors (endothelin-1).³¹ Suggested dosing regimens of magnesium sulfate based on randomized trial data are 4 g IV loading dose over 10 to 15 minutes followed by infusion of 1 g per hour for 24 hours or 4 g IV loading dose with 10 g intramuscular (IM) followed by 5 g IM every 4 hours for 24 hours. Many other dosing regimens exist.³² Infusions or repeat dosing should be combined with clinical monitoring of urine output, respiratory rate, and deep tendon reflexes. Serum monitoring of magnesium levels should be performed for signs of toxicity or renal impairment. Magnesium crosses the placenta and may result in neonatal lethargy, hypotension, and respiratory depression if administered for prolonged duration (more than 48 hours).²⁹ In a Cochrane Summaries review, as compared to placebo or no anticonvulsant, magnesium was shown to decrease the risk of progression to eclampsia (relative risk [RR], 0.41; CI, 95%), decrease the risk of placental abruption (RR, 0.64; CI, 95%), and increase caesarean section (RR, 1.05; CI, 95%) but does not clearly affect maternal morbidity, stillbirth, or neonatal death or neurosensory disability at age 18 months.³² Reductions in maternal death were found to be nonsignificant.³³

Cardiac Dysrhythmias

Excess magnesium blocks myocardial calcium influx resulting in decreased sinus node activity, prolonged atrioventricular conduction time, and increased atrioventricular node refractoriness. Arrhythmias associated with hypomagnesemia are often³⁴ accompanied by hypokalemia. Normalization of both electrolytes is recommended.²⁸ Magnesium administration may decrease the incidence of severe arrhythmia after myocardial infarction, but use is limited by the incidence of hypotension.²⁹ There is no evidence that magnesium infusion during human cardiopulmonary resuscitation increases survival to hospital discharge; however, magnesium is recommended for patients with polymorphic wide complex tachycardia associated with familial or acquired long QT syndrome (torsades de pointes).³⁵ For digoxin-induced tachyarrhythmias in hypomagnesemic patients, magnesium should be administered while awaiting digoxin antibodies.²⁹ Prophylactic administration of magnesium during cardiopulmonary bypass has been shown to decrease the incidence of postoperative atrial fibrillation after coronary artery bypass surgery.³⁴

Analgesia

Magnesium has antinociceptive effects when administered IV or intrathecally, possibly due to inhibition of calcium influx, antagonism of NMDA receptors, or prevention of NMDA signaling. Data to support the use of magnesium as an analgesic or for preventative analgesia at this point is conflicting.²⁹

Asthma

Magnesium causes bronchodilatation via inhibition of calcium-mediated smooth muscle contraction, inhibition of histamine release from mast cells, and inhibition of nicotinic acetylcholine release. The IV magnesium (not inhaled) has been reported to improve bronchodilatation when standard therapies have failed; however, responses are variable.^{28,36}

Pheochromocytoma

Magnesium's arteriolar-dilating effects combined with reduction in catecholamine release may be beneficial in the management of patients with pheochromocytoma prior to tumor excision and in hemodynamic

catecholamine crisis.^{37,38}

Calcium

As an important component of the skeleton, there is more calcium in the body than any other mineral. The plasma concentration of calcium is maintained between 4.5 and 5.5 mEq/L (8.5 and 10.5 mg/dL) by an endocrine control system involving vitamin D, parathyroid hormone, and calcitonin, which regulate intestinal absorption, renal reabsorption, and bone turnover. Total plasma calcium consists of calcium bound to albumin and proteins (40%), calcium complexed with citrate and phosphorus ions (9%), and freely diffusible ionized calcium (51%).³⁹ It is the ionized fraction of calcium that produces physiologic effects and is normally 2 to 2.5 mEq/L. The ionized concentration of calcium depends on arterial pH, with acidosis increasing and alkalosis decreasing the concentration. Additionally, plasma albumin binds nonionized calcium; thus, in low albumin states, less nonionized calcium is protein bound making more available to return to storage sites, such as bone and teeth. This may decrease the total plasma calcium, but symptoms of hypocalcemia do not occur unless the ionized calcium concentration is also decreased. Thus, nonionized plasma calcium levels must be interpreted with knowledge of the plasma albumin concentration and can be corrected according to the following formula: corrected Ca^{++} (mg/dL) = measured Ca^{++} (mg/dL) + [0.8 × (4.0 – albumin (mg/dL)].⁴⁰ However, calculations to correct serum nonionized calcium for hypoalbuminemia may not be reliable in critically ill patients.⁴¹

Role of Calcium

The majority of total body calcium (>99%) is present in bone and provides the skeleton with strength and a reservoir to maintain the intracellular and extracellular calcium concentrations. Calcium is important for neuromuscular transmission, skeletal muscle contraction, cardiac muscle contractility, blood coagulation, and intracellular signaling in its function as a second messenger. In cardiac myocytes, calcium regulates contraction, relaxation, and electrical signals that determine rhythm and triggers hypertrophy via calcineurin mechanisms.⁴² In vascular smooth muscle, calcium induces a change in contractile state, increasing and decreasing vessel diameter.⁴³

Hypocalcemia

Hypocalcemia can result from decreased plasma concentration of albumin, hypoparathyroidism, acute pancreatitis, vitamin D deficiency, chronic renal failure associated with hyperphosphatemia, and citrate binding of calcium. This can result from transfused blood products, particularly fresh frozen plasma and platelets, also in hepatic failure and reduced citrate metabolism^{44,45} or use of citrate in dialysis or plasmapheresis,⁴⁶ sepsis, and critical illness.⁴⁶ Malabsorptive states rarely result in hypocalcemia as serum levels are maintained by bone calcium stores. Symptoms of hypocalcemia include neuromuscular excitability, including muscle twitching, spasms, tingling, numbness, carpopedal spasm, tetany, seizures, and cardiac dysrhythmias.⁴⁷ Calcium can be administered by oral or IV route. The IV preparations include calcium chloride which provides 27 mg of elemental calcium per milliliter and calcium gluconate, which provides 9 mg.⁴⁶ The IV calcium chloride may cause local irritation and necrosis if extravasated into the subcutaneous tissues and therefore is best administered centrally.

Hypercalcemia

Hyperparathyroidism is the most important cause of hypercalcemia and may be primary from parathyroid adenoma (85%), parathyroid hyperplasia (10%), which may be associated with multiple endocrine neoplasia syndromes, or, rarely (<1%), parathyroid carcinoma. Secondary hyperparathyroidism results from abnormal feedback loops present in renal failure and tertiary hyperparathyroidism from overactive responses to normal negative feedback mechanisms. Malignancies, such as squamous cell lung, breast, prostate, colon, adult T cell, and multiple myeloma, may result in release of parathyroid hormone-related peptide from tumor cells, resulting in inappropriate hypercalcemia.⁴⁶ Malignancy-related hypercalcemia may also result from osteolytic activity at sites of skeletal metastases commonly seen in breast cancer, multiple myeloma, and lymphoma,

and, rarely, malignancy-related hypercalcemia may result from tumor release of vitamin D.⁴⁰ Hypercalcemia may be associated with benign familial hypocalciuric hypercalcemia syndrome resulting from a mutation in calcium-sensing receptors. Hypercalcemia is also associated with granulomatous diseases such as sarcoidosis, tuberculosis, leprosy, coccidioidomycosis, and histoplasmosis and may result from excessive dietary supplement or medication side effects as a result of diuretic or lithium administration. Symptoms of hypercalcemia result from smooth muscle relaxation in the gut (constipation, anorexia, nausea, vomiting), decreased neuromuscular transmission (lethargy, hypotonia, confusion), renal effects (polyuria, dehydration, nephrolithiasis), and cardiac rhythm abnormalities (QTc shortening, J waves following QRS complex) as well as pancreatitis.⁴⁶

Treatment of hypercalcemia depends on the exact etiology but usually includes promoting renal excretion of calcium with IV fluids and loop diuretics while avoiding dehydration that would worsen any renal injury. Medications contributing to hypercalcemia should be discontinued and parathyroidectomy performed if indicated. Corticosteroids can be used to lower excessive calcium levels by inhibiting the effects of vitamin D, reducing intestinal absorption, and increasing renal excretion. Hydrocortisone 200 to 400 mg IV per day for 3 to 5 days⁴⁶ or prednisone 40 to 100 mg per day orally are recommended treatments for hypercalcemia associated with lymphoma and myeloma.⁴⁰ Bisphosphonates to inhibit osteoclast bone resorption may be useful: pamidronate 60 to 90 mg IV or zoledronate 4 mg IV. Gallium nitrate 100 to 200 mg/mL per day IV infusion for 5 days is used to inhibit osteoclastic bone resorption for paraneoplastic hypercalcemia refractory to bisphosphonate therapy.⁴⁰ Calcitonin 4 to 8 international units/kg subcutaneously or IM every 12 hours is less effective than bisphosphonates⁴⁰ or gallium nitrate⁴⁶ and works by inhibiting bone resorption and increasing renal calcium excretion. Mithramycin 25 µg/kg IV blocks bone resorption by inhibiting osteoclast RNA synthesis, but its use is limited by frequent dosing and toxicity (renal, hepatic, and hematologic).⁴⁰ Hemodialysis may also be used to treat acute, severe hypercalcemia.

Bone Composition

Bone is composed of an organic matrix that is strengthened by deposits of calcium salts. The organic matrix is greater than 90% collagen fibers, and the remainder is a homogeneous material called **ground substance**. Ground substance is composed of proteoglycans that include chondroitin sulfate and hyaluronic acid. Salts deposited in the organic matrix of bone are composed principally of calcium and phosphate ions in a combination known as **hydroxyapatites**.

The initial stage of bone production is the secretion by osteoclasts of collagen and ground substance. Calcium salts precipitate on the surfaces of collagen fibers, forming nidi that grow into hydroxyapatite crystals. Bone is continually being deposited by osteoblasts and is constantly being absorbed where osteoclasts are active. The bone-absorptive activity of osteoclasts is regulated by the parathyroid gland. Except in growing bones, the rate of bone deposition and absorption are equal, so the total mass of bone remains constant.

Because physical stress stimulates new bone formation, calcium is deposited by the osteoblasts in proportion to the compression load that the bone must carry. The deposition of bone at points of compression may be caused by small electrical currents induced by stress, called the **piezoelectric effect**, stimulating osteoblastic activity at the negative end of current flow. Osteoblasts are maximally activated at a bone fracture, the resulting bulge of osteoblastic tissue and new bone matrix being known as **callus**.

Osteoblasts secrete large amounts of alkaline phosphatase when they are actively depositing bone matrix. As a result, the rate of new bone formation is reflected by elevation of plasma concentration in alkaline phosphatase. Alkaline phosphatase concentrations are also increased by any disease process that causes destruction of bone (eg, metastatic cancer, osteomalacia, and rickets).

Calcium salts almost never precipitate in normal tissues other than bone. A notable exception, however, is atherosclerosis, in which calcium precipitates in the walls of large arteries. Calcium salts are also frequently deposited in degenerating tissues or in old blood clots.

Bisphosphonates

Bisphosphonates are drugs with a phosphorus-carbon-phosphorus (P-C-P) chemical structure that resemble inorganic pyrophosphate (**Figure 17.3**).⁴⁸ Inorganic pyrophosphate is involved in regulation of bone mineralization by binding hydroxyapatite crystals, inhibiting calcification. The phosphate groups of bisphosphonates, like inorganic pyrophosphate, bind hydroxyapatite crystals and become incorporated into sites of active bone remodeling, thus inhibiting calcification. The hydroxyl group attached to the central carbon further increases bisphosphonate's ability to bind calcium, and the final structural grouping is attached to the central carbon to determine the bisphosphonate's potency for inhibition of bone resorption. First-generation bisphosphonates (etidronate, clodronate, tiludronate), similar to inorganic pyrophosphate, become incorporated into adenosine triphosphate (ATP) by class II aminoacyl-transfer RNA synthetases after osteoclast-mediated uptake from bone and mineral surface. This abnormal ATP cannot be hydrolyzed, accumulates, and is believed to be cytotoxic to osteoclasts. Second- and third-generation bisphosphonates (alendronate, risedronate, ibandronate, pamidronate, and zoledronic acid) contain nitrogen or amino groups in this position, which increases the antiresorptive potency by binding and inhibiting farnesyl pyrophosphate synthase, leading to osteoclast apoptosis. Second- and third-generation bisphosphonate-induced osteoclast apoptosis can be detected by a reduction in biochemical markers of bone resorption; maximum suppression occurs within 3 months of initiation of oral therapy. Suppression is noted to be more rapid following IV administration. Duration of effect is a function of potency for mineral matrix binding, with zoledronic acid suppressing biochemical markers of bone resorption for up to 1 year in women with postmenopausal osteoporosis.

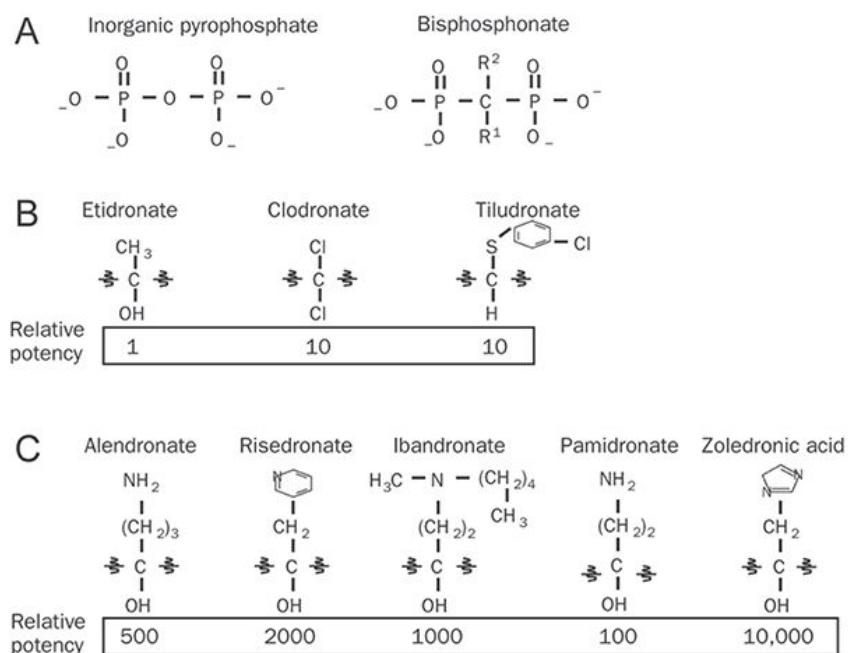

FIGURE 17.3 Inorganic pyrophosphate (PPi) and bisphosphonates. Reprinted from Drake MT, Clarke BL, Khosla S. Bisphosphonates: mechanism of action and role in clinical practice. Mayo Clin Proc. 2008;83(9):1032-1045. Copyright © 2008 Mayo Foundation for Medical Education and Research. With permission.

Clinical Uses

Bisphosphonates are useful in treating clinical conditions characterized by increased osteoclast-mediated bone resorption; for example, osteoporosis, Paget disease of bone, osteogenesis imperfecta, hypercalcemia, and malignant bony metastasis.

Pharmacokinetics

Oral bioavailability of bisphosphonates is low as they are hydrophilic with less than 1% absorbed after an oral dose. About 50% of the absorbed drug is retained in the skeleton, depending on renal function, rate of bone turnover, and binding site availability, and the remainder of drug is eliminated unchanged in the urine.^{48,49}

Side Effects

Hypocalcemia may follow IV bisphosphonate infusion; treatment is supportive with calcium and vitamin D supplementation. Ten percent to 42% of patients receiving nitrogen-containing bisphosphonates IV may experience an acute phase reaction⁴⁹ with fever, myalgias, arthralgias, headaches, and influenza-like symptoms. The incidence of this reaction decreases with each subsequent infusion; pretreatment with antihistamines and antipyretics⁴⁹ can reduce the incidence and severity of symptoms. Severe musculoskeletal pain may occur at any point after initiating bisphosphonates. Ocular inflammation (conjunctivitis, uveitis, episcleritis, scleritis) has been associated with both oral and IV bisphosphonate. Symptoms resolve within a few weeks of discontinuation. Esophageal irritation and erosion can occur with oral bisphosphonate therapy, particularly in the presence of gastroesophageal reflux disease or esophageal stricture; thus, it is often recommended that upright posture be maintained for 30 minutes after ingestion and that oral preparations be taken with a full glass of water.⁴⁹ Osteonecrosis of the jaw is associated with high-dose IV bisphosphonate use, primarily zoledronic acid and pamidronate, for oncologic conditions with an incidence of 1 to 10 per 100 patients. Associated risk factors for this complication include poor oral hygiene, history of recent dental procedures, denture use, and prolonged exposure to high IV bisphosphonate doses. The condition is rare for oral therapy of osteoporosis (1 in 10,000 to 1 in 100,000).^{48,49} Bisphosphonate dosing should be adjusted in patients with renal insufficiency, and its use is cautioned in patients with creatinine clearance less than 30 mL per minute because IV therapy may lead to rapid deterioration of renal function. Serious atrial fibrillation (life-threatening or resulting in hospitalization or disability) occurred more often in patients treated with zoledronic acid than placebo (1.3% vs 0.5%, $P < .001$) in the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly trial; however, there was no difference in the overall number of atrial fibrillation events in the two groups, and post hoc analysis of other trials has not yielded an association.⁴⁹ Hepatotoxicity has been reported with alendronate and zolendronate.⁴⁹

Denosumab

Denosumab is another antiresorptive therapy for metabolic bone diseases. It is a human monoclonal antibody against the receptor activator of NF- κ B ligand or RANKL. RANKL is required to differentiate and activate osteoclasts. Denosumab is reversible, administered biannually via subcutaneous route, and is not eliminated by the kidneys. Like the bisphosphonates, it is also associated with osteonecrosis of the jaw.⁵⁰

Potassium

Potassium is the second most common cation in the body and the principal intracellular cation. Approximately 3,500 mEq of potassium are present in the body of a 70-kg patient (40–50 mEq/kg). With 98% of the body's potassium being intracellular,⁵¹ the concentration in the extracellular fluid is about 4 mEq/L, and the intracellular concentration is 150 mEq/L. Because of this huge difference in concentration, estimation of total body potassium content from serum potassium values is inaccurate, even though the vast majority of potassium (>90%) is readily exchangeable between the intra- and extracellular compartments.

Role of Potassium

Potassium has an important influence on the control of osmotic pressure and is a catalyst of numerous enzymatic reactions. It is involved in the function of excitable cell membranes (nerves, skeletal muscles, cardiac muscle) and is directly involved in the function of the kidneys. In cardiac cells, potassium decreases action potential duration, electrical inhomogeneity, and risk of digoxin toxicity. Potassium is an endothelial-dependent vasodilator; it decreases vascular smooth muscle cell proliferation and inhibits thrombus formation and platelet activation.⁵¹ Disturbances of potassium homeostasis contribute to cardiac dysrhythmias, skeletal muscle weakness, and acid–base disturbances.

The kidney is the principal organ involved in body potassium homeostasis, primarily through control of active potassium secretion in the urine. This is different from most other electrolytes, which are regulated by control of reabsorption in the distal tubule. A number of hormones influence renal potassium secretion including aldosterone, glucocorticoids, catecholamines, and arginine vasopressin. Aldosterone acts at the renal collecting duct to increase reabsorption of sodium ions, which favors potassium secretion. Arginine vasopressin also increases secretion of potassium at the distal collecting tubule. Glucocorticoids influence renal potassium secretion by a direct action in the renal parenchyma. Catecholamines decrease renal secretion of potassium by an effect on the distal collecting system. Acidosis opposes and alkalosis favors potassium secretion. When uremia develops, gastrointestinal secretion of potassium increases, and when creatinine clearance is less than 20% of normal, gastrointestinal potassium loss can approach 20% of uptake.

Drugs Causing Hypokalemia

Diuretics that induce renal potassium loss are probably the most common cause of hypokalemia, but there are a number of other drugs that may result in this condition. Catecholamines shift potassium intracellularly, predominantly into the liver and skeletal muscle cells, and administration of β -adrenergic agonists in the treatment of bronchial asthma or premature labor may cause hypokalemia; in fact, β agonists may be useful in the treatment of hyperkalemia. Theophylline also causes potassium to move into cells, and hypokalemia should be anticipated in the presence of theophylline toxicity. Insulin induces potassium to move into cells and is used to treat severe hyperkalemia. Hypokalemia is caused by gastrointestinal losses of potassium from chronic laxative abuse or overaggressive bowel preparation for abdominal surgery. Large doses of penicillin and its synthetic derivatives increase excretion of potassium in the urine, and the direct nephrotoxicity of aminoglycoside antibiotics can also lead to excessive potassium loss.

Drugs Causing Hyperkalemia

Drugs that increase serum potassium concentrations do so by redistribution, suppression of aldosterone secretion, inhibition of potassium secretion in the distal collecting duct, or by direct cell destruction. Extracellular movement of potassium can result in plasma hyperkalemia without an increase in total body potassium. For example, succinylcholine causes a release of potassium from skeletal muscle cells, resulting in an increase of the serum potassium concentration by as much as 0.5 mEq/L. Digitalis toxicity can cause hyperkalemia by preventing potassium entry into cells. β -Adrenergic antagonists can cause a modest increase in the serum potassium concentration by virtue of an extracellular shift. Nonsteroidal antiinflammatory drugs may cause hyperkalemia by preventing aldosterone release. Potassium-sparing diuretics such as spironolactone inhibit the secretion of potassium in the distal collecting duct and can cause clinical hyperkalemia. Abrupt cell lysis from chemotherapy for acute blood cell proliferative malignancies can cause hyperkalemia through the release of intracellular potassium. Hyperkalemia can also occur with exogenous red blood cell transfusions as a result of lysed red blood cells resulting in higher levels of extracellular potassium.

Hypokalemia

Skeletal muscle weakness and a predisposition to cardiac dysrhythmias are the most prominent symptoms of clinically significant hypokalemia. At the cellular level, hypokalemia causes hyperpolarity, increases resting potential, hastens depolarization, and increases automaticity and excitability of cardiac cells,⁵² predisposing to tachydysrhythmias, including torsade de pointes⁵³ and atrial fibrillation,⁵² and sudden cardiac death particularly in the setting of acute myocardial infarction.⁵¹ Potassium depletion also produces diastolic dysfunction of the myocardium.⁵¹

Treatment

It is important to determine the cause of hypokalemia before aggressive potassium replacement is initiated. For example, if serum potassium concentrations are acutely decreased due to intracellular redistribution and potassium therapy is initiated, potentially serious hyperkalemia could occur. If total body depletion is the cause of hypokalemia, the amount of increase in the plasma concentration of potassium produced by supplementation may be small due to rapid redistribution into intracellular sites.

Life-threatening hypokalemia, presenting as malignant cardiac dysrhythmias, acute digitalis intoxication, or extreme neuromuscular collapse, requires supplemental IV potassium administration. The rate of potassium infusion depends on the urgency of the indication, with a common recommendation being administration of IV potassium no greater than 10 mEq per hour peripherally and 20 mEq per hour centrally in adults. Morbidity associated with supplemental potassium therapy is not trivial. Patients with diminished internal potassium regulation, especially diabetics and renal failure patients, are at risk for accidental treatment-induced hyperkalemia.

Hyperkalemia

The earliest sign of hyperkalemia is peaked T waves on ECG, which typically occurs when the serum potassium concentration reaches 6 mEq/L. As the extracellular concentration increases further, the transmembrane gradient is decreased, with prolongation of the P-R interval and QRS widening on the ECG. At this point, the risk of asystole or ventricular fibrillation due to cardiac conduction blockade increases dramatically. Asystole may also occur due to decreased automaticity in the sinoatrial node. Occasionally, hyperkalemia presents with neuromuscular symptoms such as paresthesias and skeletal muscle weakness.

Treatment

The decision to treat hyperkalemia, in contrast to hypokalemia, is based on the degree of increase in the serum potassium concentration and the symptoms and signs that are present. If ECG changes other than peaked T waves occur, or if the serum potassium concentration is greater than 6.5 mEq/L, the incidence of serious cardiac compromise is high and rapid intervention is indicated.

Calcium is administered to rapidly offset the adverse effects of potassium on cardiac conduction and contractility. Calcium activates calcium ion channels so that ion flux through these channels generates an action potential and restores myocardial contractility, effectively antagonizing the adverse cardiac effects of hyperkalemia. The IV administration of calcium must be slower in patients on digitalis preparations because acute hypercalcemia can precipitate digitalis toxicity. Serum potassium concentrations are not significantly changed by IV administration of calcium.

Other measures to treat hyperkalemia include IV administration of sodium bicarbonate, glucose-insulin mixtures, and β agonists to shift extracellular potassium ions into the cells. Alkalization of the blood with sodium bicarbonate, 0.5 to 1.0 mEq/kg IV, rapidly moves potassium into cells, decreasing the serum potassium level for as long as the arterial pH is increased. Glucose-insulin infusion (50 mL of 50% glucose plus 10 units of regular insulin) produces a sustained transfer of extracellular potassium into cells, resulting in a 1.5 to 2.5 mEq/L decrease in the serum potassium concentration after approximately 30 minutes. Sodium polystyrene sulfonate (Kayexalate) is an orally or rectally administered sodium exchange resin used to remove extracellular potassium in exchange for sodium in the large intestine. Potassium removal from the body also may be achieved by loop diuretics or, most rapidly and effectively, hemodialysis.

Phosphate

Phosphate is the major intracellular anion. The majority (85%) of total body phosphate is stored in the bone as hydroxyapatite crystals within the organic matrix. Most of the remainder is stored in soft tissue as phosphate, with only 1% located in the plasma.⁵⁴ The normal plasma concentration of phosphate is 3.0 to 4.5 mg/dL, accounting for both organic and inorganic forms.

Phosphate is important in energy metabolism, intracellular signaling (cyclic adenosine monophosphate and cyclic guanosine monophosphate), cell structure (phospholipids), oxygen delivery (2,3-disphosphoglycerate), regulation of the glycolytic pathway, the immune system, the coagulation cascade, and buffering to maintain normal acid-base balance. Phosphorus regulation is a result of the interplay of phosphate and calcium levels, vitamin D, and parathyroid hormone on gastrointestinal absorption, renal reabsorption, and bone storage. Phosphorous absorption from the gastrointestinal tract and reabsorption in the kidney proximal convoluted tubules is stimulated by vitamin D, and renal reabsorption of phosphorous is inhibited by the effects of parathyroid hormone. Renal disease disrupts this regulation, and ectopic tissue calcification as well as hyperphosphatemia may result.³⁹

A decrease in the plasma concentration of phosphate permits the presence of a higher plasma concentration of calcium and inhibits deposition of new bone salts. Hypophosphatemia (phosphorus concentration <1.5 mg/dL) causes a decrease in the concentration of ATP and 2,3-diphosphoglycerate in erythrocytes. Profound skeletal muscle weakness sufficient to contribute to hypoventilation may be caused by hypophosphatemia as well as central nervous system dysfunction and peripheral neuropathy. Causes of hypophosphatemia include alcohol abuse; prolonged parenteral nutrition; medications such as acetazolamide, catecholamines, and theophylline; paracetamol overdose; large burns; recovery from hypothermia; hemodialysis; salicylate poisoning; and gram-negative bacteremia.⁵⁴

Iron

Iron present in food is absorbed from the proximal small intestine, especially the duodenum, into the circulation, where it is bound to transferrin. Transferrin is a glycoprotein that delivers iron to specific receptors on cell membranes. Approximately 80% of the iron in plasma enters the bone marrow to be incorporated into new erythrocytes. In addition to bone marrow, iron is incorporated into reticuloendothelial cells of the liver and spleen. Iron is also an essential component of many enzymes necessary for energy transfer. A normal range for the plasma iron concentration is 50 to 150 µg/dL.

Iron that is stored in tissues is bound to protein as ferritin or in an aggregated form known as **hemosiderin**. Hemoglobin synthesis is the principal determinant of the plasma iron turnover rate. When blood loss occurs, hemoglobin concentration is maintained by mobilization of tissue iron stores. Indeed, hemoglobin concentrations become chronically decreased only after these iron reserves are depleted. For this reason, the presence of a normal hemoglobin concentration is not a sensitive indicator of tissue iron stores. The infant, parturient, and menstruating female may have iron requirements exceeding amounts available in the diet and develop iron-deficiency anemia. Absorption of iron from the gastrointestinal tract is increased by ascorbic acid (vitamin C) or in the presence of iron deficiency. Antacids bind iron and impair its systemic absorption.

Iron Deficiency

Iron deficiency is estimated to be present in 20% to 40% of menstruating females but only about 5% of adult males and postmenopausal females. Attempts to prevent this deficiency of iron in large parts of the population include the addition of iron to flour, use of iron-fortified formulas for infants, and the prescription of iron-containing vitamin supplements during pregnancy.

Causes

Causes of iron-deficiency anemia include inadequate dietary intake of iron, increased iron requirements due to pregnancy or blood loss, or interference with absorption from the gastrointestinal tract. Most nutritional iron deficiency in the United States is mild. Severe iron deficiency is usually the result of blood loss, either from the gastrointestinal tract or, in females, from the uterus. Partial gastrectomy,⁵⁵ malabsorptive bariatric surgery,⁵⁶ and sprue are causes of inadequate iron absorption.

Diagnosis

Iron deficiency initially results in a decrease in iron stores and a parallel decrease in the erythrocyte content of iron. Depleted iron stores are indicated by decreased plasma concentrations of ferritin and the absence of reticuloendothelial hemosiderin in a bone marrow aspirate. Plasma ferritin concentrations of less than 12 µg/dL are diagnostic of iron deficiency. Iron-deficiency anemia is defined as depletion of total body iron associated with a decreased red cell hemoglobin concentration. The large physiologic variation in hemoglobin concentration, however, makes it difficult to reliably identify all individuals with iron-deficiency anemia. Because iron-deficiency anemia is so common in infants, menstruating females, and recent parturients, mild anemia in these patients is typically treated empirically with iron supplementation before pursuing a more exhaustive diagnostic workup. However, in males and postmenopausal females, iron deficiency is much less common so it is important to search for a cause of blood loss whenever anemia is present.

Treatment

Prophylactic use of iron preparations should be reserved for individuals at high risk for developing iron deficiency, such as pregnant and lactating females, low-birth-weight infants, and females with heavy menses. The inappropriate prophylactic use of iron should be avoided in adults because excessive accumulation of iron may damage tissues.

In iron-deficiency anemia, administration of medicinal iron increases the rate of erythrocyte production, resulting in a rise in hemoglobin concentration within 72 hours. If the concentration deficit of hemoglobin before treatment is more than 3 g/dL, therapeutic doses of oral or parenteral iron should increase the hemoglobin about 0.2 g/dL per day. An increase of 2 g/dL or more in the plasma concentration of hemoglobin within 3 weeks is evidence of a positive response to iron. If this response to iron therapy is not seen, other causes of anemia should be considered, such as the chronic blood loss, infectious process, or impaired gastrointestinal iron absorption.

There is no justification for continuing iron therapy beyond 3 weeks if a favorable response has not occurred. If a response to iron therapy is demonstrated, the iron should be continued until the hemoglobin concentration is normal and continued for 4 to 6 more weeks to reestablish iron stores. Full replenishment of tissue iron stores requires several months of therapy.

Oral Iron

Ferrous sulfate administered orally is the most frequent choice for the treatment of iron-deficiency anemia and is available as syrup, pills, or tablets. Ferric salts are less efficiently absorbed than ferrous salts from the gastrointestinal tract. Although other salts of the ferrous form of iron are available, they offer little or no advantage over sulfate preparations. The usual therapeutic dose of iron for adults to treat iron-deficiency anemia is 2 to 3 mg/kg (200 mg daily) in three divided doses. Prophylaxis and treatment of mild nutritional iron deficiency can be achieved with modest dosages of iron, such as 15 to 30 mg daily.

Nausea and upper abdominal pain are the most frequent side effects of oral iron therapy, particularly if the dosage is greater than 200 mg daily. Hemochromatosis is unlikely to result from oral iron therapy that is administered to treat nutritional anemia. Fatal poisoning from overdose of iron is rare, but children 1 to 2 years of age are most vulnerable. Symptoms of severe iron poisoning may occur within 30 minutes as vomiting, abdominal pain, and diarrhea. In addition, there may be sedation, hyperventilation due to acidosis, and cardiovascular collapse. Hemorrhagic gastroenteritis and hepatic damage are often prominent at autopsy in fatal iron toxicity. If iron overdose is suspected, a plasma concentration of greater than 0.5 mg/dL confirms the presence of a life-threatening situation, which should be treated with deferoxamine.

Parenteral Iron

Parenteral iron acts similarly to oral iron but should be used only if patients cannot tolerate or do not respond to oral therapy. In addition, tissue iron stores may be restored more rapidly with parenteral iron than oral therapy. There is no evidence, however, that the increase in hemoglobin is more prompt with parenteral iron than with oral iron.

Iron dextran injection contains 50 mg/mL of iron and is available for IM or IV use. After absorption, the iron must be split from the glucose molecule of dextran to become available to tissues. The IM injection is painful, and there is concern about malignant changes at the injection site. For these reasons, IV administration of iron is preferred over IM injection. A dose of 500 mg of iron can be infused over 5 to 10 minutes.

The principal major adverse effect of parenteral iron therapy is the rare occurrence of a severe allergic reaction presumably due to the presence of dextran. Less severe reactions include headache, fever, generalized lymphadenopathy, and arthralgias. Hemosiderosis is more likely to occur with parenteral iron therapy because it bypasses gastrointestinal absorptive regulatory mechanisms.

Copper

Copper is present in ceruloplasmin and is a constituent of other enzymes, including dopamine β -hydroxylase and cytochrome C oxidase. It is bound to albumin and is an essential component of several proteins. Copper

is thought to act as a catalyst in the storage and release of iron from hemoglobin. It is believed to be essential for the formation of connective tissues, hematopoiesis, and function of the central nervous system. Copper deficiency is rare in the presence of an adequate diet. Supplements of copper should be given during prolonged hyperalimentation.

Zinc

Zinc is an enzymatic cofactor essential for cell growth and the synthesis of nucleic acid, carbohydrates, and proteins. Adequate zinc is provided by a diet containing sufficient animal protein. Diets in which protein is obtained primarily from vegetable sources may not supply adequate zinc. Zinc deficiency may occur in elderly or debilitated patients or during periods of increased requirements as in growing children, pregnancy, lactation, or infection. Severe zinc deficiency occurs most often in the presence of malabsorption syndromes. Symptoms of zinc deficiency include disturbances in taste and smell, suboptimal growth in children, hepatosplenomegaly, alopecia, cutaneous rashes, glossitis, and stomatitis.

Chromium

Chromium is important in a cofactor complex with insulin and thus is involved in normal glucose utilization. Deficiency has been accompanied by a diabetes-like syndrome, peripheral neuropathy, and encephalopathy.

Selenium

Selenium is a constituent of several metabolically important enzymes. A selenium-dependent glutathione peroxidase is present in human erythrocytes. There seems to be a close relationship between vitamin E and selenium. Deficiency of selenium has been associated with cardiomyopathy, suggesting the need to add this trace element to supplements administered during prolonged hyperalimentation.

Manganese

Manganese is concentrated in mitochondria, especially in the liver, pancreas, kidneys, and pituitary. It influences the synthesis of mucopolysaccharides, stimulates hepatic synthesis of cholesterol and fatty acids, and is a cofactor in many enzymes. Deficiency is unknown clinically, but supplementation is recommended during prolonged hyperalimentation.

Molybdenum

Molybdenum is an essential constituent of many enzymes. It is well absorbed from the gastrointestinal tract and is present in bones, liver, and kidneys. Deficiency is rare, whereas excessive ingestion has been associated with a gout-like syndrome.

Sympathomimetic Drugs*

Updated by: Javier Lorenzo

Naturally Occurring Catecholamines

Naturally occurring catecholamines are epinephrine, norepinephrine, and dopamine ([Table 18.1](#) and [Figure 18.1](#)).

TABLE 18.1

Classification and comparative pharmacology of sympathomimetics

	Receptors stimulated			Mechanism of action	Cardiac effects		
	α	β ₁	β ₂		Cardiac output	Heart rate	Dysrhythmias
Natural catecholamines							
Epinephrine	+	++	++	Direct	++	++	+++
Norepinephrine	+++	++	+	Direct	-	-	+
Dopamine	++	++	+	Direct	+++	+	+
Synthetic catecholamines							
Isoproterenol	0	+++	+++	Direct	+++	+++	+++
Dobutamine	0	+++	+	Direct	+++	+	±
Synthetic noncatecholamines							
Ephedrine	++	+	+	Direct and indirect	++	++	++
Phenylephrine	+++	0	+	Direct	-	-	NC
	Peripheral vascular resistance	Renal blood flow	Mean arterial pressure	Airway resistance	Central nervous system stimulation	Single intravenous dose (70-kg adult)	Continuous infusion dose (70-kg adult)
Natural catecholamines							
Epinephrine	±	--	+	--	Yes	2-10 mcg	1-35 mcg/min
Norepinephrine	+++	---	+++	NC	No	Not used	2-35 mcg/min
Dopamine	+	+++	+	NC	No	Not Used	2-20 µg/kg/minute
Synthetic catecholamines							
Isoproterenol	--	-	±	----	Yes	1-4 µg	1-5 µg/minute
Dobutamine	NC	++	+	NC		Not used	2-10 µg/kg/minute
Synthetic noncatecholamines							
Ephedrine	+	--	++	--	Yes	10-25 µg	Not used
Phenylephrine	+++	---	+++	NC	No	50-100 µg	20-300 mcg/min

Abbreviations: 0, none; ±, variable response; +, minimal increase; ++, moderate increase; +++, marked increase; -, minimal decrease; --, moderate decrease; ---, marked decrease; NC, no change.

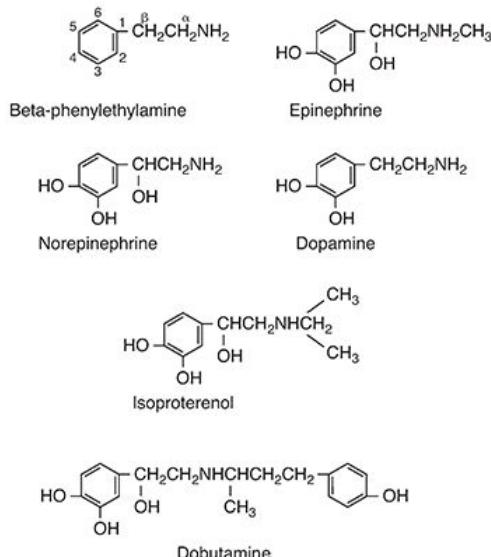

FIGURE 18.1 Sympathomimetics are derived from β -phenylethylamine, with a catecholamine being any compound that has hydroxyl groups on the 3 and 4 carbon positions of the benzene ring. The naturally occurring catecholamines are epinephrine, norepinephrine, and dopamine. Isoproterenol and dobutamine are synthetic catecholamines.

Epinephrine

Epinephrine is the prototype sympathomimetic. It is a circulating hormone synthesized, stored, and released from the adrenal medulla. Its natural functions upon release into the circulation include regulation of myocardial contractility, heart rate, vascular and bronchial smooth muscle tone, glandular secretions, and metabolic processes such as glycogenolysis and lipolysis. It is a potent activator of α -adrenergic receptors and also activates β_1 and β_2 receptors. Oral administration is not effective as epinephrine is rapidly metabolized in the gastrointestinal mucosa and liver. Therefore, epinephrine is administered subcutaneously, intravenously, or intramuscularly. Absorption after subcutaneous injection is slow because of local epinephrine-induced vasoconstriction. Epinephrine is poorly lipid soluble, preventing its entrance into the central nervous system (CNS) and accounting for the lack of cerebral effects. In cases of limited intravenous (IV) access such as in neonatal resuscitation, epinephrine can be administered via endotracheal tube.¹

Clinical Uses

As an agonist for all adrenergic receptors, epinephrine is an ideal agent for the treatment of life-threatening allergic reactions/anaphylaxis, of severe asthma and bronchospasm, and during cardiopulmonary resuscitation.² During periods of hemodynamic instability, it promotes myocardial contractility and increases vascular resistance. It also promotes inotropy during weaning from cardiopulmonary bypass. The Surviving Sepsis guidelines continue to support the use of epinephrine, either as a single agent or in combination with norepinephrine, to maintain adequate blood pressure in sepsis.^{3–5} Lastly, epinephrine is added to local anesthetic solutions to decrease systemic absorption prolonging the duration of action of the anesthetic for regional and local anesthesia. Epinephrine is used in local and field blocks to promote a bloodless surgical field.

Cardiovascular Effects

The cardiovascular effects of epinephrine result from stimulation of α - and β -adrenergic receptors (see **Table 18.1**).⁴ Stimulation of α_1 receptors leads to arteriolar vasoconstriction and pulmonary artery vasoconstriction. The α_1 receptors are predominantly located in cutaneous, splanchnic, and renal vascular beds. The β_2 receptor stimulation leads to vasodilation, predominantly in the skeletal muscles. The relative balance of α_1

and β_2 receptors in the vasculature of an organ determines epinephrine's overall effect on blood flow to the organ. In general, beta receptors are more sensitive to lower epinephrine doses, whereas effects on alpha receptors predominate at higher doses. Initial tachycardia may be followed by heart rate decreases due to baroreceptor reflexes. Venous return is also enhanced by vasoconstriction from the high density of alpha receptors in the venous vasculature system. Blood pressure is increased by an increase in cardiac index as well as an increase in systemic vascular resistance.

Epinephrine stimulates β_1 receptors causing an increase in heart rate, myocardial contractility, and cardiac output. The net effect of these systemic blood pressure changes is an increase in pulse pressure and a mild change in mean arterial pressure.

Epinephrine increases heart rate by accelerating the rate of spontaneous phase 4 depolarization, which also increases the likelihood of cardiac dysrhythmias. Epinephrine increases conduction velocity and decreases the refractory period in the atrioventricular node, bundle of His, Purkinje fibers, and ventricular muscle. It also may increase automaticity of latent pacemakers. Tachycardia, premature ventricular contraction, ventricular tachycardia, and ventricular fibrillation all may occur.

Increased cardiac output reflects epinephrine-induced increases in heart rate, myocardial contractility, and venous return. Repeated doses of epinephrine produce similar cardiovascular effects in contrast to the tachyphylaxis that accompanies administration of synthetic noncatecholamines that cause the release of norepinephrine, such as ephedrine. Myocardial oxygen consumption is increased with enhanced left ventricular preload, increased contractility, increased afterload, and tachycardia. Diastolic function is improved by increasing the rate of myocardial relaxation, and early left ventricular filling is enhanced. Epinephrine stimulates renal β receptors, resulting in increased secretion of renin. In usual therapeutic doses, epinephrine has no significant vasoconstrictive effect on cerebral arterioles. Coronary blood flow is enhanced by epinephrine,⁶ even at doses that do not alter systemic blood pressure.

The hemodynamic effects of epinephrine are attenuated and can be blocked by prior administration of α - or β -adrenergic receptor antagonists.⁴ Supratherapeutic doses of epinephrine may lead to acute heart failure, pulmonary edema, arrhythmias, hypertension, and myocardial ischemia.

Airway Smooth Muscle

Smooth muscles of the bronchi are relaxed by epinephrine-induced activation of β_2 receptors. By increasing intracellular concentrations of cyclic adenosine monophosphate (cAMP), β_2 stimulation decreases release of vasoactive mediators associated with symptoms of bronchial asthma. The bronchodilating effects of epinephrine are not seen in the presence of β -adrenergic blockade. In the presence of β -adrenergic blockade, epinephrine instead induces bronchoconstriction from stimulation of bronchial α receptors.

Metabolic Effects

Epinephrine has the most significant effect on metabolism of all the catecholamines.⁷ β_1 Receptor stimulation increases liver glycogenolysis and adipose tissue lipolysis, whereas α_1 receptor stimulation inhibits release of insulin. Liver glycogenolysis results from activation of hepatic phosphorylase enzyme. Lipolysis is due to epinephrine-induced activation of triglyceride lipase, which accelerates the breakdown of triglycerides to form free fatty acids and glycerol. Infusions of epinephrine usually increase plasma concentrations of glucose, cholesterol, phospholipids, and low-density lipoproteins. Release of endogenous epinephrine and the resulting glycogenolysis and inhibition of insulin secretion is the most likely explanation for perioperative hyperglycemia. In addition, epinephrine can inhibit peripheral glucose uptake, which is also due in part to inhibition of insulin secretion.

A multicenter, randomized, controlled, double-blind study of 330 patients with septic shock showed no difference in the duration of vasopressor use, intensive care unit or hospital length of stay, or 28- and 90-day mortality when vasopressor therapy with epinephrine plus placebo was compared with combined norepinephrine and dobutamine; however, the epinephrine group did have significantly lower arterial pH values over the first 4 days, with significantly higher arterial lactate values on day 1.⁸ Increased plasma concentrations of lactate presumably reflect epinephrine-induced glycogenolysis in skeletal muscles. Some

studies demonstrate that epinephrine-induced hyperlactatemia is primarily a transient phenomenon associated with inhibition of pyruvate dehydrogenase and has no relationship with cellular hypoxia and tissue perfusion or associated metabolic acidosis.⁹

Electrolytes

Selective β_2 -adrenergic agonist effects of epinephrine are speculated to reflect activation of the sodium-potassium pump in skeletal muscles, leading to a transfer of potassium ions into cells (Figure 18.2).⁹ The observation that serum potassium measurements in blood samples obtained immediately before induction of anesthesia are lower than measurements 1 to 3 days preoperatively is presumed to reflect stress-induced release of epinephrine (Figure 18.3).¹⁰ The ability of a nonselective β_1 and β_2 antagonist (propranolol) but not a cardioselective β_1 antagonist (atenolol) to prevent “preoperative hypokalemia” is consistent for a β_2 -adrenergic agonist effect as the explanation for potassium transfer (Figure 18.4).¹¹ In making therapeutic decisions based on a preinduction serum potassium measurement, especially in patients without a reason to experience hypokalemia, one should consider the possible role of preoperative anxiety and the release of epinephrine.

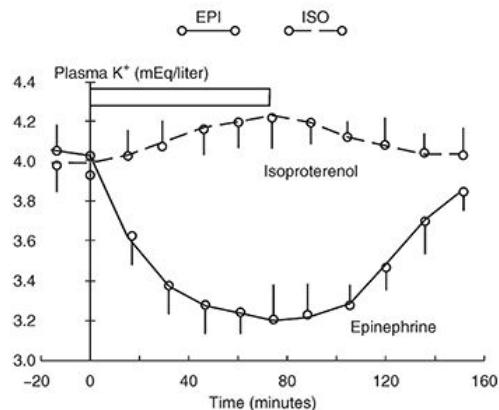

FIGURE 18.2 Selective β_2 -adrenergic agonist effects of epinephrine are responsible for stimulating the movement of potassium ions (K^+) into cells, with a resulting decrease in the serum potassium concentration. Epinephrine-induced hypokalemia may contribute to cardiac dysrhythmias, which occasionally accompany stimulation of the sympathetic nervous system. Conversely, epinephrine may stimulate the release of potassium from the liver, tending to offset the decrease in extracellular concentration of this ion produced by entrance into skeletal muscles.

Ocular Effects

Epinephrine causes contraction of the radial muscles of the iris, producing mydriasis (dilation of the pupil). Contraction of the orbital muscles produces an appearance of exophthalmos.

Gastrointestinal and Genitourinary Effects

Epinephrine, norepinephrine, and isoproterenol produce relaxation of gastrointestinal smooth muscle. Activation of β -adrenergic receptors relaxes the detrusor muscle of the bladder, whereas activation of α -adrenergic receptors contracts the trigone and sphincter muscles.

Hepatosplanchnic vasoconstriction occurs as well as impaired renal blood flow as cardiac output is diverted to the dilated skeletal muscle vasculature.¹² This results in decreased hepatosplanchnic oxygen exchange and lactate clearance. The impairment of splanchnic circulation that occurs is greater than that associated with norepinephrine or dopamine.^{13,14} It may be dependent on the severity of the shock state and the dose of epinephrine used.

Norepinephrine

Norepinephrine is the endogenous neurotransmitter synthesized and stored in postganglionic sympathetic nerve endings and released with sympathetic nerve stimulation. It is a hydroxylated derivative of dopamine and the immediate precursor of epinephrine. Norepinephrine stimulates β_1 - and α_1 -adrenergic receptors. It is

approximately equal in potency to epinephrine for stimulation of β_1 receptors but, unlike epinephrine, has minimal effect at β_2 receptors (see [Table 18.1](#)).

Through its action on β_1 receptors, norepinephrine increases heart rate, conduction, and contractility. Norepinephrine is a potent α_1 agonist producing intense arterial and venous vasoconstriction in all vascular beds except for the coronary arteries.¹⁵ Norepinephrine causes greater increase in systemic vascular resistance and diastolic blood pressure, mean arterial pressure, and systolic blood pressure than epinephrine. Venous vasoconstriction decreases venous capacitance, thereby increasing venous return to augment stroke volume and cardiac output. Norepinephrine increases mean arterial pressure primarily by vasoconstriction and to lesser degree by increasing stroke volume and cardiac output. At higher doses, vasoconstriction predominates to an even greater extent. Norepinephrine and epinephrine increase total peripheral vascular resistance more than dobutamine (described in the following text). Unlike epinephrine, norepinephrine has minimal metabolic effects. Hyperglycemia is unlikely to occur as a result of norepinephrine administration. Like epinephrine, norepinephrine dilates coronary arteries.¹⁵ The primary method of elimination is by reuptake into the adrenergic nerve endings where it is stored for subsequent release with only small amounts being metabolized.

Clinical Uses

Norepinephrine is the first-line vasopressor in patients with septic shock.^{5,7} Norepinephrine has more potent α -adrenergic receptor activating properties than epinephrine; it is therefore useful for increasing vascular tone in patients with distributive shock. The primary use of norepinephrine is as a potent vasoconstrictor to increase total peripheral vascular resistance and mean arterial pressure. Norepinephrine is also used for patients with low systemic vascular resistance after cardiopulmonary bypass. In patients with coronary artery disease, norepinephrine can be used to maintain coronary perfusion pressure, although it should be balanced with the resultant increased afterload associated with high doses.

Side Effects

Norepinephrine can exert a favorable effect on right ventricular function,¹⁵ but it should be used cautiously in patients with right ventricular failure. Norepinephrine increases venous return to the heart and also raises pulmonary artery pressures via stimulation of pulmonary vascular α_1 -adrenergic receptors. Both of these may be poorly tolerated by patients with right heart failure.

The use of norepinephrine as an inotropic agent is limited by its action as a potent vasoconstrictor. The increased peripheral resistance and afterload may decrease cardiac output and increase the work of the left ventricle. Its use is also limited by the potential for tachycardia, although its arrhythmogenic potential is less than that of epinephrine and dopamine. One of the major concerns with norepinephrine use is organ ischemia. Excessive vasoconstriction and decreased perfusion of renal, splanchnic, and peripheral vascular beds may lead to end-organ hypoperfusion and ischemia. Renal arteriolar vasoconstriction may lead to oliguria and renal failure. However, when large doses of norepinephrine accompanied by adequate fluid volume resuscitation are used with caution to treat profound hypotension, perfusion pressure and renal blood flow are preserved.¹⁶

Dopamine

Dopamine is an endogenous catecholamine that is the immediate precursor of norepinephrine. Dopamine regulates cardiac, vascular, and endocrine function and is an important neurotransmitter in the central and peripheral nervous systems. The pharmacology of dopamine is complex as this catecholamine differentially stimulates a variety of dopaminergic as well as adrenergic receptors. It is a relatively nonspecific agonist at both dopamine 1 (D_1) and dopamine 2 (D_2) receptors and the α - and β -adrenergic receptors. When activated, D_1 receptors elicit vasodilation in renal, mesenteric, coronary, and cerebral vascular beds and inhibition of sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase).¹⁶ Activation of these receptors is mediated by adenylate cyclase stimulation. D_2 receptors are principally prejunctional in postganglionic sympathetic

nerves, and when these receptors are activated, norepinephrine release from sympathetic nerve endings is inhibited.^{17,18} D₂ receptors are also present in the pituitary gland, emetic center of the medulla, and kidney. Dopamine receptors may also be associated with the neural mechanism for “reward” that is associated with cocaine and alcohol dependence. Systemic administration of dopamine does not activate these reward centers because dopamine is considered too polar to cross the blood–brain barrier.

Traditionally, the pharmacokinetics of dopamine has been attributed to dose-dependent effects on varying receptors.¹⁷ In reality, there is significant variation between patients and even within the same patient in terms of which receptors are activated at what doses by dopamine.

At low IV infusion rates (0.5-3 µg/kg/minute), dopamine primarily stimulates D₁ and D₂ receptors leading to vasodilation, decreased arterial blood pressure, and increased renal and splanchnic vascular blood flow. Diuresis and natriuresis also occur. The decrease in diastolic blood pressure might lead to a reflex increase in heart rate. At higher infusion rates (3-10 µg/kg/minute), dopamine primarily stimulates β₁-adrenergic receptors in the heart as well as α receptors in the peripheral vasculature. It also induces norepinephrine release from vascular sympathetic neurons. The activation of β receptors leads to increased cardiac output by increasing chronotropy and contractility along with vasodilation and afterload reduction. As the infusion rate is increased even further (>10 µg/kg/minute), dopamine predominantly stimulates α₁ receptors, acting similarly to a pure α agonist. The predominant stimulation of vascular smooth muscle α₁ receptors at these higher doses lead to arterial and venous vasoconstriction, increased systemic vascular resistance, and increased blood pressure attenuating further increases in cardiac output. Reflex bradycardia may also occur at this point.

This aforementioned dose-dependent model of dopamine’s effects is too simplistic, even in healthy individuals. There are a wide range of clinical responses depending on individual variability in pharmacokinetics as well as other variables. For example, despite identical IV infusion rates, there may be a 10- to 75-fold variability in plasma dopamine concentrations produced even in healthy individuals with normal drug metabolism.¹⁹ The etiology of the wide pharmacokinetic variability and variation in individual responses is likely multifactorial, reflecting differences in drug distribution, elimination, and endogenous levels, among other factors. Such differences may be more profound in critically ill patients due to changes in circulating proteins and volume of distribution. Hence, the effects of dopamine cannot be predicted based on the dose,²⁰ and the drug must be titrated to effect.

Rapid metabolism of dopamine with an elimination half-life of 1 to 2 minutes mandates its use as a continuous infusion (1-20 µg/kg/minute) to maintain therapeutic plasma concentrations. Extravasation of dopamine, like norepinephrine, produces intense local vasoconstriction, which may be treated with local infiltration of phentolamine.²¹ Dopamine is not effective orally and does not cross the blood–brain barrier in sufficient amounts to cause CNS effects. The immediate precursor of dopamine, L-dopa, is absorbed from the gastrointestinal tract and readily crosses the blood–brain barrier. Dopamine is partially protein bound. Approximately 25% is converted to norepinephrine. Dopamine undergoes metabolism in the liver with conjugation to sulfates and glucuronides, pulmonary endothelium by catechol-O-methyltransferase (COMT), and excretion by the kidneys.

Clinical Uses

Dopamine is used clinically to increase cardiac output in patients with decreased contractility, low systemic blood pressure, and low urine output as may be present after cardiopulmonary bypass or in chronic heart failure.²⁰ It is unique among the catecholamines in being able to simultaneously increase myocardial contractility, renal blood flow, glomerular filtration rate, excretion of sodium, and urine output.²¹

In patients with cardiogenic shock, dopamine is not preferred over norepinephrine as the first-line agent because a subgroup analysis from a randomized trial found that patients with cardiogenic shock who received dopamine had a much higher mortality rate than those who received norepinephrine.²² In addition, dysrhythmias were more common in the dopamine group.

Renal-Dose Dopamine

The term **renal-dose dopamine** or **low-dose dopamine** refers to the continuous infusion of small doses (1-3 µg/kg/minute) of dopamine to patients to promote renal blood flow. In healthy individuals, low-dose dopamine increases renal blood flow and induces natriuresis and diuresis. Theoretically, dopamine's renal vasodilating effects may be useful in patients with impaired renal function or in patients at risk for decreased renal perfusion as may occur with decreased cardiac output. Dopamine binds to D₁ and D₂ receptors in the proximal tubule, thick ascending loop of Henle, and cortical collecting ducts inhibiting Na⁺-K⁺ ATPase activity, increasing Na⁺ excretion, inducing natriuresis and diuresis.²³ The activation of D₂ in inner medullary collecting ducts stimulates prostaglandin E₂ production. This antagonizes the effects of antidiuretic hormone and results in increased free water clearance. Prostaglandin E₂ enhances blood flow in the inner medulla. Inhibition of aldosterone also increases sodium excretion and diuresis. Hence, dopamine has direct and indirect effects on the renal vasculature in addition to functioning as a diuretic.

The term **renal-dose** or **low-dose dopamine** is misleading as dopamine has many effects at sites other than the kidneys, even at low doses. Dopamine's effects based on dose alone are unpredictable. Low-dose dopamine also implies an unproven beneficial effect on renal function.²⁴⁻²⁶ The use of dopamine after the renal insult has occurred has not been shown to improve glomerular filtration rate. There is evidence that the beneficial effect of low-dose dopamine on renal blood flow and glomerular filtration rate observed in healthy individuals is due to drug-induced increases in cardiac output, and this benefit is lost in early renal failure.²⁶

No randomized controlled studies have demonstrated a decrease in the incidence of acute renal failure when dopamine is administered to patients considered to be at risk for developing acute renal failure in multiple patient populations including major vascular surgery,²⁷ cardiopulmonary bypass, intensive care,²⁸ heart failure, sepsis,²⁹ transplantation, patients exposed to nephrotoxic drugs³⁰ confirming the results of two meta-analyses,^{24,25} finding that dopamine does not prevent or reverse acute renal failure or improve outcome. Low-dose dopamine is associated with multiple complications affecting the cardiovascular, pulmonary, gastrointestinal, endocrine, and immune systems. A multicenter observational study demonstrated that dopamine is an independent risk factor for death for patients with shock due to any cause.³¹ In the absence of data confirming the efficacy of dopamine in preventing acute renal failure, renal-dose dopamine cannot be recommended. In fact, not only does low-dose dopamine not confer to any renal protective mechanism, it may in fact be detrimental.³²

Cardiovascular Effects

Dopamine is associated with dose-dependent sinus tachycardia and the potential to cause ventricular arrhythmias³³ and may predispose to myocardial ischemia by precipitating tachycardia, increasing contractility, increasing afterload, and precipitating coronary artery vasospasm. Dopamine increases peripheral vascular resistance and pulmonary artery pressures.

Gastrointestinal Effects

Gastrointestinal mucosal ischemia and subsequent translocation of bacteria and bacterial toxins play an important role in the development of multiple organ dysfunction syndrome. Dopamine's effect on splanchnic blood flow and gastric intramucosal pH is controversial and inconsistent. There is no evidence that low-dose dopamine has beneficial effects on splanchnic function or reduces the progression to multiorgan failure in sepsis. In septic patients, dopamine but not norepinephrine, as administered to maintain an acceptable mean arterial pressure, resulted in an uncompensated increase in splanchnic oxygen requirements. Although dopamine infusion in septic patients led to increased hepatosplanchic perfusion, hepatosplanchic oxygen uptake was reduced suggesting an impairment of hepatosplanchic metabolism.³⁴ Dopamine agonists interfere with gastrointestinal motility. Low-dose dopamine has been demonstrated to slow gastric motility in mechanically ventilated intensive care patients.³⁵

Endocrine and Immunologic Effects

Dopamine disrupts metabolic and immunologic functions through its effects on hormones and lymphocyte function. In the acute phase of an illness, dopamine induces the pattern of hypopituitarism seen in prolonged

critical illness and chronic stress. When dopamine is used in the chronic phase of illness, it further suppresses the circulating concentrations of pituitary hormones.³⁶ Dopamine depresses the immune status by reducing serum prolactin levels. Prolactin is an immunoregulatory hormone affecting T and B lymphocytes. Dopamine inhibits lymphocyte proliferation, immunoglobulin synthesis, and cytokine production and promotes lymphocyte apoptosis. Dopamine also decreases the secretion of growth hormone, which has anabolic, lipolytic, and immune-stimulating properties. Growth hormone deficiency can contribute to impaired anabolism and a negative nitrogen balance. Dopamine's overall effect is to suppress the secretion and function of anterior pituitary hormones, aggravating catabolism and cellular immune function and inducing central hypothyroidism.³⁶

Respiratory Effects

The infusion of low-dose dopamine in healthy subjects as well as heart failure patients interferes with the ventilatory response to arterial hypoxemia and hypercapnia, reflecting the role of dopamine as an inhibitory neurotransmitter at the carotid bodies.³⁷ The result is depression of ventilation in patients who are being treated with dopamine to increase myocardial contractility.³⁸ Dopamine also decreases arterial oxygen saturation by impairing regional ventilation/perfusion matching in the lungs.³⁹ Dose-dependent reductions in arterial PO_2 with increasing rates of dopamine in critically ill patients after major surgery have been demonstrated.⁴⁰

Intraocular Pressure

Continuous infusions of dopamine to critically ill patients are associated with increases in intraocular pressure.⁴¹ This may create a risk in patients with preexisting glaucoma especially if they are sedated and mechanically ventilated.

Synthetic Catecholamines

The two clinically useful synthetic catecholamines are isoproterenol and dobutamine (see [Table 18.1](#) and [Figure 18.1](#)).

Isoproterenol

Isoproterenol is the most potent activator of all the sympathomimetics with β_1 and β_2 receptor activity. In clinical doses, isoproterenol is devoid of α agonist effects and does not cause the vasoconstriction associated with the naturally occurring catecholamines.

The cardiovascular effects of isoproterenol reflect activation of β_1 receptors in the heart and β_2 receptors in skeletal muscle and to a lesser extent renal and splanchnic vascular beds. In an adult, continuous infusion of isoproterenol, 1 to 5 μg per minute, greatly increases heart rate, myocardial contractility, and cardiac automaticity, whereas vasodilation in skeletal muscles decreases systemic vascular resistance. Although cardiac output may increase thereby increasing systolic blood pressure, the mean arterial pressure may decrease due to decreases in systemic vascular resistance and associated decreases in diastolic blood pressure.

Increases in cardiac output may be attenuated by impaired left ventricular filling due to tachycardia as well as decreased preload from venous vasodilation. Decreased diastolic blood pressure, increased heart rate, and cardiac dysrhythmias may lead to a decrease in coronary blood flow at the same time that myocardial oxygen requirements are increased by tachycardia and increased myocardial contractility.⁴² Compensatory baroreceptor-mediated reflex slowing of the heart rate does not occur during infusion of isoproterenol because mean arterial pressure is not increased. This combination of events may be deleterious in patients with coronary artery disease. Compared to dobutamine, for a comparable increase in cardiac output, isoproterenol is associated with larger decreases in total peripheral vascular resistance and blood pressure.⁴³ It is also associated with more tachycardia both from direct β effects as well as a reflex increase in heart rate with decreased vascular tone. Metabolism of isoproterenol in the liver by COMT is rapid, necessitating a continuous infusion to maintain therapeutic plasma concentrations.

Clinical Uses

A continuous infusion of isoproterenol, 1 to 5 µg per minute, is effective in increasing the heart rate in adults in the presence of heart block. Isoproterenol is used to provide sustained increases in heart rate before insertion of a temporary or permanent cardiac pacemaker in the treatment of bradycardias.

Isoproterenol's ability to decrease pulmonary vascular resistance may be useful in the management of pulmonary hypertension and right ventricular dysfunction.⁴⁴ The use of isoproterenol as an inotropic drug has decreased with the availability of inotropic agents such as dobutamine and phosphodiesterase inhibitors.

Likewise, the use of isoproterenol as a bronchodilator has been supplanted by the availability of specific β_2 agonists.

Adverse Effects

Vasodilation and decreased blood pressure may limit the use of isoproterenol. In addition, it can lead to tachyarrhythmias. The combination of decreased diastolic blood pressure and increased heart rate and dysrhythmias may lead to myocardial ischemia.

Dobutamine

Dobutamine is a synthetic catecholamine derived from isoproterenol consisting of a 50:50 racemic mixture of two stereoisomers.⁴⁵ The (-) enantiomer is a potent α_1 -adrenergic agonist as well as a weak β_1 - and β_2 -adrenergic agonist. The (+) enantiomer is a competitive antagonist at the α_1 receptor site as well as a potent β_1 - and β_2 -adrenergic agonist.⁴⁶ Dobutamine has potent β_1 -adrenergic effects with weaker β_2 -adrenergic activity. Its effect on α receptors increases at higher doses. Dobutamine's cardiovascular effects are a result of the combination of activity of its two stereoisomers.^{46,47}

Dobutamine acts primarily as a positive inotropic agent. Dobutamine leads to an increase in intracellular cAMP, increasing calcium release from the sarcoplasmic reticulum to increase contractility. Cardiac output is increased primarily by an increase in stroke volume. Contractility is increased from its action on myocardial β_1 and α_1 receptors and, to a lesser extent, by decreased afterload from its effect on vascular smooth muscle β_2 receptors. Dobutamine has weak effects on vascular tone causing peripheral vasodilation. At higher doses, the (-) isomer stimulates α_1 receptors, limiting further vasodilation. Blood pressure usually is not significantly affected as α_1 -mediated vasoconstriction by the (-) enantiomer is countered by α_1 antagonism by the (+) enantiomer and by its β_2 activity, although the latter may be unmasked by β blockade therapy.^{46,47}

Dobutamine affects heart rate through its action on β_1 -adrenergic receptors. Dobutamine stimulates sinoatrial node automaticity as well as atrioventricular nodal and ventricular conduction.³³ The increase in calcium that facilitates increased contractility also facilitates increased arrhythmias. At low doses, increases in heart rate may be minimal. However, high doses of dobutamine (>10 µg/kg/minute IV) may predispose the patient to tachycardia and cardiac dysrhythmias. Dobutamine increases myocardial oxygen consumption by increasing tachycardia and myocardial contractility.

Dobutamine causes modest reductions in pulmonary arterial pressure and vascular resistance through its effects on β_2 receptors. In patients with increased pulmonary artery pressure after mitral valve replacement, an infusion of dobutamine (up to 10 µg/kg/minute) increases cardiac output and decreases systemic and pulmonary vascular resistance.⁴⁸ Rapid metabolism of dobutamine (half-life of 2 minutes) necessitates its administration as a continuous infusion of 2 to 10 µg/kg/minute to maintain therapeutic plasma concentrations. Tachyphylaxis may occur as it acts on β -adrenergic receptors. Dobutamine undergoes biotransformation in the liver to inactive glucuronide conjugates and 3-O-methyl dobutamine, most of which is excreted in the urine.⁴⁹

Clinical Uses

Dobutamine produces potent β -adrenergic agonist effects at doses less than 5 µg/kg/minute IV increasing myocardial contractility (β_1 and α_1 receptors) and causing a modest degree of peripheral vasodilation (β_2

receptors). Dobutamine is used to improve cardiac output in patients with heart failure.⁵⁰ Dobutamine is also useful for weaning from cardiopulmonary bypass.⁵¹

It may be of use in patients with pulmonary hypertension, although its effect on the pulmonary vasculature is less than that of the phosphodiesterase inhibitors. Combinations of drugs may be useful to increase the spectrum of activity and improve the distribution of cardiac output. For example, vasodilators may be combined with dobutamine or dopamine to decrease afterload, optimizing cardiac output in the presence of increased systemic vascular resistance. Myocardial oxygen consumption is increased by the increasing tachycardia and contractility, whereas coronary blood flow is decreased by vasodilation.⁴⁹ These properties make dobutamine useful for pharmacologic stress testing to detect potential areas of myocardial ischemia.

The most recent Surviving Sepsis guidelines recommend that a trial of dobutamine infusion be administered or added to preexisting vasopressor therapy in the presence of myocardial dysfunction⁵ defined as elevated cardiac filling pressures and low cardiac output. Therapy with dobutamine is also recommended for patients with ongoing signs of hypoperfusion despite achievement of adequate intravascular volume and mean arterial pressure. These guidelines recommendation, however, are based on a paucity of outcomes data from randomized controlled trials.

Adverse Effects

The use of dobutamine may be limited by the occurrence of tachyarrhythmias, although it is less likely than dopamine or isoproterenol. Sinus tachycardia occurs most commonly, although ventricular arrhythmias may also occur.³³ Tachyarrhythmias occur more frequently at higher dosages or in patients with underlying arrhythmias or heart failure.

Synthetic Noncatecholamines

The commonly used noncatecholamine sympathomimetic drugs are ephedrine and phenylephrine ([Figure 18.5](#)). These will be familiar to every reader.

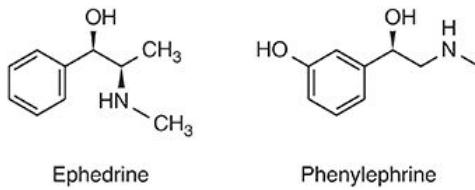

FIGURE 18.5 Synthetic noncatecholamine sympathomimetics.

Ephedrine

Ephedrine is an indirect-acting synthetic sympathomimetic that stimulates α- and β-adrenergic receptors. The pharmacologic effects of ephedrine are partly due to direct stimulation of adrenergic receptors (direct-acting)⁵² and partly due to stimulation of release of endogenous norepinephrine (indirect-acting). Ephedrine is resistant to metabolism by monoamine oxidase in the gastrointestinal tract, thus permitting unchanged drug to be absorbed into the circulation after oral administration. Intramuscular injection of ephedrine is clinically acceptable because drug-induced local vasoconstriction is insufficient to delay systemic absorption or lead to tissue injury.

Ephedrine, unlike epinephrine, does not produce marked hyperglycemia. Mydriasis accompanies the administration of ephedrine, and CNS stimulation does occur, although less than that produced by amphetamine.

Clinical Uses

Ephedrine, 5 to 10 mg IV administered to adults, is a commonly selected sympathomimetic to increase systemic blood pressure in the presence of sympathetic nervous system blockade produced by regional anesthesia or hypotension due to inhaled or injected anesthetics. In an animal model, ephedrine more

specifically corrected the noncardiac circulatory changes produced by spinal anesthesia than did a selective α or β agonist drug.⁵³ For many years, ephedrine was considered the preferred sympathomimetic for administration to parturients experiencing decreased systemic blood pressure owing to spinal or epidural anesthesia. Support for this practice was the observation in pregnant ewes that uterine blood flow was not greatly altered when ephedrine was administered to restore maternal blood pressure to normal after sympathetic nervous system blockade.⁵⁴ Recent reviews of trials of ephedrine versus phenylephrine have concluded that systemic blood pressure control is similar with both drugs but phenylephrine is associated with a higher umbilical artery pH at delivery than ephedrine.⁵⁴ Administration of phenylephrine by infusion during cesarean section to maintain maternal systolic blood pressure at baseline is associated with a lower incidence of fetal acidosis than is ephedrine.⁵⁵ Based on these data, it seems that α agonists such as phenylephrine may be preferable to ephedrine for treatment of maternal hypotension.

Ephedrine, 0.5 mg/kg intramuscularly, has an antiemetic effect similar to that of droperidol but with less sedation when administered to patients undergoing outpatient laparoscopy using general anesthesia.⁵⁶

Cardiovascular Effects

The cardiovascular effects of ephedrine resemble those of epinephrine, but its systemic blood pressure-elevating response is less intense and lasts longer. The IV ephedrine results in increases in systolic and diastolic blood pressure, heart rate, and cardiac output. Renal and splanchnic blood flows are decreased, whereas coronary and skeletal muscle blood flows are increased. Systemic vascular resistance may be altered minimally because vasoconstriction in some vascular beds is offset by vasodilation (β_2 stimulation) in other areas. These cardiovascular effects are due, in part, to α receptor-mediated peripheral arterial and venous vasoconstriction. The principal mechanism, however, for cardiovascular effects produced by ephedrine is increased myocardial contractility due to activation of β_1 receptors. In the presence of preexisting β -adrenergic blockade, the cardiovascular effects of ephedrine may resemble responses more typical of α -adrenergic receptor stimulation.

Phenylephrine

Phenylephrine, 3-hydroxyphenylethylamine, is a synthetic noncatecholamine. Phenylephrine differs from epinephrine only in lacking a 4-hydroxyl group on the benzene ring. Clinically, phenylephrine mimics the effects of norepinephrine but is less potent and longer lasting. Phenylephrine principally stimulates α_1 -adrenergic receptors by a direct effect, with only a small part of the pharmacologic response being due to its ability to evoke the release of norepinephrine (indirect-acting).⁵⁷ Phenylephrine exerts minimal effects on β -adrenergic receptors. The dose of phenylephrine necessary to stimulate α_1 receptors is far less than the dose that stimulates α_2 receptors. Phenylephrine primarily causes venoconstriction rather than arterial constriction. The CNS stimulation is minimal.

Clinical Uses

Phenylephrine, 50 to 200 μ g IV bolus, is often administered to adults to treat systemic blood pressure decreases that accompany sympathetic nervous system blockade produced by a regional anesthetic and peripheral vasodilation following administration of IV or inhaled anesthetics.⁵⁸ Phenylephrine is believed to be particularly useful in patients with coronary artery disease and in patients with aortic stenosis because it increases coronary perfusion pressure without chronotropic side effects, unlike most other sympathomimetics. Phenylephrine has been used as a continuous infusion (20-100 μ g per minute) in adults to maintain normal blood pressure during surgery. The reflex vagal effects produced by phenylephrine can be used to slow heart rate in the presence of hemodynamically significant supraventricular tachydysrhythmias.

Due to the potential for decreasing stroke volume, the Surviving Sepsis guidelines do not recommend phenylephrine for the treatment of septic shock unless patients experience serious arrhythmias with norepinephrine, have high cardiac output, or require salvage therapy.⁵

Cardiovascular Effects

Rapid IV injection of phenylephrine to patients with coronary artery disease produces dose-dependent peripheral vasoconstriction and increases in systemic blood pressure, which are accompanied by decreases in cardiac output (**Figure 18.6**).⁵⁹ Decreases in cardiac output may reflect increased afterload but more likely are due to baroreceptor-mediated reflex bradycardia in response to drug-induced increases in diastolic blood pressure. It is possible that decreases in cardiac output could limit the associated increases in systemic blood pressure. Rapid administration of phenylephrine, 1 µg/kg IV, to anesthetized patients with coronary artery disease causes a transient impairment of left ventricular global function.⁶⁰ Oral clonidine premedication augments the pressor response to phenylephrine, presumably due to clonidine-induced potentiation of α_1 -mediated vasoconstriction.⁶¹ Renal, splanchnic, and cutaneous blood flows are decreased, but coronary blood flow is increased. Pulmonary artery pressure is increased by phenylephrine.

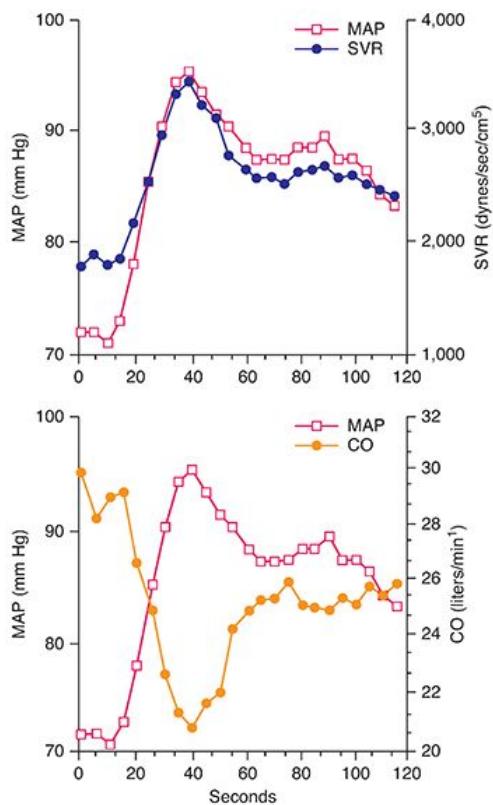

FIGURE 18.6 Hemodynamic response to rapid intravenous injection of phenylephrine in a single patient. Mean arterial pressure (MAP) and systemic vascular resistance (SVR) increase, and cardiac output (CO) decreases in response to phenylephrine, with peak effects occurring 42 seconds after drug administration. Reprinted with permission from Schwinn DA, Reeves JG. Time course and hemodynamic effects of alpha-1-adrenergic bolus administration in anesthetized patients with myocardial disease. Treatment of Overdose

Systemic manifestations of sympathetic nervous system activation (systemic hypertension, tachycardia, baroreceptor-mediated bradycardia) may accompany vascular absorption of α agonists (phenylephrine, epinephrine) when used as topical or injected vasoconstrictors in the surgical field. Phentolamine, an α_1 -adrenergic receptor antagonist, is an appropriate pharmacologic choice for phenylephrine toxicity.⁶² Because β_1 receptor blockade reduces cardiac output, treatment of phenylephrine-induced hypertensive crisis with β -adrenergic blocking drugs is *contraindicated*. However, systemic hypertension induced by intravenously administered α agonists may not require treatment. The duration of action of IV phenylephrine and

epinephrine is brief and hypertension may resolve spontaneously without pharmacologic interventions. Severe hypertension may require pharmacologic interventions, but treatment must not decrease the ability of the stressed myocardium to increase contractility and heart rate. In this circumstance, vasodilating drugs such as nitroprusside or nitroglycerin may be helpful.

Selective β_2 -Adrenergic Agonists

Selective β_2 -adrenergic agonists relax bronchiole and uterine smooth muscle but in contrast to isoproterenol generally lack stimulating (β_1) effects on the heart. Nevertheless, high concentrations of these drugs are likely to cause stimulation of β_1 receptors. The chemical structure of selective β_2 -adrenergic agonists (placement of hydroxyl groups on the benzene ring at sites different than the catecholamines) renders them resistant to methylation by COMT, thus contributing to their sustained duration of action. The commonly used β_2 -adrenergic agonists are albuterol, metaproterenol, and terbutaline (Figure 18.7) (Table 18.2).

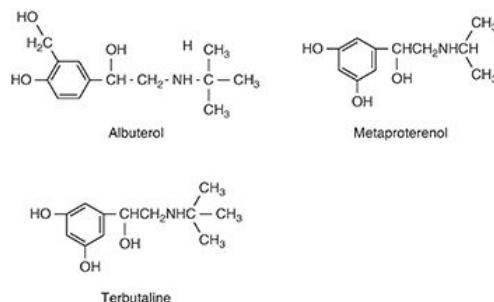

FIGURE 18.7 Selective β_2 -adrenergic agonists.

TABLE 18.2

Comparative pharmacology of selective β_2 -adrenergic agonist bronchodilators

	β_2 Selectivity	Peak effect (minutes)	Duration of action (hour)	Concentration (μ g per puff)	Method of administration
Albuterol	High	30-60	4	90	MDI, oral
Metaproterenol	Moderate	30-60	3-4	200	Oral, subcutaneous
Terbutaline	High	60	4	200	MDI, oral, subcutaneous

Abbreviation: MDI, metered-dose inhaler.

Clinical Uses

β_2 -Adrenergic agonists are the preferred treatment for acute episodes of asthma and the prevention of exercise-induced asthma.⁶³ Currently used β_2 -adrenergic agonists may be divided into those with an intermediate duration of action (3-6 hours) and those that are long acting (>12 hours).⁶³ Among the intermediate-acting drugs, there is little reason to choose one over the other. β_2 -Adrenergic agonists are also used regularly in patients with chronic obstructive pulmonary disease, resulting in improved air flow and exercise tolerance. The long-acting β_2 -adrenergic agonist salmeterol is highly lipophilic and has a high affinity for the β_2 receptor, resulting in prolonged activation at this site. In addition to the treatment of bronchospasm, β_2 -adrenergic agonists may also be administered as continuous infusions to stop premature uterine contractions (tocolytics).

Route of Administration

β_2 -Adrenergic bronchodilators can be administered orally, by inhalation, subcutaneously, or intravenously. The inhaled route is preferred because the side effects are fewer for any given degree of bronchodilation. Inhalation is as effective as parenteral administration for treating acute, severe attacks of asthma in most patients, although some who have severe bronchial obstruction may benefit initially from parenteral therapy.

Inhaled β_2 -adrenergic agonists can be administered as an aerosol from a jet or ultrasonic nebulizer or they can be administered from a metered-dose inhaler either as a propellant-generated aerosol or as a breath-propelled dry powder. With optimal inhalation technique (discharge the inhaler while taking a slow deep breath over 5-6 seconds and then hold the breath at full inspiration for 10 seconds), approximately 12% of the drug is delivered from the metered-dose inhaler to the lungs; the remainder is deposited in the mouth, pharynx, and larynx.⁶³ The presence of an endotracheal tube decreases by approximately 50% to 70% the amount of drug delivered by a metered-dose inhaler that reaches the trachea.⁶⁴ Actuation of the metered-dose inhaler during a mechanically delivered inspiration increases the amount of drug that passes beyond the distal end of the tracheal tube.

Side Effects

The widespread distribution of β_2 -adrenergic receptors makes it likely that undesired responses may result when β_2 -adrenergic agonists undergo systemic absorption. The ability to minimize these systemic side effects by decreasing plasma drug concentrations is an advantage of administering β_2 -adrenergic bronchodilators by inhalation.

The principal side effect in awake subjects of β_2 -adrenergic agonists treatment is tremor, which is caused by direct stimulation of β_2 receptors in skeletal muscles. Increased heart rate is less common with the selective β_2 -adrenergic agonists, but even stimulation of β_2 receptors may result in vasodilation and reflex tachycardia. As there are β_2 -adrenergic receptors in the heart, direct stimulation of the heart results from the use of selective β_2 -adrenergic agonists. In patients with acute, severe asthma, β_2 -adrenergic agonists may cause a transient decrease in arterial oxygenation presumed to reflect relaxation of compensatory vasoconstriction in areas of decreased ventilation.

Lactic acidosis may occur in association with β_2 agonist therapy, perhaps reflecting excess glycogenolysis and lipolysis from β_2 receptor activation.⁶⁵

Albuterol

Albuterol is the preferred selective β_2 -adrenergic agonist for the treatment of acute bronchospasm due to asthma. Administration is most often by metered-dose inhaler, producing about 100 μg per puff; the usual dose is two puffs delivered during deep inhalations 1 to 5 minutes apart. This dose may be repeated every 4 to 6 hours, not to exceed 16 to 20 puffs daily. Alternatively, 2.5 to 5 mg of albuterol (0.5-1 mL of 0.5% solution in 5 mL of normal saline) may be administered by nebulization every 15 minutes for three to four doses, followed by treatments hourly during the initial hours of therapy. The duration of action of an inhaled dose is about 4 hours, but significant relief of symptoms may persist up to 8 hours. The effects of albuterol and volatile anesthetics on bronchomotor tone are additive.⁶⁶

Continuous nebulization of albuterol using a large reservoir system to deliver up to 15 mg per hour for 2 hours may be appropriate and necessary in the presence of life-threatening asthma. Tachycardia and hypokalemia may accompany these large doses of albuterol. Nevertheless, larger doses and more frequent dosing intervals for inhaled β -adrenergic agonist therapy are needed in acute severe asthma due to decreased deposition at the site of action (low tidal volumes and narrowed airways), alteration in the dose-response curve, and altered duration of activity. Inhaled albuterol (four puffs) blunts airway responses to tracheal intubation in asthmatic patients.⁶⁷

Metaproterenol

Metaproterenol is a selective β_2 -adrenergic agonist used to treat asthma. Administered by metered-dose inhaler, the daily dosage should not exceed 16 puffs, with each metered-aerosol actuation delivering approximately 650 μg .

Terbutaline

Terbutaline is a predominantly β_2 -adrenergic agonist that may be administered orally, subcutaneously, or by inhalation to treat asthma. Terbutaline is used frequently by oral route to suppress labor. The subcutaneous administration of terbutaline (0.25 mg) produces responses that resemble those of epinephrine, but the duration of action is longer. The subcutaneous dose of terbutaline for children is 0.01 mg/kg. Administered by metered-dose inhaler, the daily dose should not exceed 16 to 20 puffs, with each metered-dose actuation delivering about 200 μg .

Cardiac Glycosides

Digitalis is the term used for cardiac glycosides that occur naturally in many plants, including the foxglove plant. Digoxin, digitoxin, and ouabain are examples of clinically useful cardiac glycosides ([Figure 18.8](#)). Of these, only digoxin remains commonly used.

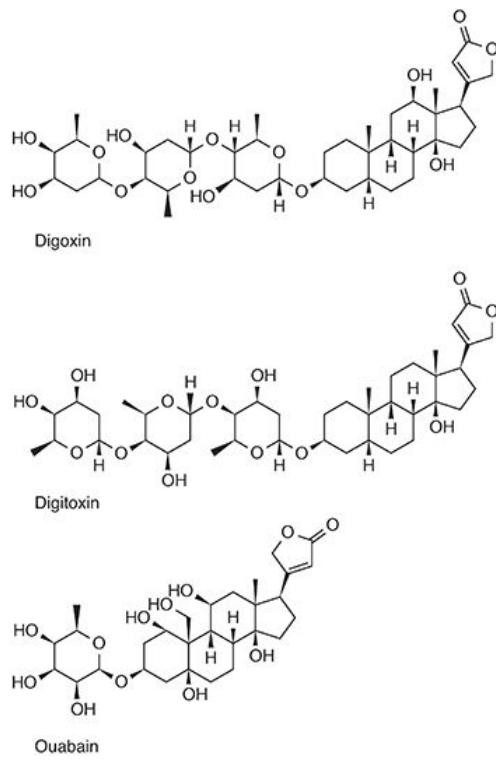

FIGURE 18.8 Cardiac glycosides.

Digoxin

Digoxin is used most often during the perioperative period for the management of supraventricular tachydysrhythmias (paroxysmal atrial tachycardia, atrial fibrillation, atrial flutter) associated with a rapid ventricular response rate based on the ability of these drugs to slow conduction of cardiac impulses through the atrioventricular node. The use of digoxin to treat acute decreases in left ventricular contractility is uncommon because of the availability of more efficacious drugs. Heart failure patients treated with digoxin have a lower incidence of hospitalizations but their mortality is not decreased.[68,69](#) Based on this observation, digoxin may be selected only for treatment of symptoms that persist after a comprehensive neurohormonal blockade (angiotensin-converting enzyme inhibitors, β -adrenergic antagonists, aldosterone antagonists),

which have been shown to decrease overall mortality in heart failure patients.⁶⁸ Nevertheless, digoxin continues to have an important therapeutic role in the treatment of chronic heart failure.

Direct current cardioversion in the presence of digoxin toxicity may be hazardous because of increased risk of developing cardiac dysrhythmias, including ventricular fibrillation. Hypokalemia should be corrected and lidocaine IV should be prophylactically given to decrease the likelihood of a ventricular dysrhythmias. Digoxin may be harmful in patients with hypertrophic subaortic stenosis because increased myocardial contractility intensifies the resistance to ventricular ejection.

Pharmacokinetics

The bioavailability of oral digoxin is 60% to 80%.⁷⁰ In some patients, the digoxin levels may be reduced by up to 40% due to digestion by colonic bacteria. Peak plasma concentrations are observed 1 to 3 hours following oral administration. Following IV administration, the bioavailability is 100%, and peak plasma concentrations are observed immediately following administration as expected for all drugs. Digoxin is eliminated almost entirely by renal excretion, with a half-life of 1 to 2 days. The half-life is inversely proportional to glomerular filtration rate and thus increases with age or renal disease.

Figure 18.9 shows the plasma and effect site time course of 0.5 mg of digoxin, given either orally (**Figure 18.9A**) or intravenously (**Figure 18.9B**), based on the pharmacokinetic model of Jelliffe et al.⁷¹ The time course of digoxin is reflected in the effect site concentration, shown in red, rather than the plasma concentration, shown in blue. The effect site is thought to include the myocardium, along with most other tissues.

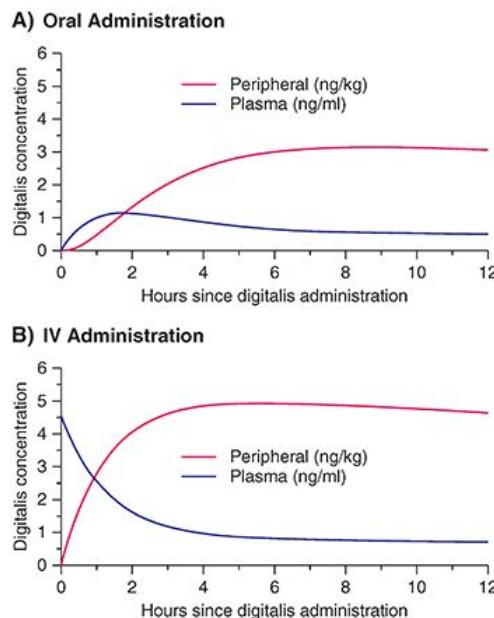

FIGURE 18.9 Simulated plasma (blue line) and peripheral (red line) concentrations of digoxin following a 0.5-mg oral (A) or intravenous (B) dose. *The simulation is based on the pharmacokinetic model of Jelliffe RW, Milman M, Schumitzky A, et al. A two-compartment population pharmacokinetic-pharmacodynamic model of digoxin in adults, with implications for dosage. Ther Drug Monit. 2014;36(3):387-393.*

The onset time for oral digoxin is 0.5 to 2 hours, with a peak effect about 6 hours after ingestion. With IV use, the onset time is 10 to 30 minutes, with a peak effect 2 to 4 hours after administration. After achievement of therapeutic plasma concentrations of digoxin by either the oral or IV route, the maintenance oral dose is adjusted according to the individual patient's response, the electrocardiogram (ECG), and the plasma concentration of digoxin.

Mechanism of Action

The complex mechanisms of the positive inotropic effect evoked by cardiac glycosides include direct effects on the heart that modify its electrical and mechanical activity and indirect effects evoked by reflex alterations in autonomic nervous system activity. Cardiac glycosides selectively and reversibly inhibit the $\text{Na}^+ \text{-K}^+$ ATPase ion transport system (sodium pump) located in the sarcolemma (cell wall) of cardiac cells. Cardiac glycosides bind to the α subunit on the extracellular surface of the ATPase enzyme, inducing a conformational change that interferes with outward transport of sodium ions across cardiac cell membranes. The result is an increase in intercellular sodium. A second transporter is the sodium-calcium exchanger, which transports calcium out of the cell in exchange for sodium. Intracellular sodium accumulates when the sodium-potassium exchanger is blocked by cardiac glycosides. The resulting increase in cellular sodium ion concentration in turn blocks the sodium-calcium exchanger and increases intracellular calcium. Increased intracellular calcium is the primary mechanism of inotropic action for digitalis and related cardiac glycosides. The positive inotropic effects produced by cardiac glycosides occur without changes in heart rate and are associated with decreases in left ventricular preload, afterload, wall tension, and oxygen consumption in the failing heart.⁷²

The principal cardiovascular effect of digitalis glycosides administered to patients with cardiac failure is a dose-dependent increase in myocardial contractility that becomes significant with less than full digitalizing doses. The positive inotropic effect manifests as increased stroke volume, decreased heart size, and decreased left ventricular end-diastolic pressure (LVEDP). Indeed, cardiac glycosides can double stroke volume from a failing and dilated left ventricle. The ventricular function curve (Frank-Starling curve) is shifted to the left ([Figure 18.10](#)). Improved renal perfusion due to an overall increase in cardiac output favors mobilization and excretion of edema fluid, accounting for the diuresis that often accompanies the administration of cardiac glycosides to patients in cardiac failure. Excessive sympathetic nervous system activity that occurs as a compensatory response to cardiac failure is decreased with the improved circulation that accompanies administration of cardiac glycosides. The resulting decrease in systemic vascular resistance further enhances forward left ventricular stroke volume.

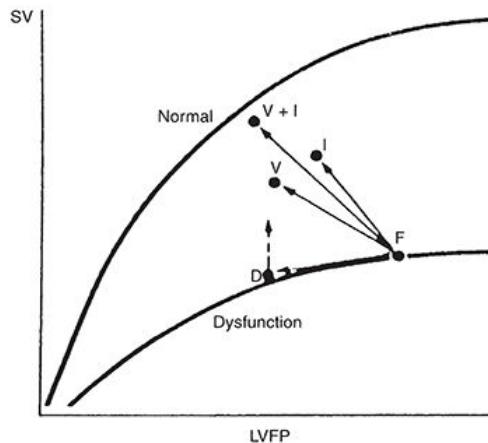

FIGURE 18.10 Cardiac glycosides shift the ventricular function curve of the failing myocardium to the left. Abbreviations: LVFP, left ventricular filling pressure; SV, stroke volume.

Cardiac glycosides also increase myocardial contractility in the absence of cardiac failure. Nevertheless, the resulting tendency for cardiac output to increase may be offset by decreases in heart rate and direct vasoconstricting effects of cardiac glycosides on arterial and, to a lesser extent, venous smooth muscle. Indeed, cardiac output is often unchanged or even decreased when cardiac glycosides are administered to patients with normal hearts.

In addition to positive inotropic effects, cardiac glycosides enhance parasympathetic nervous system activity, leading to delayed conduction of cardiac impulses through the atrioventricular node and decreases in heart rate. The magnitude of this negative dromotropic and chronotropic effect depends on the preexisting activity of the autonomic nervous system. Increased parasympathetic nervous system activity decreases

contractility in the atria, but direct positive inotropic effects of cardiac glycosides more than offset these nervous system–induced negative inotropic effects on the ventricles.

The electrophysiologic effects of therapeutic plasma concentrations of cardiac glycosides manifest on the ECG as (1) prolonged P-R intervals due to delayed conduction of cardiac impulses through the atrioventricular node, (2) shortened QTc intervals because of more rapid ventricular repolarization, (3) ST segment depression (scaphoid or scooped out) due to a decreased slope of phase 3 depolarization of cardiac action potentials, and (4) diminished amplitude or inversion of T waves. The P-R interval is rarely prolonged to longer than 0.25 second, and the effect on the QTc interval is independent of parasympathetic nervous system activity. Changes in the ST segment and T wave do not correlate with therapeutic plasma concentrations of cardiac glycosides. Furthermore, ST-segment and T-wave changes on the ECG may suggest myocardial ischemia. When digitalis is discontinued, the changes on the ECG disappear in several weeks.

Toxicity

Cardiac glycosides have a narrow therapeutic range. The serum digoxin concentration does not necessarily correlate with toxicity. Numerous reports have described asymptomatic patients with a “toxic” level, whereas others describe patients with significant toxicity symptoms but with a serum digoxin level in the therapeutic range.⁷³ The most frequent cause of digitalis toxicity in the absence of renal dysfunction is the concurrent administration of diuretics that cause potassium depletion. Hypokalemia probably increases myocardial binding of cardiac glycosides, resulting in an excess drug effect. Indeed, binding of cardiac glycosides to the Na⁺-K⁺ ATPase enzyme complex is inhibited by increases in the plasma concentration of potassium. Other electrolyte abnormalities that contribute to digitalis toxicity include hypercalcemia and hypomagnesemia. An increase in sympathetic nervous system activity as produced by arterial hypoxemia increases the likelihood of digitalis toxicity.

Elderly patients with decreased renal function are vulnerable to the development of digitalis toxicity if usual doses of digoxin are administered. Impaired renal function and electrolyte changes (hypokalemia, hypomagnesemia) that may accompany cardiopulmonary bypass could predispose the patient to the development of digitalis toxicity.

Diagnosis

Determination of the plasma digoxin concentration may be useful to indicate the likely presence of digitalis toxicity. A plasma digoxin concentration of less than 0.5 ng/mL eliminates the possibility of digitalis toxicity. Plasma concentrations between 0.5 and 2.5 ng/mL are usually considered therapeutic, but some patients can have toxicity even at this range. Levels greater than 3 ng/mL are in a toxic range. Infants and children have an increased tolerance to cardiac glycosides, and their range of therapeutic concentrations for digoxin is 2.5 to 3.5 ng/mL. Anorexia, nausea, and vomiting are early manifestations of digitalis toxicity. These symptoms, when present preoperatively in patients receiving cardiac glycosides, should arouse suspicion of digitalis toxicity.

There are no unequivocal features on the ECG that confirm the presence of digitalis toxicity.⁷⁴ Nevertheless, toxic plasma concentrations of digitalis typically cause atrial or ventricular cardiac dysrhythmias (increased automaticity) and delayed conduction of cardiac impulses through the atrioventricular node (prolonged P-R interval on the ECG), culminating in incomplete to complete heart block. Atrial tachycardia with block is the most common cardiac dysrhythmia attributed to digitalis toxicity. Activity of the sinoatrial node may also be directly inhibited by high doses of cardiac glycosides. Conduction of cardiac impulses through specialized conducting tissues of the ventricles is not altered, as evidenced by the failure of even toxic plasma concentrations of digoxin to alter the duration of the QRS complex on the ECG. Ventricular fibrillation is the most frequent cause of death from digitalis toxicity.

Treatment

Treatment of digitalis toxicity includes (1) correction of predisposing causes (hypokalemia, hypomagnesemia, arterial hypoxemia), (2) administration of drugs (phenytoin, lidocaine, atropine) to treat cardiac dysrhythmias, and (3) insertion of a temporary artificial transvenous cardiac pacemaker if complete

heart block is present. Supplemental potassium decreases the binding of digitalis to cardiac muscle and directly antagonizes the cardiotoxic effects of cardiac glycosides. Serum potassium concentrations should be determined before treatment because supplemental potassium in the presence of a high preexisting plasma level of potassium will intensify atrioventricular block and depress the automaticity of ectopic pacemakers in the ventricles, leading to complete heart block. Phenytoin (0.5-1.5 mg/kg IV over 5 minutes) or lidocaine (1-2 mg/kg IV) are effective in suppressing ventricular cardiac dysrhythmias caused by digitalis. Phenytoin is also effective in suppressing atrial dysrhythmias. Atropine, 35 to 70 µg/kg IV, can be administered to increase heart rate by offsetting excessive parasympathetic nervous system activity produced by toxic plasma concentrations of digitalis. Propranolol is effective in suppressing increased automaticity produced by digitalis toxicity, but its tendency to increase atrioventricular node refractoriness limits its usefulness when conduction blockade is present. Life-threatening digitalis toxicity can be treated by administering digoxin antibodies,⁷⁵ decreasing the plasma concentration of digoxin. The digoxin-antibody complex is eliminated by the kidneys. Hemodialysis is not recommended for digoxin removal due to high tissue distribution of the drug at steady state.

Drug Interactions

Sympathomimetics with β-adrenergic agonist effects may increase the likelihood of cardiac dysrhythmias in the presence of cardiac glycosides.⁷⁶ The IV administration of calcium may precipitate cardiac dysrhythmias in patients receiving cardiac glycosides. Any drug that facilitates renal loss of potassium increases the likelihood of hypokalemia and associated digitalis toxicity. The simultaneous administration of an oral antacid and digitalis decreases the gastrointestinal absorption of cardiac glycosides. Fentanyl, enflurane, and, to a lesser extent, isoflurane protect against digitalis-enhanced cardiac automaticity.⁷⁷

Selective Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors are a heterogeneous group of noncatecholamine nonglycoside compounds that exert a competitive inhibitory action on phosphodiesterase enzymes. Multiple types of phosphodiesterase enzymes exist in different tissues (cardiac muscle, vascular smooth muscle, platelets, liver, and lungs) possessing different cyclic nucleotide substrate specificity. Selective phosphodiesterase inhibitors exert different physiologic effects depending on their enzyme fraction specificity.⁷⁸ Selective inhibitors of phosphodiesterase fraction III (PDE III) (**Figure 18.11**) decrease the hydrolysis of cAMP, leading to increased intracellular concentrations of cAMP in the myocardium and vascular smooth muscle. They also have an indirect effect on cyclic guanosine monophosphate-dependent protein kinase in vascular smooth muscle. In myocardium, increased intracellular cAMP concentrations result in stimulation of protein kinases that phosphorylate the sarcoplasmic reticulum, increasing inward calcium current, increasing intracellular calcium and contractility. In vascular smooth muscle, increased cAMP decreases calcium available for contraction by facilitating the uptake of calcium by the sarcoplasmic reticulum, leading to smooth muscle relaxation and vasodilation. Although PDE III isoenzymes exist in airway smooth muscle, bronchodilation is not a predominant clinical effect of the current cardiac-selective PDE III inhibitors.

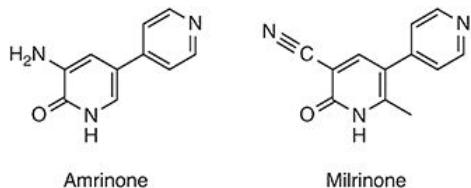

FIGURE 18.11 Selective inhibitors of phosphodiesterase subtype III, amrinone and milrinone.

The overall effect of selective PDE III inhibitors is to combine positive inotropic effects with smooth muscle relaxation in both arteriolar and venous beds. Hence, they have been termed **inodilators**. Physiologic effects include increased contractility, increased cardiac output, and decreased LVEDP in addition to increased venous capacitance, decreased filling pressures (central venous pressure and pulmonary capillary wedge pressure), and decreased venous return to the heart. Mean pulmonary artery pressures and pulmonary

and systemic vascular resistance are decreased. Selective PDE III inhibitors also improve the lusitropic (relaxed) state of the heart.⁷⁹ Diastolic relaxation is facilitated by enhanced calcium removal from the sarcoplasm, thereby improving ventricular filling.

These inodilators decrease preload and afterload. Hence, theoretically, wall tension and myocardial oxygen consumption should decrease, in contrast to dobutamine, which increases myocardial oxygen consumption as it increases contractility.

Selective PDE III inhibitors act independently of β -adrenergic receptors and will increase myocardial contractility in patients with myocardial depression from β receptor blockade and in patients who have downregulation of β -adrenergic receptors and are refractory to catecholamine therapy. The effects of catecholamines, which also increase cAMP concentrations but through β -adrenergic stimulation, are potentially enhanced by PDE III inhibition. The hemodynamic response to selective PDE inhibitors exceeds that of cardiac glycosides and is synergistic to the actions of catecholamines. These drugs can be used in conjunction with digitalis without provoking digitalis toxicity. The PDE III inhibitors have their greatest clinical usefulness in patients who would benefit from combined inotropic and vasodilator therapy.

Milrinone

Milrinone is a bipyridine derivative of amrinone with almost 30 times the inotropic potency of amrinone but less adverse side effects. Because of its reduced incidence of side effects, milrinone has replaced amrinone in clinical use. Cardiac output improves both as a result of increased inotropy as well as vascular smooth muscle relaxation of peripheral and pulmonary vessels.⁸⁰ Dose-dependent increases in cardiac index occur with minimal increases in myocardial oxygen consumption. Decreases in LVEDP, mean arterial pressure, central venous pressure, pulmonary artery occlusion pressure, pulmonary vascular resistance, and systemic vascular resistance occur as well as improvements in diastolic function.⁸¹

Milrinone is administered as an IV bolus of 50 $\mu\text{g}/\text{kg}$ over 10 minutes followed by a continuous infusion of 0.375 to 0.75 $\mu\text{g}/\text{kg}/\text{minute}$ to maintain plasma milrinone concentrations at or above therapeutic levels.⁸² A bolus dose of 50 $\mu\text{g}/\text{kg}$ was found to be as effective as a dose of 75 $\mu\text{g}/\text{kg}$ with fewer side effects and more effective than a dose of 25 $\mu\text{g}/\text{kg}$.⁸³ The maximum daily dose of milrinone should not exceed 1.3 mg/kg/day. Approximately 70% of the drug in circulation is protein bound. The elimination half-time is 2.7 hours, and about 80% of the drug is excreted unchanged by the kidneys with a minor part undergoing glucuronide conjugation before excretion. The dose should be decreased in patients with severe renal dysfunction.

Clinical Uses

Milrinone may be useful in the management of acute left ventricular dysfunction such as after cardiac surgery. Successful weaning of high-risk patients from cardiopulmonary bypass may be enhanced by administration of milrinone.⁸³⁻⁸⁵ Milrinone may potentiate the effects of adrenergic agents as well as help increase inotropy in chronic heart failure patients who have downregulation of β_1 -adrenergic receptors. In patients with congestive heart failure, symptomatic and hemodynamic improvements as well as improvement in exercise have been reported, although milrinone use does not slow the natural progression of disease.⁸⁶ Routine short-term milrinone treatment for acute exacerbation of chronic heart failure without hypotension from a low cardiac output state is not supported,⁸⁷ although milrinone may be used as a bridge to orthotopic heart transplantation. It is particularly useful in the setting of pulmonary hypertension. Milrinone decreases pulmonary artery pressures more effectively than other positive inotropic agents, even dobutamine.^{88,89} The inotropic effects of milrinone are reduced by acidosis, presumably reflecting decreased cAMP formation in acidotic muscle.⁹⁰

Both milrinone and dobutamine improve cardiac index and decrease cardiac filling pressures, although milrinone may be more effective for the latter with significant reductions in right and left heart filling pressures. Milrinone is associated with more vasodilation and greater decreases in systemic vascular resistance and blood pressure than dobutamine. Unlike dobutamine, milrinone rarely causes tachycardia. Both agents may increase myocardial oxygen consumption with milrinone doing so to a lesser extent. The choice between dobutamine and milrinone may be based on hemodynamic differences. Milrinone may be preferred

in situations with high filling pressures, elevated pulmonary artery pressure, need for continued β blockade, decreased responsiveness to catecholamine therapy, and increased risk for tachyarrhythmias. Dobutamine may be preferred in situations with significant vasodilation or renal dysfunction.

Milrinone has the additional role of being able to reverse vasospasm in arterial grafts.⁹¹ Milrinone is also thought to have antiinflammatory effects, and thus, perioperative administration may dilate splanchnic vasculature and attenuate systemic inflammation in the acute phase response after cardiopulmonary bypass.⁹²

Side Effects

Rapid administration of milrinone may decrease systemic vascular resistance, decrease venous return, and result in hypotension. The hypotension may be attenuated by slower bolus administration and concomitant administration with vasopressors. Despite its beneficial hemodynamic actions, chronic oral therapy with milrinone may increase morbidity and mortality in patients with severe chronic heart failure and is not approved by the U.S. Food and Drug Administration for this indication.⁹³ The mechanism for this remains unknown, although a proarrhythmic effect has been suggested. Because of its higher potency, milrinone has less of an effect on platelets than amrinone. Although both agents inhibit in vitro platelet aggregation, short-term milrinone use did not cause significant changes in platelet number or function after cardiopulmonary bypass beyond the usual effects of cardiopulmonary bypass and cardiac surgery.⁹⁴

Calcium

Calcium is present in the body in greater amounts than any other mineral. Calcium is important for (1) neuromuscular transmission, (2) skeletal muscle contraction, (3) cardiac muscle contractility, (4) blood coagulation, and (5) exocytosis necessary for release of neurotransmitters. In addition, calcium is the principal component of bone. The cytoplasmic concentration of ionized calcium is maintained at low levels by extrusion from the cells and sequestration of calcium ions within cellular organelles, particularly mitochondria, and in the sarcoplasmic reticulum of skeletal muscles. The large gradient for calcium across cell membranes, or across the membranes of calcium storing organelles, is essential for calcium's role in transmembrane signaling in response to various electrical or chemical stimuli.

Calcium is a potent inotrope. Increasing the plasma concentrations of ionized calcium with exogenous administration of calcium chloride or calcium gluconate is commonly used to treat cardiac depression as may accompany delivery of volatile anesthetics, transfusion of citrated blood, and following termination of cardiopulmonary bypass. Calcium is necessary for excitation-contraction coupling in vascular smooth muscle and may result in a vasoconstricting effect on coronary arteries that impairs coupling of coronary blood flow to augment myocardial oxygen demand.⁹⁵

Calcium Measurement

The plasma concentration of calcium is maintained between 4.3 and 5.3 mEq/L (8.5-10.5 mg/dL) by endocrine control of ion transport in the kidney, intestine, and bone, mediated by vitamin D, parathyroid hormone, and calcitonin.⁹⁶ Total plasma calcium consists of (1) calcium bound to albumin, (2) calcium complexed with citrate and phosphorus ions, and (3) freely diffusible ionized calcium. As would be expected, total plasma calcium decreases with low serum albumin and with hypophosphatemia.

It is the ionized calcium, and not the total plasma calcium, that produces the physiologic effects of calcium. Therefore, hypoalbuminemia and hypophosphatemia typically are not associated with signs of hypocalcemia. Conversely, large transfusions may be associated with acute hypocalcemia because of the binding of ionized calcium to the citrate anticoagulant.

Ionized calcium typically represents approximately 45% of the total plasma concentration. The ionized fraction of calcium changes with pH because calcium and hydrogen ions compete for the binding site on albumin. Acidosis increases ionized calcium, whereas alkalosis reduces ionized calcium.

Calcium Sensitizers

Levosimendan

Levosimendan is the first drug in a novel class of inotropes that increases contractility by increasing the sensitivity of the myocardium to calcium ([Figure 18.12](#)). The inotropic enhancement is a result of binding of levosimendan to troponin C, increasing the sensitivity of troponin to calcium.^{[97,98](#)} Levosimendan also activates adenosine triphosphate-regulated potassium channels,^{[99](#)} causing vasodilation^{[100](#)} and myocardial protection.^{[101](#)} As a result, cardiac output is increased with decreased systemic vascular resistance and pulmonary vascular resistance. Oral bioavailability is 85%. Metabolism is largely hepatic with renal excretion.

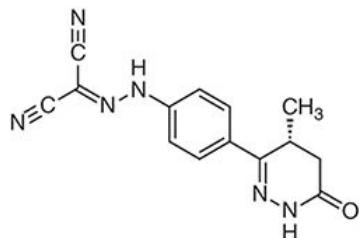

FIGURE 18.12 Levosimendan, the first of a new class of inotropes: calcium sensitizers.

Levosimendan was developed with an indication for the treatment of cardiogenic shock. A reduction in 180-day mortality has not been demonstrated compared to dobutamine in a meta-analysis performed by the Cochrane Collaboration.^{[102](#)} However, a more recent meta-analysis suggested improved survival for patients with chronic heart failure.^{[103](#)} Levosimendan is often considered in situations where conventional therapy for acute severe chronic heart failure is not considered adequate. Levosimendan has also failed to show any benefit in 30-day mortality after cardiac surgery when added to usual care.^{[104](#)} Perioperative levosimendan might reduce the risk of kidney injury following cardiac surgery.^{[105](#)}

Pharmacokinetics

Levosimendan is available as a solution for IV administration. The IV loading dose is 6 to 12 µg/kg given over 10 minutes, followed by an infusion of 0.05 to 2 µg/kg/minute.^{[106](#)} It has a half-life of about 1.5 hours. The clinical effects persist beyond the duration expected from the rapid half-life, likely the result of an active metabolite.^{[107](#)}

Sympatholytics

Steven E. Miller

α - and β -Adrenergic Receptor Antagonists

α - and β -Adrenergic receptor antagonists prevent the interaction of the endogenous neurotransmitter such as norepinephrine or sympathomimetics with the corresponding adrenergic receptors.¹ Interference with normal adrenergic receptor function attenuates sympathetic nervous system homeostatic mechanisms and evokes predictable pharmacologic responses. Presynaptic agonism of α_2 receptors will result in a similar attenuation of sympathetic outflow by downregulating the release of neurotransmitters to the postsynaptic nerve.

α -Adrenergic Receptor Antagonists

α -Adrenergic receptor antagonists bind selectively to α -adrenergic receptors and interfere with the ability of catecholamines or other sympathomimetics to provoke α -receptor responses. Drug-induced α -adrenergic blockade prevents the effects of catecholamines and sympathomimetics on the heart and peripheral vasculature. The inhibitory action of epinephrine on insulin secretion is prevented. Orthostatic hypotension, baroreceptor-mediated reflex tachycardia, and impotence are invariable side effects of α -adrenergic blockade. Furthermore, absence of β -adrenergic blockade permits maximum expression of cardiac stimulation from norepinephrine, typically leading to tachycardia. These side effects prevent the use of nonselective α -adrenergic antagonists in the management of ambulatory essential hypertension.

Mechanism of Action

Phentolamine, prazosin, and yohimbine are competitive (reversible binding with receptors) α -adrenergic antagonists.² In contrast, phenoxybenzamine binds covalently to α -adrenergic receptors to produce an irreversible and insurmountable type of α -receptor blockade. Once α -blockade has been established with phenoxybenzamine, even massive doses of sympathomimetics are ineffective until the effect of phenoxybenzamine is terminated by metabolism.

Phentolamine and phenoxybenzamine are nonselective α -antagonists acting at postsynaptic α_1 receptors as well as presynaptic α_2 receptors. Prazosin is elective for α_1 receptors, whereas yohimbine is selective for α_2 receptors.

Phentolamine

Phentolamine is a substituted imidazoline derivative that produces transient nonselective α -adrenergic blockade ([Figure 19.1](#)). Administered intravenously (IV), phentolamine produces peripheral vasodilation and a decrease in systemic blood pressure that manifests within 2 minutes and lasts 10 to 15 minutes. This vasodilation reflects α_1 -receptor blockade and a direct action of phentolamine on vascular smooth muscle. Decreases in blood pressure elicit baroreceptor-mediated increases in sympathetic nervous system activity manifesting as cardiac stimulation. In addition to reflex stimulation, phentolamine-induced α_2 -receptor blockade permits enhanced neural release of norepinephrine manifesting as increased heart rate and cardiac output. Indeed, cardiac dysrhythmias and angina pectoris may accompany the administration of phentolamine. Hyperperistalsis, abdominal pain, and diarrhea may be caused by a predominance of parasympathetic nervous system activity. Phentolamine undergoes principally hepatic metabolism and only about 10% of the drug is excreted unchanged in the urine.

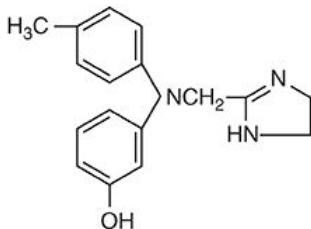

FIGURE 19.1 Phentolamine.

Clinical Uses

The principal use of phentolamine is the treatment of acute hypertensive emergencies, as may accompany intraoperative manipulation of a pheochromocytoma or autonomic nervous system hyperreflexia. Administration of phentolamine, 30 to 70 µg/kg IV (1-5 mg), produces a prompt but transient decrease in systemic blood pressure. A continuous infusion of phentolamine (0.1-2 mg per minute) may be used to maintain normal blood pressure during the intraoperative resection of a pheochromocytoma. Local infiltration with a phentolamine-containing solution (5-15 mg in 10 mL of normal saline) is appropriate when a vasoconstricting sympathomimetic is accidentally administered extravascularly.

Phenoxybenzamine

Phenoxybenzamine is a haloalkylamine derivative that acts as a nonselective α -adrenergic antagonist by combining covalently with α -adrenergic receptors ([Figure 19.2](#)). Blockade at postsynaptic α_1 receptors is more intense than at α_2 receptors.

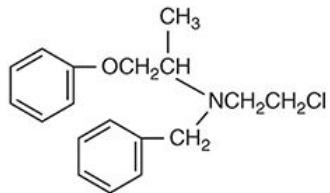

FIGURE 19.2 Phenoxybenzamine.

Pharmacokinetics

Absorption of phenoxybenzamine from the gastrointestinal tract is incomplete. Onset of α -adrenergic blockade is slow, taking up to 60 minutes to reach peak effect even after IV administration. This delay in onset is due to the time required for structural modification of the phenoxybenzamine molecule, which is necessary to render the drug pharmacologically active. The elimination half-time of phenoxybenzamine is about 24 hours, emphasizing the likelihood of cumulative effects with repeated doses.

Cardiovascular Effects

Phenoxybenzamine administered to a supine, normovolemic patient in the absence of increased sympathetic nervous system activity produces little change in systemic blood pressure. Orthostatic hypotension, however, is prominent, especially in the presence of preexisting hypertension or hypovolemia. In addition, impairment of compensatory vasoconstriction results in exaggerated blood pressure decreases in response to blood loss or vasodilating drugs such as volatile anesthetics. Despite decreases in blood pressure, cardiac output is often increased and renal blood flow is not greatly altered unless preexisting renal vasoconstriction is present or significant hypotension results. Cerebral and coronary vascular resistances are nearly unchanged. α -Adrenergic blockade produced by maternal treatment may result in neonatal hypotension and respiratory distress in the first 72 hours of life.³

Noncardiac Effects

Phenoxybenzamine prevents the inhibitory action of epinephrine on the secretion of insulin, but catecholamine-induced glycogenolysis in skeletal muscles or lipolysis is not altered. Stimulation of the radial fibers of the iris is prevented, and miosis is a prominent component of the response to phenoxybenzamine. Sedation may accompany chronic phenoxybenzamine therapy. Nasal stuffiness is due to unopposed vasodilation in mucous membranes in the presence of α -adrenergic blockade and resultant engorgement of the turbinates.

Clinical Uses

Phenoxybenzamine 0.5 to 1.0 mg/kg orally (prazosin is an alternative) is administered preoperatively to control blood pressure in patients with pheochromocytoma. Chronic α -adrenergic blockade, by relieving intense peripheral vasoconstriction, permits expansion of intravascular fluid volume as reflected by a decrease in both hemoglobin and hematocrit. Excessive vasoconstriction with associated tissue ischemia, as accompanies hemorrhagic shock, may be reversed by phenoxybenzamine but only after intravascular fluid volume has been replenished or the resultant hypotension will instead exacerbate the low-flow state.

Treatment of peripheral vascular disease characterized by intermittent claudication is not favorably influenced by α -adrenergic blockade because cutaneous rather than skeletal muscle blood flow is increased. The most beneficial clinical responses to α -adrenergic blockade are in diseases with a large component of cutaneous vasoconstriction, such as Raynaud disease, where smaller arteries that supply blood to skin narrow, limiting blood circulation to affected areas.

Yohimbine

Yohimbine is a selective antagonist at presynaptic α_2 receptors, leading to enhanced release of norepinephrine from nerve endings. As a result, this drug may be useful in the treatment of the rare patient suffering from idiopathic orthostatic hypotension. In the past, yohimbine has been used in male patients suffering from erectile dysfunction or impotence resulting from vascular, diabetic, or psychogenic origins. Yohimbine readily crosses the blood-brain barrier and may be associated with increased skeletal muscle activity and tremor. Excessive doses of yohimbine may produce tachycardia, hypertension, rhinorrhea, paresthesias, and dissociative states. Observations that α_2 -adrenergic agonists can decrease anesthetic requirements by actions on presynaptic α_2 receptors in the central nervous system (CNS) suggest a possible interaction of yohimbine with volatile anesthetics.⁴

Doxazosin

Doxazosin is approved for both treatment of hypertension and benign prostatic hypertrophy (BPH). It is a selective postsynaptic α_1 -receptor antagonist that is 65% bioavailable with oral administration. Peak levels of doxazosin are seen 2 to 3 hours following oral administration and effectively relaxes prostatic and vascular smooth muscle. Doxazosin is primarily metabolized in the liver by O-demethylation and excreted in the feces. The terminal elimination life of doxazosin is 22 hours and is recommended as a single daily dose in the morning.

Prazosin

Prazosin is a selective postsynaptic α_1 -receptor antagonist that leaves intact the inhibiting effect of α_2 -receptor activity on norepinephrine release from nerve endings. As a result, prazosin is less likely than nonselective α -adrenergic antagonists to evoke reflex tachycardia. Prazosin dilates both arterioles and veins. Following oral administration, the onset of action is approximately 30 minutes and the duration of action is about 4 to 6 hours. Elimination of prazosin is principally by hepatic metabolism.

Terazosin

α -Blocker therapy of BPH is based on α_1 -mediated innervation of prostatic smooth muscle that controls contraction of the prostate and obstruction of the bladder outlet. Terazosin is a long-acting, orally effective

α_1 -adrenergic antagonist that may be useful in the treatment of benign prostatic hyperplasia by virtue of its ability to relax prostatic smooth muscle.

Tamsulosin

Tamsulosin is an orally effective α_{1a} -adrenergic antagonist that is indicated for the treatment of the signs and symptoms of BPH. Side effects may include orthostatic hypotension, vertigo, and syncope. Tamsulosin also has a noninsignificant risk of sexual side effects including ejaculatory dysfunction. The clearance of tamsulosin is decreased in the presence of cimetidine.

Alfuzosin

Alfuzosin is also a selective inhibitor of α_{1a} -adrenergic receptors and has been used to treat BPH specifically in younger populations. Unlike tamsulosin, sexual side effects seem to be much less common without a decrease in prostatic relaxation ability. Side effects of alfuzosin include dizziness and systemic hypotension with reflex tachycardia. Alfuzosin undergoes extensive liver metabolism by multiple mechanisms into inactive metabolites that are then excreted nearly 3:1 in the bile; only 11% remains unchanged and is excreted by the kidneys.

Sildosin

Sildosin is a very selective α_{1a} -adrenergic receptor antagonist with more prostate specific activity and less systemic side effects than other drugs for the treatment of BPH.⁵ It has very rapid oral absorption but is only 32% bioavailable. It is processed by two different hepatic pathways, and the primary metabolite is active but with only 50% of the parent compound's activity. The metabolite's are excreted in the 3:2 hepatically versus renally.

Tolazoline

Tolazoline is a competitive nonselective α -adrenergic receptor antagonist. This drug has been used to treat persistent pulmonary hypertension of the newborn, but its use for this purpose has been largely replaced by nitric oxide. Side effects of tolazoline include systemic hypotension with reflex tachycardia, cardiac dysrhythmias, and pulmonary and gastrointestinal hemorrhages. Tolazoline is excreted mainly unchanged by the kidneys.

α_2 -Adrenergic Receptor Agonists

α_2 -Adrenergic receptor agonists bind selectively to presynaptic α_2 -adrenergic receptors and, by a negative feedback mechanism, decrease the release of norepinephrine from presynaptic nerve terminals and reduce sympathetic outflow with similar decreases in blood pressure as α_1 antagonists. Most α_2 receptors are found in the CNS, especially in the brainstem and the locus ceruleus. Peripheral inhibition of α_2 receptors can result in inhibition of insulin release and induction of glucagon from the pancreas. Clinical pharmacologic effects include hypotension, bradycardia, and central sedation with some mild effects of analgesia all related to the sympatholytic effects.

Mechanism of Action

α_2 -Adrenergic receptor agonists have selective affinity for α_2 -adrenergic receptors and act competitively. Binding of α_2 agonists can be displaced from binding sites in the CNS resulting in reversal of the CNS effects. Withdrawal after even short-term use can result in a rebound effect with a dramatic increase in sympathetic outflow causing elevations in heart rate and hypertension to even dangerous levels.

Clonidine

Administration results in dose-dependent decreases in heart rate and blood pressure and is used clinically to treat resistant hypertension, tremors from central stimulant medications, and opioid withdrawal.⁶ Clonidine is

a partial agonist of α_2 receptors with a 400:1 α_2 - α_1 receptor preference. Clonidine is available in an IV, oral, and transdermal preparation and is metabolized in the liver but is excreted mostly unchanged in the urine and to a lesser extent in the bile and feces. Terminal half-life is approximately 12 to 16 hours but can be extremely variable with any liver or kidney dysfunction.

Dexmedetomidine

Dexmedetomidine is a selective α_2 agonist with a 1,600:1 preference for α_2 -receptors. It is IV administered as an infusion from 0.1 to 1.5 $\mu\text{g}/\text{kg}$ per minute with a terminal elimination half-life of 2 hours. Most often, this α_2 agonist is used in the intensive care and operating room settings as a sedative and analgesic due to its central sympatholytic effects. Dexmedetomidine undergoes extensive biotransformation in the liver and is excreted mostly in the urine; liver impairment can dramatically increase plasma levels and duration of action due to significantly decreased metabolism during infusion. Its potent binding and short half-life can induce physiologic dependence and result in the aforementioned withdrawal phenomenon after only days of administration resulting in tachycardia, hypertension, and anxiety. Interestingly, large IV boluses (0.25-1 $\mu\text{g}/\text{kg}$ over 3-5 minutes) result in a paradoxical hypertension with a decrease in heart rate and resembles phenylephrine as a resultant effect of crossover α_1 stimulation.

β -Adrenergic Receptor Antagonists

β -Adrenergic receptor antagonists bind selectively to β -adrenergic receptors and interfere with the ability of catecholamines or other sympathomimetics to provoke β responses. Drug-induced β -adrenergic blockade prevents the effects of catecholamines and sympathomimetics on the heart and the smooth muscles of the airways and blood vessels. β -Antagonist therapy should be continued throughout the perioperative period to maintain desirable drug effects and to avoid the risk of sympathetic nervous system hyperactivity (rebound) associated with abrupt discontinuation of these drugs. Propranolol is the standard β -adrenergic antagonist drug to which all other β -adrenergic antagonists are commonly compared.

Mechanism of Action

β -Adrenergic receptor antagonists exhibit selective affinity for β -adrenergic receptors where they act by competitive inhibition. Binding of antagonist drugs to β -adrenergic receptors is reversible such that the drug can be displaced from the occupied receptors if sufficiently large amounts of agonist become available. Competitive antagonism causes a rightward displacement of the dose-response curve for the agonist, but the slope of the curve remains unchanged, emphasizing that sufficiently large doses of the agonist may still exert a full pharmacologic effect. Chronic administration of β -adrenergic antagonists is associated with an increase in the number of β -adrenergic receptors and an eventual need to uptitrate medication doses to maintain the same pharmacologic effects.

β -Adrenergic receptors are G protein-coupled receptors and their occupancy by agonists (norepinephrine, epinephrine) stimulates G proteins that in turn activate adenylyl cyclase to produce cyclic adenosine monophosphate (cAMP). Protein kinases are activated by cAMP, which in turn phosphorylate proteins including L-type voltage-dependent calcium channels and troponin C in a variety of tissues (especially myocardium). The net effect of β -adrenergic stimulation in the heart is to produce positive chronotropic, inotropic, and dromotropic effects along with a negative lusitropic effect and inadvertent positive bathmotropy. These are the responses that are blunted by β -adrenergic receptor antagonists and it is estimated that about 75% of β receptors in the myocardium are β_1 , whereas β_2 receptors account for about 20% of β receptors.

Structure-Activity Relationships

β -Adrenergic antagonists are derivatives of the β agonist drug isoproterenol ([Figure 19.3](#)). Substitutions on the benzene ring determine whether the drug acts on β -adrenergic receptors as an antagonist or agonist. The levorotatory forms of β antagonists and agonists are more potent than the dextrorotatory forms. For example,

the dextrorotatory isomer of propranolol has less than 1% of the potency of the levorotatory isomer for blocking β -adrenergic receptors.

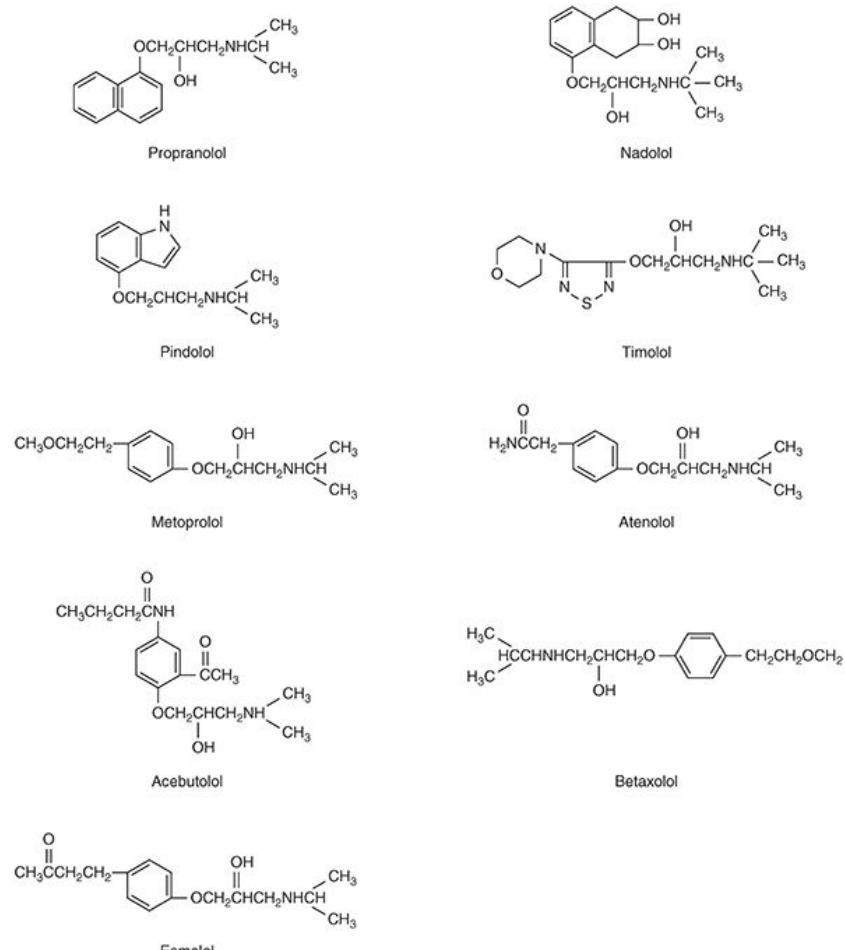

FIGURE 19.3 β -Adrenergic antagonists.

Classification

β -Adrenergic receptor antagonists are classified as nonselective for β_1 and β_2 receptors (propranolol, nadolol, timolol, pindolol) and cardioselective (metoprolol, atenolol, acebutolol, betaxolol, esmolol, bisoprolol, nebivolol) for β_1 receptors ([Tables 19.1](#) and [19.2](#)). It is important to recognize that β -receptor selectivity is dose dependent and is lost when large doses of an antagonist are administered. This emphasizes that selectivity should not be interpreted as specificity for a specific type of β -adrenergic receptor. β -Adrenergic antagonists are further classified as partial or pure antagonists on the basis of the presence or absence of intrinsic sympathomimetic activity (see [Tables 19.1](#) and [19.2](#)). Drugs that exhibit cardiac selectivity for β_1 receptors (cardioselective) are better suited for administration to patients with asthma and reactive airway disease. Theoretically, cardioselective drugs are better suited for treatment of patients with essential hypertension because these drugs lack inhibition of peripheral β_2 receptors that produce vasodilation.

TABLE 19.1

Comparative characteristics of β -adrenergic receptor antagonists

Comparative characteristics of β-adrenergic receptor antagonists effective in the treatment of congestive heart failure

	Metoprolol (extended release)	Carvedilol	Bisoprolol
Cardiac selectivity	Yes	No	Yes
Partial agonist activity	No	No	No
Initial oral dose ^a	6.25 mg twice daily	3.125 mg twice daily	1.25 mg daily
Desired dosage range ^a	50-150 mg daily	25-50 mg twice daily	5 mg daily

^aRecommended doses for treatment of patients with mild to moderate congestive heart failure.

β₁-Receptor blockade is associated with slowing of the sinus rate, slowing of conduction of cardiac impulses through the atrioventricular node, a decrease in inotropy, an increase in lusitropy, and usually a decrease in bathmotropy. These effects are relatively greater during activity than during rest. The result is a decrease in myocardial oxygen demand with a subsequent decrease in the occurrence of myocardial ischemia during exercise. The decrease in heart rate also increases diastolic perfusion time, which may enhance myocardial perfusion. β₂-Receptor blockade increases the risk of bronchospasm in patients with reactive airway disease and may worsen the clinical symptoms of peripheral vascular disease.

β-Adrenergic antagonists may produce some degree of membrane stabilization in the heart (inhibition of propagation of action potentials across the cell membrane similar to sodium channel blockers that are class I antiarrhythmic) and thus resemble quinidine. This membrane stabilization effect, however, is detectable only at plasma concentrations that are far higher than needed to produce clinically adequate β-adrenergic blockade.

Pharmacokinetics

The principal difference in pharmacokinetics between all the β-adrenergic receptor antagonists is the elimination half-time ranging from brief for esmolol (about 10 minutes) to hours for the other drugs (see **Table 19.1**). Elimination half-time is considered in the perioperative period when redosing intervals are being

developed or when conversion to another β -adrenergic receptor drug is planned. Among the β -adrenergic receptor antagonists, only propranolol and nebivolol are highly protein bound. The volume of distribution of these drugs is high, and they are rapidly distributed following IV administration.

β -Adrenergic receptor antagonists are eliminated by several different pathways, and this must be considered in the presence of renal and/or hepatic dysfunction (see [Table 19.1](#)). The therapeutic plasma concentration varies greatly among these drugs and between patients (interpatient variability). Explanations for interpatient variability include differences in basal sympathetic nervous system tone, flat dose-response curves for the drug so changes in plasma concentrations evoke minimal changes in pharmacologic effects, impact of active metabolites, and genetic differences in β -adrenergic receptors that influence how an individual patient responds to a given drug and plasma concentration.

Propranolol

Propranolol is a nonselective β -adrenergic receptor antagonist that lacks intrinsic sympathomimetic activity and thus is a pure antagonist (see [Table 19.1](#)). Antagonism of β_1 and β_2 receptors produced by propranolol is about equal. As the first β -adrenergic antagonist introduced clinically, propranolol is usually the standard drug to which β -adrenergic antagonists are compared. Typically, propranolol is administered in stepwise increments until physiologic plasma concentrations have been attained, as indicated by a resting heart rate of 55 to 60 beats per minute.

Cardiac Effects

The most important pharmacologic effects of propranolol are on the heart. Because of β_1 -receptor blockade, propranolol decreases heart rate and myocardial contractility, resulting in decreased cardiac output. These effects on heart rate and cardiac output are especially prominent during exercise or in the presence of increased sympathetic nervous system activity. Heart rate slowing induced by propranolol lasts longer than the negative inotropic effects, suggesting a possible subdivision of β_1 receptors. Concomitant blockade of β_2 receptors by propranolol increases peripheral vascular resistance, including coronary vascular resistance. Although prolongation of systolic ejection and dilatation of the cardiac ventricles caused by propranolol increases myocardial oxygen requirements, the oxygen-sparing effects of decreased heart rate and myocardial contractility predominate. As a result, propranolol may relieve myocardial ischemia, even though drug-induced increases in coronary vascular resistance oppose coronary blood flow. Sodium retention associated with propranolol therapy most likely results from intrarenal hemodynamic changes that accompany drug-induced decreases in cardiac output.

Pharmacokinetics

Propranolol is rapidly and almost completely absorbed from the gastrointestinal tract, but systemic availability of the drug is limited by extensive hepatic first-pass metabolism, which may account for 90% to 95% of the absorbed dose. There is considerable individual variation in the magnitude of hepatic first-pass metabolism, accounting for up to 20-fold differences in plasma concentrations of propranolol in patients after oral administration of comparable doses.⁷ Hepatic first-pass metabolism is the reason the oral dose of propranolol (40-800 mg per day) must be substantially greater than the IV dose (0.05 mg/kg given in increments of 0.5-1.0 mg every 5 minutes). Propranolol is not effective when administered intramuscularly.

Protein Binding

Propranolol is extensively bound (90%-95%) to plasma proteins. Heparin-induced increases in plasma concentrations of free fatty acids due to increased lipoprotein lipase activity result in decreased plasma protein binding of propranolol ([Figure 19.4](#)).⁸ In addition, hemodilution that occurs when cardiopulmonary bypass is initiated may alter protein binding of drugs because of the nonphysiologic protein concentration in the pump prime.

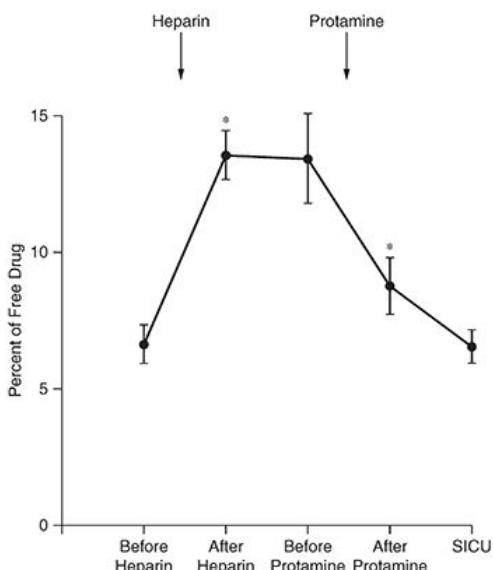

FIGURE 19.4 Heparin administration is associated with decreased plasma protein binding of propranolol manifesting as an increased plasma concentration of free (unbound) drug. (Mean \pm standard error; $*P < .05$.) Abbreviation: SICU, surgical intensive care unit. Reprinted with permission from Wood M, Shand DG, Wood AJ. Propranolol binding in plasma during cardiopulmonary bypass. Anesthesiology. 1979;51(6):512-516. Copyright © 1979 American Society of Anesthesiologists, Inc.

Metabolism

Clearance of propranolol from the plasma is by hepatic metabolism. An active metabolite, 4-hydroxypropranolol, is detectable in the plasma after oral administration of propranolol. Indeed, cardiac β -blocking activity after equivalent doses of propranolol is greater after oral than after IV administration, presumably reflecting the effects of this metabolite, which is equivalent in activity to the parent compound. The elimination half-time of propranolol is 2 to 3 hours, whereas that of 4-hydroxypropranolol is even briefer. The plasma concentration of propranolol or the total dose does not correlate with its therapeutic effects. Furthermore, the assay for propranolol may not detect 4-hydroxypropranolol.

Elimination of propranolol is greatly decreased when hepatic blood flow decreases. In this regard, propranolol may decrease its own clearance rate by decreasing cardiac output and hepatic blood flow. Alterations in hepatic enzyme activity may also influence the rate of hepatic metabolism. Renal failure does not alter the elimination half-time of propranolol, but accumulation of metabolites may occur.

Clearance of Local Anesthetics

Propranolol decreases clearance of amide local anesthetics by decreasing hepatic blood flow and inhibiting metabolism in the liver.⁹ For example, in humans, propranolol causes clearance to be decreased to a much greater extent (46%) than would be predicted from a maximum 25% decrease in hepatic blood flow, implying that drug metabolism in the liver has also been affected.¹⁰ Bupivacaine clearance is relatively insensitive to changes in hepatic blood flow (low-extraction drug), suggesting that the 35% decrease in clearance of this local anesthetic reflects propranolol-induced decreases in metabolism (Figure 19.5).⁹ Because clearance of drugs with low extraction ratios is inversely related to plasma protein binding, an increase in bupivacaine binding to α_1 -acid glycoprotein (responsible for 90% binding of bupivacaine) caused by propranolol could explain a decrease in clearance. Nevertheless, propranolol does not alter α_1 -acid glycoprotein concentrations.¹⁰ It is conceivable that systemic toxicity of bupivacaine could be increased by propranolol and presumably other β antagonists that interfere with the clearance of this and other amide local anesthetics. It has also been demonstrated that propranolol pretreatment can result in increased concentration of mepivacaine serum concentrations.¹¹

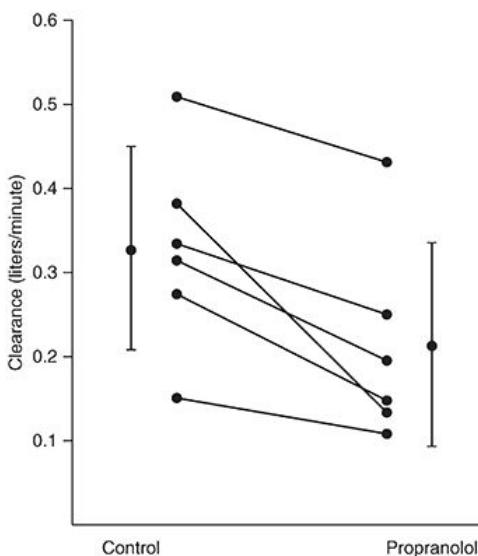

FIGURE 19.5 Bupivacaine clearance is decreased 35% in subjects treated with propranolol compared with control measurements. Reprinted with permission from Bowdle TA, Freund PR, Slattery JT. Propranolol reduces bupivacaine clearance. *Anesthesiology*. 1987;66(1):36-38. Copyright © 1987 American Society of Anesthesiologists, Inc.

Clearance of Opioids

Pulmonary first-pass uptake of fentanyl is substantially decreased in patients being treated chronically with propranolol.¹² As a result, 2 to 4 times as much injected fentanyl enters the systemic circulation in the time period immediately after injection. This response most likely reflects the ability of one basic lipophilic amine (propranolol) to inhibit the pulmonary uptake of a second basic lipophilic amine (fentanyl).

Nadolol and Pindolol

Nadolol and pindolol are nonselective β -adrenergic receptor antagonists; nadolol is unique in that its long duration of action permits once daily administration.

Pharmacokinetics

Nadolol is slowly and incompletely absorbed (an estimated 30%) from the gastrointestinal tract. Metabolism does not occur, with about 75% of the drug being excreted unchanged in urine and the remainder in bile. Therefore, wide individual variations in plasma concentrations that occur with nadolol cannot be attributed to differences in metabolism, as occur with propranolol. The elimination half-time is 20 to 40 hours, accounting for the need to administer this drug only once a day. The elimination half-time of pindolol is 3 to 4 hours, and this is increased to longer than 11 hours in patients with renal failure.

Timolol

Timolol is a nonselective β -adrenergic receptor antagonist that is as effective as propranolol for various therapeutic indications. In addition, timolol is effective in the treatment of glaucoma because of its ability to decrease intraocular pressure, presumably by decreasing the production of aqueous humor. Timolol is administered as eyedrops in the treatment of glaucoma, but systemic absorption may be sufficient to cause resting bradycardia and increased airway resistance. Indeed, bradycardia and hypotension that are refractory to treatment with atropine have been observed during anesthesia in pediatric and adult patients receiving topical timolol with or without pilocarpine.¹³ Timolol may be associated with impaired control of ventilation in neonates, resulting in unexpected postoperative apnea.¹⁴ Immaturity of the neonate's blood-brain barrier may facilitate access of this drug to the CNS.

Pharmacokinetics

Timolol is rapidly and almost completely absorbed after oral administration. Nevertheless, extensive first-pass hepatic metabolism limits the amount of drug reaching the systemic circulation to about 50% of that absorbed from the gastrointestinal tract. Protein binding of timolol is not extensive. The elimination half-time is about 4 hours.

Metoprolol

Metoprolol is a selective β_1 -adrenergic receptor antagonist that prevents inotropic and chronotropic responses to β -adrenergic stimulation. Conversely, bronchodilator, vasodilator, and metabolic effects of β_2 receptors remain intact such that metoprolol is less likely to cause adverse effects in patients with chronic obstructive airway disease or peripheral vascular disease and in patients vulnerable to hypoglycemia. It is important to recognize, however, that selectivity is dose related, and large doses of metoprolol are likely to become nonselective, exerting antagonist effects at β_2 receptors as well as β_1 receptors. Indeed, airway resistance may increase in asthmatic patients treated with metoprolol, although the magnitude of increase will be less than that evoked by propranolol. Furthermore, metoprolol-induced increases in airway resistance are more readily reversed with β_2 -adrenergic agonists such as terbutaline.

Pharmacokinetics

Metoprolol is readily absorbed from the gastrointestinal tract, but this is offset by substantial hepatic first-pass metabolism such that only about 40% of the drug reaches the systemic circulation. Protein binding is low; it is estimated to account for about 10% of the drug. None of the hepatic metabolites have been identified as active. A small amount (<10%) of the drug appears unchanged in urine. There are two available oral formulation of metoprolol: metoprolol tartrate and metoprolol succinate. The elimination half-time of metoprolol tartrate is 2 to 3 hours and correlates to a need for at least a twice daily dosing strategy with a 3 or 4 times daily strategy providing a more reliable control of heart rate. Metoprolol succinate results in a significantly extended time to peak concentrations and overall decreased plasma concentrations compared to metoprolol tartrate at equal daily doses. Metoprolol succinate elimination half-time is 5 to 7 hours and can be used in once daily dosing regimens but in some patients can still result in β -blocker withdrawal tachycardia at 24 hours necessitating twice daily dosing. Overall, plasma concentrations of metoprolol do not correlate with therapeutic effects of the drug.

Atenolol

Atenolol is an even more selective β_1 -adrenergic antagonist that may have specific value in patients in whom the continued presence of β_2 -receptor activity is desirable. In patients at risk for coronary artery disease who must undergo noncardiac surgery, treatment with IV atenolol before and immediately after surgery, followed by oral therapy during the remainder of the hospitalization, decreases mortality and the incidence of cardiovascular complications for as long as 2 years.¹⁵ Perioperative administration of atenolol to patients at high risk for coronary artery disease significantly decreases the incidence of postoperative myocardial ischemia.¹⁶

The antihypertensive effect of atenolol is prolonged, permitting this drug to be administered once daily for the treatment of hypertension. Like nadolol, atenolol does not enter the CNS in large amounts, but fatigue and mental depression still occur. Unlike nonselective β -adrenergic antagonists, atenolol does not appear to potentiate insulin-induced hypoglycemia and can thus be administered with caution to patients with diabetes mellitus whose hypertension is not controlled by other antihypertensives.

Pharmacokinetics

About 50% of an orally administered dose of atenolol is absorbed from the gastrointestinal tract, with peak concentrations occurring 1 to 2 hours after oral administration. Atenolol undergoes little or no hepatic metabolism and is eliminated principally by renal excretion. The elimination half-time is 6 to 7 hours; this may increase to more than 24 hours in patients with renal failure.

Betaxolol

Betaxolol is a cardioselective β_1 -adrenergic antagonist with no intrinsic sympathomimetic activity and weak membrane-stabilizing activity. High doses can be expected to produce some β_2 -adrenergic antagonist effects on bronchial and vascular smooth muscle. Absorption after an oral dose is nearly complete. Its elimination half-time is 11 to 22 hours, making it one of the longest acting β -adrenergic antagonists. Clearance is primarily by metabolism, with renal elimination contributing less to overall removal of the drug from the plasma. A single oral dose daily is useful for the treatment of hypertension. A topical preparation is used as an alternative to timolol for treatment of chronic open-angle glaucoma. The risk of bronchoconstriction in patients with airway hyperreactivity may be less with betaxolol than with timolol.

Bisoprolol

Bisoprolol is one of the most β_1 -selective antagonist drugs, and it does not have any significant intrinsic agonist activity. The elimination half-time is 9 to 12 hours. Bisoprolol is eliminated equally by renal and nonrenal mechanisms. Metabolites are pharmacologically inactive. The most prominent pharmacologic effect of bisoprolol is a negative chronotropic effect. Bisoprolol is useful in the treatment of essential hypertension and has been shown to improve survival in patients with mild to moderate congestive heart failure (see [Table 19.2](#)).

Nebivolol

Nebivolol is a very potent and most selective β_1 -antagonist drug¹⁷ listed thus far as it is 3.5 times more selective than bisoprolol¹⁸ and also does not have any significant intrinsic agonist activity. Above doses of 10 mg, or in those patients with certain cytochrome P450 polymorphisms, nebivolol can exhibit low β_2 antagonism as well. With an elimination half-time of 12 to 19 hours, it is a once daily regimen that allows accidental delay in subsequent doses without withdrawal. Nebivolol is equally eliminated in the urine unchanged and in the feces as an inactive metabolite. At this time, nebivolol is only currently approved for the treatment of essential hypertension.

Esmolol

Esmolol is a rapid-onset and short-acting selective β_1 -adrenergic receptor antagonist that is administered only IV (see [Figure 19.3](#)). After a typical initial dose of 0.5 mg/kg IV over about 60 seconds, the full therapeutic effect is evident within 5 minutes, and its action ceases within 10 to 30 minutes after administration is discontinued. These characteristics make esmolol a useful drug for preventing or treating adverse systemic blood pressure and heart rate increases that occur intraoperatively in response to noxious stimulation, as during tracheal intubation. For example, esmolol, 150 mg IV, administered about 2 minutes before direct laryngoscopy and tracheal intubation provides reliable protection against increases in both heart rate and systolic blood pressure, which predictably accompanies tracheal intubation ([Figure 19.6](#)).¹⁹

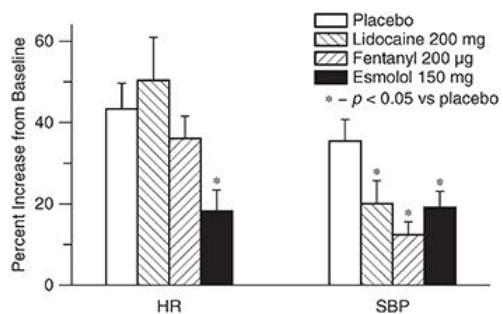

FIGURE 19.6 Maximum percent increases in heart rate (HR) and systolic blood pressure (SBP) after induction of anesthesia and direct laryngoscopy with tracheal intubation in patients pretreated with saline, lidocaine, fentanyl, or esmolol. All three drugs blunt the increase in SBP, but only esmolol is also effective in attenuating the increase in HR. *Reprinted with permission from Helfman SM, Gold MI, DeLisser EA, et al.*

Which drug prevents tachycardia and hypertension associated with tracheal intubation: lidocaine, fentanyl, or esmolol? Anesth Analg. 1991;72(4):482-486. Copyright © 1991 International Anesthesia Research Society.

Lidocaine or fentanyl is effective in blunting the increase in systolic blood pressure associated with laryngoscopy and tracheal intubation, but heart rate is not influenced (see [Figure 19.6](#)).¹⁹ Other reports describe prevention of perioperative tachycardia and hypertension with esmolol, 100 to 200 mg IV, administered over 15 seconds before the induction of anesthesia.^{20,21} Prior administration of esmolol, 500 µg/kg per minute IV, to patients undergoing electroconvulsive therapy with anesthesia induced by methohexitol plus succinylcholine results in attenuation of the heart rate increase and a decrease in the length of the electrically induced seizures.²² Esmolol has been used during resection of pheochromocytomas and may be useful in the perioperative management of thyrotoxicosis, pregnancy-induced hypertension, and epinephrine- or cocaine-induced cardiovascular toxicity.²³⁻²⁷ Detrimental effects of catecholamine release during anesthesia in patients with hypertrophic obstructive cardiomyopathy and in patients experiencing hypercyanotic spells associated with tetralogy of Fallot may be blunted by administration of esmolol.²⁸

Conversely, treatment of excessive sympathetic nervous system activity produced by cocaine or systemic absorption of topical or subcutaneous epinephrine with β-adrenergic receptor antagonists has been associated with fulminant pulmonary edema and irreversible cardiovascular collapse.²⁹ It is possible that acute drug-induced β-receptor antagonism removes the ability of the heart to increase heart rate and myocardial contractility to compensate for catecholamine-induced increases in left ventricular afterload. In this regard, persistent symptomatic systemic hypertension owing to catecholamine-induced sympathetic nervous system stimulation is more safely treated with a peripheral vasodilator drug such as sodium nitroprusside or nitroglycerin.

The β₁ selectivity of esmolol may unmask β₂-mediated vasodilation by epinephrine or epinephrine-secreting tumors.³⁰ Administration of esmolol to patients chronically treated with β-adrenergic antagonists has not been observed to produce additional negative inotropic effects.³¹ The presumed mechanism for this observation is that esmolol, in the dose used, does not occupy sufficient additional β receptors to produce detectable increases in β-blockade. Likewise, esmolol infused during cardiopulmonary bypass is not associated with adverse effects after discontinuation of cardiopulmonary bypass.³²

Esmolol (1 mg/kg IV followed by 250 µg/kg per minute IV) significantly decreases the plasma concentration of propofol required to prevent patient movement in response to a surgical skin incision.³³ This effect does not seem to be explained by a pharmacokinetic interaction between the two drugs.

Pharmacokinetics

Esmolol is available for IV administration only. The only other β-adrenergic antagonists that may be administered IV are propranolol and metoprolol. The commercial preparation of esmolol is buffered to pH 4.5 to 5.5, which may be one of the factors responsible for pain on injection. The drug is compatible with commonly used IV solutions and nondepolarizing neuromuscular blocking drugs. The elimination half-time of esmolol is about 9 minutes, reflecting its rapid hydrolysis in the blood by plasma esterases that is independent of renal and hepatic function.³⁴ Less than 1% of the drug is excreted unchanged in urine, and about 75% is recovered as an inactive acid metabolite. Clinically insignificant amounts of methanol also occur from the hydrolysis of esmolol. Plasma esterases responsible for the hydrolysis of esmolol are distinct from plasma cholinesterase, and the duration of action of succinylcholine is not predictably prolonged in patients treated with esmolol.³⁵ Evidence of the short duration of action of esmolol is return of the heart rate to predrug levels within 15 minutes after discontinuing the drug. Indeed, plasma concentrations of esmolol are usually not detectable 15 minutes after discontinuing the drug. Poor lipid solubility limits transfer of esmolol into the CNS or across the placenta.²⁴

Class-Related Side Effects

The side effects of β -adrenergic antagonists are similar for all available drugs, although the magnitude may differ depending on their selectivity and the presence or absence of intrinsic sympathomimetic activity. β -Adrenergic antagonists exert their most prominent pharmacologic effects as well as side effects on the cardiovascular system. These drugs may also alter airway resistance, carbohydrate and lipid metabolism, and the distribution of extracellular ions. β -Adrenergic antagonists may cause hypoglycemia.³⁶ Additive effects between drugs used for anesthesia and β -adrenergic antagonists may occur including sedation, bradycardia, and hypotension. Many β -Adrenergic antagonists penetrate the blood–brain barrier and cross the placenta. Gastrointestinal side effects include nausea, vomiting, and diarrhea. Fever, rash, myopathy, alopecia, and thrombocytopenia have been associated with chronic β -adrenergic antagonist treatment. β -Adrenergic antagonists have been reported to decrease plasma concentrations of high-density lipoproteins and to increase triglyceride and uric acid levels.

The principal contraindication to administration of β -adrenergic antagonists is preexisting atrioventricular heart block or acute cardiac failure not caused by tachycardia, despite being a mainstay of medical therapy for chronic congestive heart failure. Administration of β -adrenergic antagonists to hypovolemic patients with compensatory tachycardia has been known to produce profound and resistant hypotension.³⁷ Nonselective β -adrenergic antagonists or high doses of selective β -adrenergic antagonists are not recommended for administration to patients with any diagnosis of reactive or obstructive airway disease. In patients with diabetes mellitus, there is the risk that β -adrenergic blockade may mask the signs of hypo- or hyperglycemia and thus delay clinical recognition.

Cardiovascular System

β -Adrenergic antagonists produce negative inotropic and chronotropic effects. In addition, the conduction speed (dromotropy) of cardiac impulses through the atrioventricular node is slowed, and the rate of spontaneous phase 4 depolarization is decreased. Preexisting atrioventricular heart block due to any cause will likely be accentuated by β -adrenergic antagonists.

The cardiovascular effects of β -adrenergic blockade reflect removal of sympathetic nervous system innervation to the heart (β_1 -blockade) and not membrane stabilization, which occurs only at high plasma concentrations of the antagonist drug. In addition, nonselective β -adrenergic blockade resulting in β_2 -adrenergic receptor antagonism may impede left ventricular ejection due to unopposed α -adrenergic receptor-mediated peripheral vasoconstriction. The magnitude of cardiovascular effects produced by β -adrenergic antagonists is greatest when preexisting sympathetic nervous system activity is increased, as during exercise or in patients in cardiac failure. Indeed, the tachycardia of exercise is consistently attenuated by β -adrenergic antagonists, and age adjusted maximal heart rate should be further adjusted down 10 beats per minute. Furthermore, new or high dose administration of a β antagonist may precipitate cardiac failure in a patient who was previously compensated. Resting bradycardia is minimized, and cardiac failure is less likely to occur when a partial β -adrenergic antagonist with intrinsic sympathomimetic activity is administered. Acute cardiac failure is rare with oral administration of β -adrenergic antagonists.

Classically, β -adrenergic antagonists prevent inotropic and chronotropic effects of isoproterenol as well as baroreceptor-mediated increases in heart rate evoked by decreases in systemic blood pressure in response to peripheral vasodilator drugs. Conversely, the influence of β -adrenergic antagonists on the cardiac-stimulating effects of calcium, glucagon, and digitalis preparations is not detectable. Likewise, β -adrenergic antagonists do not alter the response to α -adrenergic agonists such as epinephrine or phenylephrine. In theory, the pressor effect of epinephrine is enhanced because the nonselective β antagonists prevent the β_2 vasodilation of epinephrine and leaves unopposed α -adrenergic effects to predominate. The presence of unopposed α -adrenergic-induced vasoconstriction, as might be seen if propranolol were given to a patient acutely intoxicated with cocaine, will likely provoke paradoxical hypertension and may even precipitate cardiac failure in the presence of diseased myocardium that cannot respond to sympathetic nervous system stimulation because of β -adrenergic blockade.³⁸ Unexpected hypertension has occurred in patients receiving clonidine who subsequently receive a nonselective β -adrenergic antagonist.³⁹ Presumably, blockade of the

vasodilating effect normally produced by activity of β_2 receptors leaves unopposed α -adrenergic effects to provoke peripheral vasoconstriction with resulting hypertension.

Patients with peripheral vascular disease do not tolerate well the peripheral vasoconstriction associated with β_2 -receptor blockade. Indeed, the development of cold hands and feet is a common side effect produced by nonselective β -adrenergic antagonists in this population. Vasospasm associated with Raynaud disease is also accentuated by propranolol.

The principal antidysrhythmic effect of β -adrenergic blockade is to prevent the dysrhythmogenic effect of endogenous or exogenous catecholamines or sympathomimetics. This reflects a decrease in sympathetic nervous system activity. Membrane stabilization is probably of little importance in the antidysrhythmic effects produced by usual doses of β -adrenergic antagonists.

Treatment of Excess Myocardial Depression. The usual clinical manifestations of excessive myocardial depression produced by β -adrenergic blockade include bradycardia, hypotension, and cardiogenic shock.⁴⁰ Bronchospasm and depression of ventilation may also be associated with an overdose of β -adrenergic antagonist drugs. Seizures and prolonged intraventricular conduction of cardiac impulses are thought to be the result of local anesthetic properties of certain β -adrenergic antagonists (see [Table 19.1](#)). Hypoglycemia is a rare, but life-threatening, manifestation, of β -adrenergic antagonist overdose.

Excessive bradycardia and/or decreases in cardiac output due to drug-induced β -blockade should be treated initially with atropine in incremental doses of 7 $\mu\text{g}/\text{kg}$ IV. Atropine is likely to be effective by blocking vagal effects on the heart and thus unmasking any residual sympathetic nervous system innervation. If atropine is ineffective, drugs to produce direct positive chronotropic and inotropic effects are indicated. For example, continuous infusion of the nonselective β -adrenergic agonist isoproterenol, in doses sufficient to overcome competitive β -blockade, is appropriate. The necessary dose of isoproterenol may be 2 to 25 μg per minute IV (60 μg per minute IV was not effective in one report), which is 5 to 20 times the necessary dose in the absence of β -blockade.⁴⁰ When a pure β -adrenergic antagonist is responsible for excessive cardiovascular depression, a pure β_1 -adrenergic agonist such as dobutamine is recommended because isoproterenol, with β_1 - and β_2 -adrenergic agonist effects, could produce vasodilation before its inotropic effect develops. Dopamine and epinephrine are not recommended because α -adrenergic-induced vasoconstriction is likely to occur with the high doses required to overcome β -blockade.

Glucagon administered to adults, 1 to 10 mg IV followed by 5 mg per hour IV, has been used to effectively reverse the myocardial depression produced by β -adrenergic antagonists at normal doses because it does not exert its effects by means of β -adrenergic receptors. For example, glucagon stimulates adenylyl cyclase and increases intracellular cAMP concentrations independent of β -adrenergic receptors.⁴⁰ Calcium chloride, 250 to 1,000 mg IV, may also act independent of β -adrenergic receptors to offset excessive cardiovascular depression produced by β -adrenergic antagonists. Glucagon appears to be particularly effective in the presence of life-threatening bradycardia and has been described as the drug of choice to treat massive β -adrenergic antagonist overdose.⁴⁰

In the presence of life-threatening bradycardia that is unresponsive to pharmacologic therapy, it may be necessary to place a transvenous cardiac pacemaker, but without the caveat, that massive overdose may raise myocardial thresholds to prevent electromechanical capture. Hemodialysis should be reserved to remove minimally protein-bound, renally excreted β -adrenergic antagonists in patients refractory to pharmacologic therapy.

Airway Resistance

Nonselective β -adrenergic antagonists such as propranolol consistently increase airway resistance as a manifestation of bronchoconstriction due to blockade of β_2 receptors. These airway resistance effects are exaggerated in patients with preexisting obstructive airway disease. Because bronchodilation is a β_2 -adrenergic agonist response, selective β_1 -adrenergic antagonists such as bisoprolol, metoprolol, and esmolol are less likely than propranolol to increase airway resistance.

Metabolism

β -Adrenergic antagonists alter carbohydrate and fat metabolism. For example, nonselective β -adrenergic antagonists such as propranolol interfere with glycogenolysis that ordinarily occurs in response to release of epinephrine during hypoglycemia and emphasizes the need for β_2 -receptor activity in glycogenolysis.

Furthermore, the blunting of the tachycardiac response, an important warning sign of hypoglycemia in insulin-treated diabetics, is a distinct risk of β -adrenergic antagonists. For this reason, nonselective β -adrenergic antagonists are not recommended for administration to patients with diabetes mellitus being treated with insulin or oral hypoglycemics. Altered fat metabolism is evidenced by failure of sympathomimetics or sympathetic nervous system stimulation to increase plasma concentrations of free fatty acids in the presence of β -adrenergic blockade.

Distribution of Extracellular Potassium

Distribution of potassium across cell membranes is influenced by sympathetic nervous system activity as well as insulin. Specifically, stimulation of β_2 -adrenergic receptors seems to facilitate movement of potassium intracellularly. As a result, β -adrenergic blockade inhibits uptake of potassium into skeletal muscles, and the plasma concentration of potassium may be increased. Indeed, increases in the plasma concentration of potassium associated with infusion of this ion are greater in the presence of β -adrenergic blockade produced by propranolol (Figure 19.7).⁴¹ In animals, increases in the plasma concentration of potassium after administration of succinylcholine last longer when β -adrenergic blockade is present.⁴² However, this has not been conclusively demonstrated in patients.⁴³ In view of the speculated role of β_2 receptors in regulating plasma concentrations of potassium, it is likely that selective β_1 -adrenergic antagonists would impair skeletal muscle uptake of potassium less than nonselective β -adrenergic antagonists.

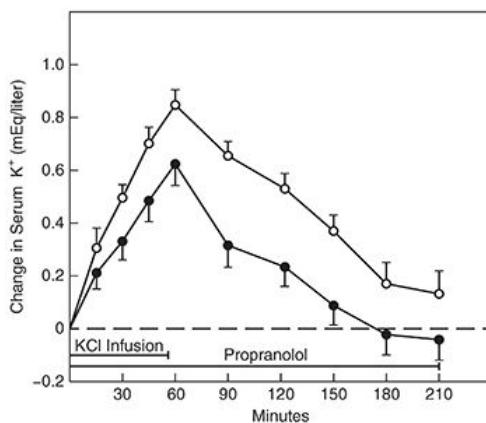

FIGURE 19.7 Increases in plasma (serum) potassium concentration (K^+) in response to infusion of potassium chloride (KCl) are greater in the presence of propranolol (clear circles) than in its absence (solid circles). (Mean \pm standard error.) From Rosa RM, Silva P, Young JB, et al. Adrenergic modulation of extrarenal potassium disposal. N Engl J Med. 1980;302(8):431-434. Interaction With Anesthetics

Myocardial depression produced by inhaled or injected anesthetics could be additive with depression produced by β -adrenergic antagonists. Nevertheless, clinical experience and controlled studies in patients and animals have confirmed that additive myocardial depression with β -adrenergic antagonists and anesthetics is not excessive, and thus, treatment with β -adrenergic antagonists may therefore be safely maintained throughout the perioperative period.¹ An exception may be patients treated with timolol in whom profound bradycardia has been observed in the presence of inhaled anesthetics.

Additive cardiovascular effects with inhaled anesthetics and β -adrenergic antagonists seem to be greatest with enflurane and least with isoflurane.¹ Sevoflurane and desflurane, like isoflurane, do not seem to be associated with significant additive cardiovascular effects when administered to patients being treated with β -adrenergic antagonists. Cardiac output and systemic blood pressure are similar with or without β -adrenergic blockade in the presence of one or two minimum alveolar concentrations of isoflurane.⁴⁴ Even acute hemorrhage does not alter the interaction between isoflurane and β -adrenergic antagonists.^{45,46} Cardiovascular responses to even high doses of opioids such as fentanyl are not altered by preexisting β -adrenergic blockade. In the presence of anesthetic drugs that increase sympathetic nervous system activity (ketamine), or when excessive sympathetic nervous system activity is present because of hypercarbia, the acute administration of a β -adrenergic antagonist may unmask direct negative inotropic effects of concomitantly administered anesthetics, with resulting decreases in systemic blood pressure and cardiac output.⁴⁷

Nervous System

β -Adrenergic antagonists may cross the blood–brain barrier to produce side effects. For example, fatigue and lethargy are commonly associated with chronic propranolol therapy. Vivid dreams are frequent, but psychotic reactions are rare. Memory loss and mental depression have been alleged to occur, although β -adrenergic antagonist therapy has not been shown to produce these effects.⁴⁸ A review of several clinical trials showed no significant increased risk of depressive symptoms and only small increased risks of fatigue and sexual dysfunction, although long-term and high dosage effects on the nervous system are less clear.^{49–51} Peripheral paresthesias have been described. Atenolol and nadolol are less lipid soluble than other β -adrenergic antagonists and thus may be associated with a lower incidence of CNS effects.

Fetus

β -adrenergic antagonists can cross the placenta and cause bradycardia, hypotension, and hypoglycemia, especially in lipophilic drugs like labetalol and propranolol but may be offset by high levels of protein binding reducing their effects on the fetus.^{52,53} Clinically, labetalol is listed by the US FDA as pregnancy category C and “potential benefits may outweigh the risks.” The American College of Obstetrician Gynecologists (ACOG) currently list PO and IV labetalol as first-line therapy for acute onset or emergent hypertension in pregnancy based on long term clinical use data. Per ACOG,⁵³ although breast is likely to contain beta antagonists, this is more pronounced in hydrophilic compounds with low protein binding such as atenolol and metoprolol and much less so in labetalol and propranolol. As such, ACOG continues to support the use of these medications in the breast feeding postparturient.

Withdrawal Hypersensitivity

Acute discontinuation of β -adrenergic antagonist therapy can result in excess sympathetic nervous system activity that manifests in 24 to 48 hours. Presumably, this enhanced activity reflects an increase in the number of β -adrenergic receptors (upregulation) that occurs during chronic antagonist therapy. Continuous infusion of propranolol, 3 mg per hour IV, is effective in maintaining therapeutic plasma concentrations in adult patients who cannot take drugs orally during the perioperative period.⁵⁴

Clinical Uses

Clinical uses of β -adrenergic antagonists are multiple and in equivalent doses, all β -adrenergic antagonists seem to be equally effective in producing desired therapeutic effects (**Table 19.3**). It is accepted that patients being treated with β -adrenergic receptor antagonists should have their medication continued uninterrupted through the perioperative period. It is also recommended that patients at high risk for myocardial ischemia and presenting for major surgery should be treated with β -adrenergic receptor antagonists beginning preoperatively and continuing into the postoperative period.

TABLE 19.3

Clinical uses of β -adrenergic blockers

Treatment of essential hypertension
Management of angina pectoris
Treatment of acute coronary syndrome
Perioperative β -adrenergic receptor blockade
Treatment of intraoperative myocardial ischemia
Suppression of cardiac dysrhythmias
Management of congestive heart failure
Prevention of excessive sympathetic nervous system activity
Preoperative preparation of hyperthyroid patients
Treatment of migraine headache

Treatment of Essential Hypertension

Chronic therapy with β -adrenergic antagonists results in gradual decreases in systemic blood pressure. The antihypertensive effect of β -adrenergic blockade is largely dependent on decreases in cardiac output due to decreased heart rate. Large doses of β -adrenergic antagonists may decrease myocardial contractility as well. In many patients, systemic vascular resistance remains unchanged. An important advantage in the use of β -adrenergic antagonists for the treatment of essential hypertension is the absence of orthostatic hypotension. Often, a β -adrenergic antagonist is used in combination with a vasodilator to minimize reflex baroreceptor-mediated increases in heart rate and cardiac output produced by the vasodilator. All orally administered β -adrenergic antagonists appear to be equally effective antihypertensive drugs. Release of renin from the juxtaglomerular apparatus that occurs in response to stimulation of β_2 receptors is prevented by nonselective β -adrenergic antagonists such as propranolol. This may account for a portion of the antihypertensive effect of propranolol, especially in patients with high circulating plasma concentrations of renin. With drug-induced decreases in secretion of renin and a decreased release of aldosterone, β -adrenergic antagonists will also prevent the compensatory sodium and water retention that accompanies treatment with a vasodilator.

Management of Angina Pectoris

Orally administered β -adrenergic antagonists are equally effective in decreasing the likelihood of myocardial ischemia manifesting as angina pectoris. This desirable response reflects drug-induced decreases in myocardial oxygen requirements secondary to decreased heart rate and myocardial contractility. The effective dose usually decreases resting heart rate to less than 60 beats per minute. A more important measure is the heart rate during exercise, which should not exceed 75% of the heart rate at which myocardial ischemia occurs.

The concept that β -adrenergic antagonists and calcium channel blockers act on different determinants of the myocardial oxygen supply-to-demand ratio suggests combined uses of these drugs would be beneficial in the management of patients with coronary artery disease. Nevertheless, the evidence from clinical studies suggests that patients managed with combined therapy do not experience greater beneficial therapeutic effects but may experience more adverse effects than if they had received optimal treatment with a single drug.⁵⁵

Treatment of Acute Coronary Syndrome

It used to be recommended that all patients who experience an acute myocardial infarction receive IV β -adrenergic antagonists as early as possible, whether or not they receive reperfusion therapy. Treatment with β -adrenergic antagonists is contraindicated in the presence of severe bradycardia, unstable left ventricular failure, and atrioventricular heart block. Relative contraindications to treatment with β -adrenergic antagonists include asthma or reactive airway disease, depression, excessive fatigue, and peripheral vascular disease. Diabetes mellitus is not a contraindication to treatment with β -adrenergic antagonists recognizing that signs of hypoglycemia may be masked.

A growing body of literature is rising against the use of β -blockers in patients who present with an acute coronary syndrome within the first 8 hours, especially if they present with ST elevation myocardial infarction

or cardiogenic shock.⁵⁶ The ST elevation myocardial infarction patients had a greater risk of developing cardiogenic shock after β -blocker administration, and those in shock had a greater risk of decompensating even further.⁵⁷ However, the incidence of nonfatal reinfarction and recurrent myocardial ischemia is decreased compared with patients in whom oral metoprolol was initiated 6 days following myocardial infarction.⁵⁸ β -Adrenergic antagonist prophylaxis after acute myocardial infarction is considered to be one of the most scientifically substantiated, cost-effective preventive medical treatments. Whether β -adrenergic antagonists can decrease mortality in patients with angina pectoris who have not yet experienced a myocardial infarction is unknown.

The cardioprotective effect of β -adrenergic antagonists is present with both cardioselective and nonselective drugs (see [Tables 19.1](#) and [19.2](#)). The mechanism of the cardioprotective effect is uncertain, but antidysrhythmic actions may be important. A nonselective β -adrenergic antagonist that prevents epinephrine-induced decreases in plasma potassium concentrations (a β_2 -mediated response) may be useful in decreasing the incidence of ventricular dysrhythmias.

Perioperative β -Adrenergic Receptor Blockade

Perioperative β -adrenergic receptor blockade is recommended for patients considered at risk for myocardial ischemia (known coronary artery disease, positive preoperative stress tests, diabetes mellitus treated with insulin, left ventricular hypertrophy) during high-risk surgery (vascular surgery, thoracic surgery, intraperitoneal surgery, anticipated large blood loss).^{59,60} The goal of preoperative therapy is a resting heart rate between 65 and 80 beats per minute.⁶¹ All β -adrenergic receptor antagonists except those with intrinsic sympathetic nervous system activity decrease mortality. Perioperative myocardial ischemia is the single most important potentially reversible risk factor for mortality and cardiovascular complications after noncardiac surgery. Administration of atenolol for 7 days before and after noncardiac surgery in patients at risk for coronary artery disease may decrease mortality and the incidence of cardiovascular complications for as long as 2 years after surgery.¹⁵ In another report, administration of atenolol IV before induction of anesthesia and every 12 hours after noncardiac surgery for 7 days to patients at high risk for coronary artery disease reduced the incidence of postoperative myocardial ischemia by 30% to 50%.¹⁶ Decreases in perioperative myocardial ischemia are associated with reductions in the risk for death at 24 months. The incidence of bronchospasm, hypotension, bradycardia, and cardiac dysrhythmias was not increased in treated patients. The mechanism for the beneficial effects of perioperative β -adrenergic receptor blockade is not known but is most likely multifactorial ([Table 19.4](#)). It is not known if patients with cardiac risk factors but no signs of underlying coronary artery disease will benefit from perioperative administration of a β -adrenergic antagonist.⁶²

TABLE 19.4

Possible explanations for cardioprotective effects produced by perioperative β -adrenergic receptor blockade

Decreased myocardial oxygen consumption and demand
Less stress on potentially ischemic myocardium owing to decreased heart rate and myocardial contractility
Attenuation of effects of endogenous catecholamines
Redistribution of coronary blood flow to ischemic areas
Increased coronary blood flow owing to increased diastolic time
Plaque stabilization owing to decrease in shear forces
Cardiac antidysrhythmic effects
Antiinflammatory effects

Preoperatively, oral therapy can be initiated with atenolol 50 mg or bisoprolol 5 to 10 mg daily or metoprolol 25 to 50 mg twice daily. If the patient is seen the morning of surgery, atenolol 5 to 10 mg IV or metoprolol 5 to 10 mg IV can be titrated. Esmolol is an acceptable drug to achieve β -adrenergic receptor blockade during surgery and postoperatively in the intensive care unit where continuous IV infusions can be

monitored. Alternatively, IV atenolol or metoprolol can be administered until the patient can take oral atenolol, metoprolol, or bisoprolol. β -Adrenergic receptor antagonists with sympathomimetic actions are not likely selections to produce perioperative β -blockade. The Perioperative Ischemic Evaluation trial has raised concerns over regimens that start β -blockers in the acute preoperative setting due to an all-cause increased mortality that is driven by an increase in cerebrovascular events. Criticisms of the Perioperative Ischemic Evaluation trial⁶³ point to its very aggressive escalation regimen (as much as 400 mg metoprolol succinate dosed in 24 hours) without regard to patient's baseline hemodynamics (systolic and mean pressure reductions of >30% below preoperative levels), which is well known to cause cerebrovascular hypoperfusion and infarction. This has prompted many practitioners to only start low-dose β -blocker regimens in the preoperative period or to hold initiation until postoperatively.

Treatment of Intraoperative Myocardial Ischemia

Appearance of evidence of myocardial ischemia on the electrocardiogram or as wall motion abnormalities on the transesophageal echocardiogram may benefit from treatment with a β -adrenergic receptor blocking drug, assuming the absence of contraindications (severe reactive airway disease, right ventricular ischemia, bradycardia, shock, or left ventricular failure) and the presence of an adequate concentration of inhaled anesthetic drugs. The drug selected should be titrated to the desired heart rate (about 60 beats per minute) to attenuate myocardial ischemia. Treatment options include esmolol (1-1.5 mg/kg IV followed by a continuous infusion of 50-300 μ g/kg per minute), metoprolol (5 mg IV), atenolol (5-10 mg IV), or propranolol (1-10 mg IV). The advantage of esmolol is the ability to titrate its effects to the desired heart rate. Nitroglycerin is often added to this treatment regimen.

Suppression of Cardiac Dysrhythmias

β -Adrenergic receptor blocking drugs are effective in the treatment of cardiac dysrhythmias as a result of enhanced sympathetic nervous system stimulation (thyrotoxicosis, pheochromocytoma, perioperative stress). Intravenous esmolol and propranolol are effective for controlling the ventricular response rate to atrial fibrillation and atrial flutter. These drugs are also effective for controlling atrial dysrhythmias following cardiac surgery. Propranolol may be effective for controlling torsades de pointes in patients with prolonged QTc intervals on the electrocardiogram. Acebutolol, metoprolol, atenolol, propranolol, and timolol are approved for prevention of sudden death following acute myocardial infarction.

Management of Congestive Heart Failure

Controlled studies have demonstrated that metoprolol, carvedilol, and bisoprolol improve ejection fraction and increase survival in patients in chronic heart failure (see [Table 19.2](#)). Sustained-release metoprolol is associated with improved survival.⁶⁴ Carvedilol, a nonselective β -blocker with vasodilator and antioxidant properties, has been shown to decrease mortality associated with congestive heart failure.⁶⁵ When β -blocking drugs are used to treat congestive heart failure, the initial doses of β -blockers should be minimal and gradually increased.

Prevention of Excessive Sympathetic Nervous System Activity

β -Adrenergic blockade is associated with attenuated heart rate and blood pressure changes in response to direct laryngoscopy and tracheal intubation.^{1,66} Hypertrophic obstructive cardiomyopathies are often treated with β -adrenergic antagonists. Tachycardia and cardiac dysrhythmias associated with pheochromocytoma and hyperthyroidism are effectively suppressed by propranolol. The likelihood of cyanotic episodes in patients with tetralogy of Fallot is minimized by β -blockade. Propranolol has been used intraoperatively to prevent reflex baroreceptor-mediated increases in heart rate evoked by vasodilators administered to produce controlled hypotension. Even anxiety states as caused by public speaking have been treated with propranolol.

Preoperative Preparation of Hyperthyroid Patients

Thyrotoxic patients can be prepared for surgery in an emergency by IV administration of propranolol or esmolol or electively by oral administration of propranolol (40-320 mg daily).^{67,68} Advantages of β -

adrenergic antagonists include rapid suppression of excessive sympathetic nervous system activity and elimination of the need to administer iodine or antithyroid drugs.

Combined α - and β -Adrenergic Receptor Antagonists

Labetalol

Labetalol is a parenteral and oral antihypertensive drug that exhibits selective α_1 - and nonselective β_1 - and β_2 -adrenergic antagonist effects (**Figure 19.8**).^{69,70} Presynaptic α_2 receptors are spared by labetalol such that released norepinephrine can continue to inhibit further release of catecholamines via the negative feedback mechanism resulting from stimulation of α_2 receptors. Labetalol is one-fifth to one-tenth as potent as phentolamine in its ability to block α receptors and is approximately one-fourth to one-third as potent as propranolol in blocking β receptors. In humans, the β to α blocking potency ratio is 3:1 for oral labetalol and 7:1 for IV labetalol.

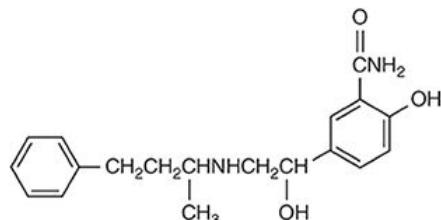

FIGURE 19.8 Labetalol.

Pharmacokinetics

Metabolism of labetalol is by conjugation of glucuronic acid with 5% of the drug recovered unchanged in urine. The elimination half-time is 5 to 8 hours and is prolonged in the presence of liver disease and unchanged by renal dysfunction.

Cardiovascular Effects

Administration of labetalol lowers systemic blood pressure by decreasing systemic vascular resistance (α_1 -blockade), whereas reflex tachycardia triggered by vasodilation is attenuated by simultaneous β -blockade. Cardiac output remains unchanged. In addition to producing vasodilation by α_1 -blockade, labetalol may cause vasodilation that is mediated by β_2 -adrenergic agonist activity.⁷¹ The maximum systemic blood pressure-lowering effect of an IV dose of labetalol (0.1-0.5 mg/kg) is present in 5 to 10 minutes.

Clinical Uses

Labetalol is a safe and effective treatment for hypertensive emergencies. For example, labetalol has been administered IV to control severe hypertension that may be associated with an epinephrine overdose as may occur during submucosal injection to produce surgical hemostasis.⁷² Conversely, caution has been urged in using β -adrenergic blockers to treat phenylephrine and epinephrine overdose resulting from systemic absorption following topical application.²⁶ Large bolus doses of labetalol (2 mg/kg IV) administered to treat hypertensive emergencies may result in excessive decreases in blood pressure, whereas smaller doses (20-80 mg IV) are less likely to produce undesirable decreases in blood pressure.^{73,74} Repeated doses of labetalol, 20 to 80 mg IV, may be administered about every 10 minutes until the desired therapeutic response is achieved.⁷⁴ Rebound hypertension after withdrawal of clonidine therapy and hypertensive responses in patients with pheochromocytoma can be effectively treated with labetalol. Labetalol is also effective in the treatment of angina pectoris. Availability of both an oral (100-600 mg twice a day) and IV preparation is useful for converting a patient with a hypertensive crisis to oral therapy after initial control with IV therapy.

Labetalol, 0.1 to 0.5 mg/kg IV, can be administered to anesthetized patients to attenuate increases in heart rate and blood pressure that are presumed to result from abrupt increases in the level of surgical

stimulation. It is possible that existing depressant effects of the anesthetic drugs could accentuate the blood pressure-lowering properties of labetalol. In contrast to the results with nitroprusside, controlled hypotension produced with intermittent injections of labetalol, 10 mg IV, is not associated with increases in heart rate, intrapulmonary shunt, or cardiac output.⁷⁵

Side Effects

Orthostatic hypotension is the most common side effect of labetalol therapy. Bronchospasm is possible in susceptible patients, reflecting the β -adrenergic antagonist effects of labetalol. Other adverse effects associated with β -adrenergic antagonists (congestive heart failure, bradycardia, heart block) are a potential risk of labetalol therapy, but the likely incidence and severity is substantially decreased. Incomplete α -adrenergic blockade in the presence of more complete β -blockade could result in excessive α stimulation.⁷² Fluid retention in patients treated chronically with labetalol is the reason for combining this drug with a diuretic during prolonged therapy.

Carvedilol

Carvedilol is a nonselective β -adrenergic receptor antagonist with α_1 -blocking activity. This drug has no intrinsic β -adrenergic agonist effect. Following oral administration, carvedilol is extensively metabolized to products with pharmacologic activity possessing weak vasodilator actions. The elimination half-time is 7 to 10 hours, and protein binding is extensive. Carvedilol is indicated for the treatment of mild to moderate congestive heart failure owing to ischemia or cardiomyopathy (see [Table 19.2](#)). This drug is also useful for the treatment of essential hypertension.

Calcium Channel Blockers

Calcium channel blockers (also known as **calcium entry blockers** and **calcium antagonists**) are a diverse group of structurally unrelated compounds that selectively interfere with inward calcium ion movement across myocardial and vascular smooth muscle cells.^{76,77} Calcium ions play a key role in the electrical excitation of cardiac cells and vascular smooth muscle cells.

Commercially available calcium channel blockers are classified based on chemical structure as phenylalkylamines, dihydropyridines, and benzothiazepines ([Table 19.5](#) and [Figure 19.9](#)). The phenylalkylamines and benzothiazepines are selective for the atrioventricular node, whereas the dihydropyridines are selective for the arteriolar beds.⁷⁸ Common side effects of calcium channel blockers include systemic hypotension, peripheral edema, flushing, and headache. The various calcium channel blockers differ in terms of side effects, usual doses, metabolism, and duration of action ([Tables 19.6](#) and [19.7](#)). Despite sharing the commonality of calcium channel inactivation, the classes of calcium channel blockers have different molecular mechanisms of action at the calcium channel subtypes, different tissue specificity, and different physiologic responses.⁷⁹

Calcium entry blockers: uses and implications for anesthesiologists. *Anesthesiology.* 1982;57(6):504-518. Copyright © 1982 American Society of Anesthesiologists, Inc.

Mechanism of Action

Calcium channel blockers bind to receptors on voltage-gated calcium ion channels (L, long-lasting; N, neural; and T, transient opening subtypes) resulting in maintenance of these channels in an inactive (closed) state. As a result, calcium influx is decreased, and there is a reduction in intracellular calcium. The L-type channel (slow channel) has five subunits: α_1 , α_2 , β , γ , and δ . The α_1 subunit forms the central part of the channel and provides the main pathway for calcium ion entry into cells. All clinically used calcium channel blockers bind to a unique site on the α_1 subunit of the L-type calcium channels and thus diminish entry of calcium ions into cells. These structurally diverse drugs differ in their tissue selectivity, their binding site location on the α_1 subunit, and their mechanism of calcium blockade.

Voltage-gated calcium ion channels are present in the cell membranes of skeletal muscle, vascular smooth muscle, cardiac muscle, mesenteric muscle, glandular cells, and neurons ([Figure 19.10](#)).⁷⁸ Calcium ion influx through L-type calcium channels is responsible for phase 2 of the cardiac action potential, which is important in excitation/contraction coupling in cardiac and vascular smooth muscle and depolarization in sinoatrial and atrioventricular nodal tissue. Thus, blockade of slow calcium channels by calcium channel blockers predictably results in slowing of the heart rate, reduction in myocardial contractility, decreased speed of conduction of cardiac impulses through the atrioventricular node, and vascular smooth muscle relaxation.⁸⁰

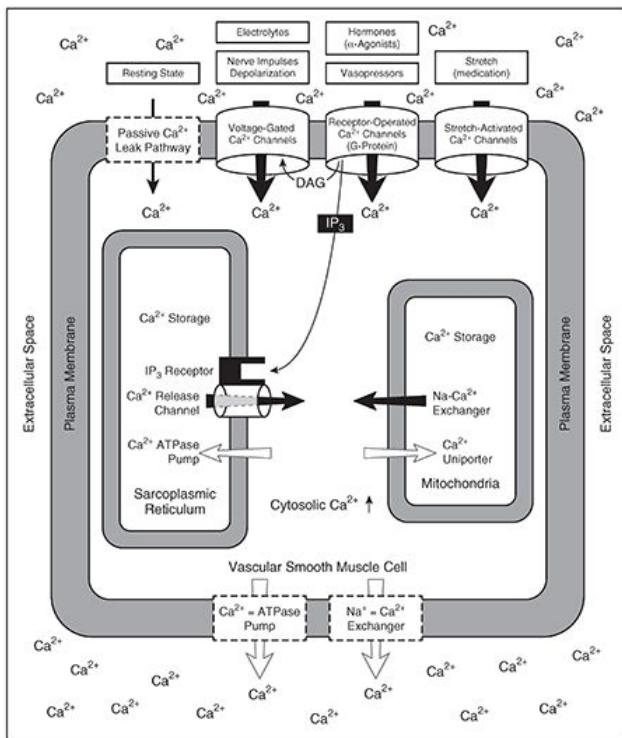

FIGURE 19.10 Calcium ion entry and exit from a vascular smooth muscle cell. Calcium enters the cytosol (black arrows) of the vascular smooth muscle cell either from the extracellular space through the plasma membrane (top of diagram) or from the intracellular storage areas. The primary entry sites for calcium ions are the voltage-gated channels. *Reprinted with permission from Kanneganti M, Halpern NA. Acute hypertension and calcium-channel blockers. New Horiz. 1996;4(1):19-25.*

Direct activation of the vascular smooth muscle cell voltage-gated channels by neural impulses initiates an action potential, calcium ion influx, and myofilament contraction (see [Figure 19.10](#)).⁷⁸ This process is known as **excitation-contraction coupling**. The intracellular calcium combines with calmodulin, the calcium-binding protein, to form the calcium-calmodulin complex. This complex activates myosin and causes the formation of cross-bridges with actin. These cross-bridges begin the process of muscular contraction.

Pharmacologic Effects

The pharmacologic effects of calcium channel blockers may be predicted by considering the normal role of calcium ions in the production of action potentials, especially in cardiac cells. It is predictable that calcium channel blockers will produce decreased myocardial contractility, decreased heart rate, decreased activity of the sinoatrial node, decreased rate of conduction of cardiac impulses through the atrioventricular node, and vascular smooth muscle relaxation with associated vasodilation and decreases in systemic blood pressure.^{80,81} Calcium channel blockers produce these effects to varying degrees (see [Table 19.6](#)).

All of the calcium channel blockers are effective for the treatment of coronary artery spasm. Calcium channel blockers decrease vascular smooth muscle contractility, thereby increasing coronary blood flow and causing peripheral vasodilation with reductions in systemic vascular resistance and systemic blood pressure. These drug-induced responses contribute to the anti-ischemic effects characteristic of calcium channel blockers. As calcium channel blockers dilate the coronary arteries via a mechanism that is different from that of nitrates, the two classes of drugs complement each other in the treatment of coronary artery spasm. Calcium channel blockers are also effective for the treatment of chronic stable angina pectoris caused by fixed obstructive coronary artery lesions and for the treatment of unstable angina pectoris.

All calcium channel blockers exert negative inotropic effects, which are most significant with verapamil and diltiazem.

Phenylalkylamines

The phenylalkylamines bind to the intracellular portion of the L-type channel α_1 subunit when the channel is in an open state and conceptually occlude the channel ([Figure 19.11](#)).⁷⁸

Verapamil

Verapamil is a synthetic derivative of papaverine that is supplied as a racemic mixture. The dextroisomer of verapamil is devoid of activity at slow calcium channels and instead acts on fast sodium channels, accounting for the local anesthetic effects of verapamil (1.6 times as potent as procaine).⁸² The levoisomer of verapamil is specific for slow calcium channels, and the predominance of this action accounts for the classification of verapamil as a calcium-blocking drug.

Side Effects

Verapamil has a major depressant effect on the atrioventricular node, a negative chronotropic effect on the sinoatrial node, a negative inotropic effect on cardiac muscle, and a moderate vasodilating effect on coronary and systemic arteries. The negative inotropic effects of verapamil seem to be exaggerated in patients with preexisting left ventricular dysfunction. For these reasons, verapamil should not be administered to patients in heart failure or patients with severe bradycardia, sinus node dysfunction, or atrioventricular nodal block. Likewise, this drug's negative inotropic and chronotropic effects may be enhanced in the presence of concomitant treatment with β -adrenergic antagonists. Isoproterenol may be useful to increase heart rate in the presence of drug-induced heart block. Verapamil may precipitate ventricular dysrhythmias in patients with Wolff-Parkinson-White syndrome.

Clinical Uses

Verapamil is effective in the treatment of supraventricular tachydysrhythmias, reflecting its primary site of action on the atrioventricular node (see [Chapter 21](#)). The mild vasodilating effects produced by verapamil make this drug useful in the treatment of vasospastic angina pectoris and essential hypertension. Indeed, calcium channel blockers are as effective as β -blockers in relieving angina pectoris. Verapamil is not as active as nifedipine in its effects on vascular smooth muscle and therefore causes a less pronounced decrease in systemic blood pressure and less reflex peripheral sympathetic nervous system activity. Verapamil is effective in the treatment of symptomatic hypertrophic cardiomyopathy with or without left ventricular outflow

obstruction.⁸³ Calcium channel antagonists should not be routinely administered for acute myocardial infarction as postinfarction mortality is not decreased.⁸⁴

Pharmacokinetics

Oral verapamil is almost completely absorbed, but extensive hepatic first-pass metabolism limits bioavailability to 10% to 20% (see [Table 19.7](#)). As a result, the oral dose (80–160 mg 3 times daily) is about 10 times the IV dose. The therapeutic plasma concentration of verapamil is 100 to 300 ng/mL. The activity of oral verapamil peaks in 30 to 45 minutes compared with about 15 minutes following IV administration. Pharmacologic effects following IV administration of verapamil appear within 2 to 3 minutes and may last 6 hours.

Demethylated metabolites of verapamil predominate, with norverapamil possessing sufficient activity to contribute to the antidyshhythmic properties of the parent drug. In view of the nearly complete hepatic metabolism of verapamil, almost none of the drug appears unchanged in the urine. Conversely, an estimated 70% of an injected dose of verapamil is recovered in urine as metabolites, and about 15% is excreted via bile. Chronic oral administration of verapamil or the presence of renal dysfunction leads to the accumulation of norverapamil.

The elimination half-time of verapamil is 6 to 12 hours, and this may be prolonged in patients with liver disease. In this regard, chronic treatment with verapamil has rarely been associated with increased plasma concentrations of transaminase enzymes. Like nifedipine, verapamil is highly protein bound (90%), and the presence of other drugs (lidocaine, diazepam, propranolol) can increase the pharmacologically active, unbound portion of the drug.

Dihydropyridines

The dihydropyridines prevent calcium entry into the vascular smooth cells by extracellular allosteric modulation of the L-type voltage-gated calcium ion channels (see [Figure 19.11](#)).⁷⁸ The primary affinity of the dihydropyridines clevidipine, nifedipine, nicardipine, isradipine, felodipine, and amlodipine is for the peripheral arterioles, whereas nimodipine favors cerebral vessels. The vasodilating effects of these drugs on venous capacitance vessels are minimal. As with other peripheral vasodilators, a reflex tachycardia attributed to sympathetic nervous system activity or baroreceptor reflexes may be observed with the acute administration of dihydropyridines.

Nifedipine

Nifedipine is a dihydropyridine derivative with greater coronary and peripheral arterial vasodilator properties than verapamil. There is minimal effect on venous capacitance vessels. Unlike verapamil, nifedipine has little or no direct depressant effect on sinoatrial or atrioventricular node activity. Peripheral vasodilation and the resulting decrease in systemic blood pressure produced by nifedipine activate baroreceptors, leading to increased peripheral sympathetic nervous system activity most often manifesting as an increased heart rate. This increased sympathetic nervous system activity counters the direct negative inotropic, chronotropic, and dromotropic effects of nifedipine. Nevertheless, nifedipine may produce excessive myocardial depression, especially in patients with preexisting left ventricular dysfunction or concomitant therapy with a β -adrenergic antagonist drug. The presence of aortic stenosis may also exaggerate the cardiac depressant effects of nifedipine.

Clinical Uses

Nifedipine is administered orally with a 10- to 30-mg dose, producing an effect in about 20 minutes with a peak effect between 60 and 90 minutes. Nifedipine is used to treat patients with angina pectoris, especially that due to coronary artery vasospasm.

Pharmacokinetics

Absorption of an oral or sublingual dose of nifedipine is about 90%, with onset of an effect being detectable within about 20 minutes after administration (see [Table 19.7](#)). It is likely that most of the absorption of

sublingual nifedipine is via the gastrointestinal tract from swallowed saliva. Protein binding approaches 90%. Hepatic metabolism is nearly complete, with elimination of inactive metabolites principally in urine (about 80%) and, to a lesser extent, in bile. The elimination half-time is 3 to 7 hours.

Side Effects

The side effects of nifedipine include flushing, vertigo, and headache. Less common side effects include peripheral edema (venous congestion), hypotension, paresthesias, and skeletal muscle weakness. Glucose intolerance and hepatic dysfunction occur rarely, but nifedipine has been associated with both an increase in glomerular filtration rate and renal blood flow at low doses or may induce renal dysfunction if perfusion pressure is dropped enough to cause a loss of blood flow resulting in a prerenal injury pattern. Abrupt discontinuation of nifedipine has been associated with coronary artery vasospasm.

Nicardipine

Nicardipine lacks effects on the sinoatrial node and atrioventricular node and has minimal myocardial depressant effects. This drug has the greatest vasodilating effects of all the calcium entry blockers, with vasodilation being particularly prominent in the coronary arteries. Combination with a β -adrenergic antagonist for the treatment of angina is a consideration because dihydropyridine calcium channel blockers do not significantly depress the sinoatrial node. Of all the antianginal drugs, the dihydropyridine calcium channel blockers produce the greatest dilatation of the peripheral arterioles. Therefore, either nifedipine or nicardipine may be particularly useful in patients who have residual hypertension despite β -adrenergic blockade.

Nicardipine is available in IV and oral preparations (other dihydropyridine calcium channel blockers are available only as oral preparations) and is highly lipophilic with a nearly complete gastrointestinal absorption but a very high first-pass metabolism reducing its bioavailability to only about 35%. The IV formulation follows a triexponential decline in plasma concentrations with an α half-life of 2.7 minutes, a β half-life of 44.8 minutes, and a terminal γ half-life of 14.4 hours. Therefore, with short-term infusions, its functional vasodilation only lasts 9 to 15 minutes, but it is this long elimination half-time is the basis for the recommendation that about 72 hours should elapse before increasing the oral doses. Nicardipine is metabolized in the liver and is highly protein bound (about 95%). The side effects of nicardipine are similar to nifedipine.

Clinical Uses

Although no longer recommended, nicardipine has been used as a tocolytic drug having a similar tocolytic effect as salbutamol but with fewer side effects.⁸⁵ When nicardipine is administered as a tocolytic, it binds to the inside of myometrial L-type voltage-dependent calcium ion channels, causing them to remain closed, and thus inhibits uterine contractility. Pulmonary edema associated with salbutamol used as a tocolytic has also been reported in a parturient treated with nicardipine.⁸⁶ Nicardipine, 40 μ g/kg IV administered immediately before performing electroconvulsive therapy, is effective in blunting acute hemodynamic responses to the treatment.⁸⁷

Clevidipine

Clevidipine is a third-generation dihydropyridine that is extremely lipophilic and ultrashort acting. It is U.S. Food and Drug Administration approved for the treatment of acute, severe hypertension and is only available in an IV form. It is cleared by plasma esterases with a metabolism half-life of approximately 1 minute that is unaffected by either liver or kidney dysfunction. However, in patients with pseudocholinesterase deficiency, metabolism was significantly delayed and functional half-life times were increased by approximately 32%.

Dosing is a simple protocol that starts at 1 to 2 mg per hour and is doubled every 90 seconds until blood pressure approaches goal, and then increases are reduced to 1 to 2 mg per hour again and only increased every 5 to 10 minutes. Although median dosing range is 4 to 8 mg per hour, doses as high as 32 mg per hour have been used but not studied extensively. The preparation of clevidipine comes as a 0.2-g of lipid per milliliter and necessitates adjustments to both enteral and parenteral nutrition at higher doses. Common side

effects include hypotension as well as tachycardia, and it bears a warning against use in hyperlipidemic states, acute or chronic pancreatitis, and heart failure with reduced ejection fraction as higher dose infusions have been associated with a negative inotropic effect that could precipitate acute decompensation.

Nimodipine

Nimodipine is a highly lipid-soluble analogue of nifedipine. Lipid solubility facilitates its entrance into the CNS, where it blocks the influx of extracellular calcium ions necessary for contraction of large cerebral arteries.

Clinical Uses

The lipid solubility of nimodipine and its ability to cross the blood–brain barrier is responsible for the potential value of this drug in treating patients with subarachnoid hemorrhage.

Cerebral Vasospasm

The vasodilating effect of nimodipine on cerebral arteries is uniquely valuable in preventing or attenuating cerebral vasospasm that often accompanies subarachnoid hemorrhage.⁸⁸ The initial event in the development of vasospasm may be an intracellular influx of calcium ions that cause contraction of smooth muscle cells in large cerebral arteries. Administration of nimodipine, 0.7 mg/kg orally as an initial dose followed by 0.35 mg/kg every 4 hours for 21 days, is associated with a decreased incidence of neurologic deficits due to cerebral vasospasm in patients who had experienced subarachnoid hemorrhage.⁸⁹ Blood and cerebrospinal fluid levels of nimodipine with this dosing regimen were 6.9 and 0.77 ng/mL, respectively. In comatose patients who cannot take oral medications, the recommendation is to extract the contents of the nimodipine capsule into a syringe and administer the drug into a nasogastric tube. To ensure delivery of the drug into the stomach via a nasogastric tube, it is necessary to add up to 30 mL of saline to the nimodipine-containing solution.⁹⁰ Side effects have not been observed with the oral administration of nimodipine. Symptoms of excessive nimodipine effect would be expected to be related to cardiovascular effects such as peripheral vasodilation with associated systemic hypotension. Theoretically, drug-induced cerebral vasodilation could evoke increases in intracranial pressure, particularly in patients with preexisting decreases in intracranial compliance.

Cerebral Protection

Nimodipine has also been evaluated for cerebral protection after global ischemia as associated with cardiac arrest. The theoretical basis for considering calcium channel blockers for this purpose is the observation that lack of oxygen interferes with maintenance of the normal calcium ion gradient across cell membranes, leading to a massive increase (at least 200-fold) in the intraneuronal concentrations of this ion. In this regard, nimodipine is associated with improved neurologic outcome when used for subarachnoid hemorrhage after aneurysm rupture.^{91,92} The dose of nimodipine used (10 µg/kg IV followed by 1 µg/kg per minute IV) was associated with decreases in blood pressure that responded to infusion of fluids and/or dopamine.

Amlodipine

Amlodipine is a dihydropyridine derivative that is available for only oral administration (5-10 mg) resulting in a peak plasma concentration in 6 to 12 hours. Elimination half-time is 30 to 40 hours, and about 90% of the drug undergoes hepatic metabolism to inactive products. Amlodipine appears to have minimal detrimental effects on myocardial contractility and provides anti-ischemic effects comparable to β-blockers in patients with acute coronary syndrome.⁸⁴ The combination of amlodipine and β-blockers may be more effective in the treatment of myocardial ischemia than either drug alone.

Benzothiazepines

Benzothiazepines act at the L-type channel passing directly through the poor and blocking calcium entry like verapamil (see [Figure 19.11](#)).⁹³ The benzothiazepine diltiazem may have two additional effects: It may act on

the sodium-potassium pump, decreasing the amount of intracellular sodium available for exchange with extracellular calcium, and it may inhibit calcium-calmodulin binding.

Diltiazem

Diltiazem, like verapamil, blocks predominantly the calcium channels of the atrioventricular node and is therefore a first-line medication for the treatment of supraventricular tachydysrhythmias (see [Chapter 21](#)). It may also be used for the chronic control of essential hypertension. The effects of diltiazem on the sinoatrial and atrioventricular nodes and its vasodilating properties appear to be intermediate between those of verapamil and the dihydropyridines. Diltiazem exerts minimal cardiodepressant effects and is unlikely to interact with β -adrenergic blocking drugs to decrease myocardial contractility.⁵⁵

Clinical Uses

The clinical use and drug interactions for diltiazem are similar to those of verapamil. Diltiazem is available as an oral capsule and can also be administered IV, especially for the management of angina pectoris. The recommended IV dose is 0.25 to 0.35 mg/kg over 2 minutes and is repeated in 15 minutes, if needed. After the initial IV dose, diltiazem can be given by continuous infusion of about 10 mg per hour for up to 24 hours.

Pharmacokinetics

Oral absorption of diltiazem is excellent with an onset of action in 15 minutes and a peak effect in about 30 minutes (see [Table 19.7](#)). The drug is 70% to 80% bound to proteins and is excreted as inactive metabolites principally in bile (about 60%) and, to a lesser extent, in urine (about 35%). Active metabolites of diltiazem include desacetyl diltiazem and desmethyl diltiazem. The elimination half-time for the parent drug is 4 to 6 hours and about 20 hours for its metabolites. As with verapamil, liver disease may necessitate a decrease in the dosage of diltiazem.

Drug Interactions

The known pharmacologic effects of calcium channel blockers on cardiac, skeletal, and vascular smooth muscle, as well as on the conduction velocity of cardiac impulses, make drug interactions possible.⁷⁷ Verapamil and diltiazem have depressant effects on the generation of cardiac action potentials at the sinoatrial node and slow the movement of cardiac impulses through the atrioventricular node. Therefore, patients with preexisting cardiac conduction abnormalities may experience greater degrees of atrioventricular heart block with concurrent administration of β -blockers or digoxin. Myocardial depression and peripheral vasodilation produced by volatile anesthetics could be exaggerated by similar actions of calcium channel blockers. The vasodilatory effects of calcium channel blockers could result in exaggerated systemic hypotension should these drugs be administered to hypovolemic patients.

The likelihood of adverse circulatory changes due to interactions between calcium channel blockers and anesthetic drugs would seem to be greater in patients with preexisting atrioventricular heart block or left ventricular dysfunction. Nevertheless, treatment with calcium channel blockers can be continued until the time of surgery without risk of significant drug interactions, especially with respect to conduction of cardiac impulses.⁹⁴ Toxicity reflecting an overdose of calcium channel blockers may be partially reversed with IV administration of calcium or dopamine.

Anesthetic Drugs

Calcium channel blockers as a class are vasodilators and myocardial depressants. In fact, the negative inotropic effects, depressant effects on sinoatrial node function, and peripheral vasodilating effects of these drugs and those of volatile anesthetics are similar, and there is evidence that volatile anesthetics inhibit calcium channels independent of protein kinase C.^{95,96} For these reasons, calcium channel blockers must be administered with caution to patients with impaired left ventricular function or hypovolemia. Patients treated with a combination of β -adrenergic blockers and nifedipine tolerate high-dose fentanyl anesthesia and do not show evidence of additive depression of cardiac function when verapamil is infused.⁹⁷ Conversely, in anesthetized patients with preexisting left ventricular dysfunction, administration of verapamil is associated

with myocardial depression and decreased cardiac output.⁹⁸ Furthermore, IV administration of verapamil or diltiazem during open chest surgery in patients with depressed ventricular function and anesthetized with a volatile anesthetic may be associated with further decreases in ventricular function.⁹⁶ The cardiac protection that has been observed in the presence of volatile anesthetics may be related to protection from calcium overload associated with ischemia and reperfusion.⁹⁹

Treatment of cardiac dysrhythmias with calcium channel blockers in anesthetized patients produces only transient decreases in systemic blood pressure and infrequent prolongation of the P-R interval on the electrocardiogram. Because of the tendency to produce atrioventricular heart block, verapamil should be used cautiously in patients being treated with digitalis or β -adrenergic blocking drugs. Nevertheless, in patients with preoperative evidence of cardiac conduction abnormalities, the chronic combined administration of calcium channel blockers and β -adrenergic antagonists is not associated with cardiac conduction abnormalities in the perioperative period (**Table 19.8**).⁹⁴ β -Adrenergic agonists increase the number of functioning slow calcium channels in myocardial cell membranes through a cAMP mechanism and readily counter the effects of calcium channel blockers. Nevertheless, there is no evidence that patients being treated chronically with calcium channel blockers are at increased risk for anesthesia.

TABLE 19.8

Effect of chronic antianginal therapy on perioperative heart rate (beats per minute) and P-R interval (milliseconds)*

	Before induction	After induction	10 minutes after cardiopulmonary bypass
Control			
Heart rate	72	71	87
P-R interval	160	156	164
Calcium channel blockers			
Heart rate	69	70	86
P-R interval	168	169	175
β-Adrenergic antagonists			
Heart rate	59	65	78
P-R interval	168	171	183
Nifedipine plus β-adrenergic antagonists			
Heart rate	67	69	86

Neuromuscular Blocking Drugs

Calcium channel blockers alone do not produce a skeletal muscle relaxant effect (**Figure 19.12**).¹⁰⁰ Conversely, these drugs do potentiate the effects of depolarizing and nondepolarizing neuromuscular blocking drugs (see **Figure 19.12**).^{100,101} This potentiation resembles that produced by mycin antibiotics in the presence of neuromuscular blocking drugs. The local anesthetic effects of verapamil and diltiazem, reflecting inhibition of sodium ion flux via fast sodium channels, may also contribute to the potentiation of neuromuscular blocking drugs. Observations of skeletal muscle weakness after administration of verapamil to a patient with muscular dystrophy are inconsistent with diminished release of neurotransmitter.¹⁰² Therefore, the neuromuscular effects of verapamil may be more likely to manifest in patients with a compromised margin of safety of neuromuscular transmission. There is no evidence that calcium channel blockers inhibit physical function in frail elderly patients.¹⁰³

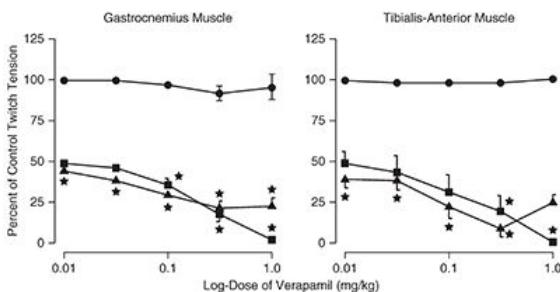

FIGURE 19.12 Infusion of verapamil in the absence of neuromuscular blocking drugs (solid circles) does not alter twitch height response (twitch tension) of indirectly stimulated rabbit skeletal muscle. When twitch tension is decreased to about 50% of control by the continuous infusion of pancuronium (solid squares) or succinylcholine (solid triangles), the addition of verapamil further decreases twitch tension. (The data points marked with “asterisk” represent a statistically significant decrease in muscle twitch tension as compared to verapamil alone. The errors represent the mean \pm standard error.) Potassium-Containing Solutions

Calcium channel blockers slow the inward movement of potassium ions. For this reason, hyperkalemia in patients being treated with verapamil may occur after much smaller amounts of exogenous potassium infusion as associated with the use of potassium chloride to treat hypokalemia or administration of stored whole blood.¹⁰⁴ In animals, however, pretreatment with verapamil does not alter the increases in plasma potassium concentrations that follow the administration of succinylcholine.¹⁰⁵

Platelet Function

Calcium channel blockers may interfere with calcium-mediated platelet function. In particular, there is an interaction between clopidogrel and calcium channel blockers related to their common metabolism by P450 enzyme 3A4. The conversion of the prodrug clopidogrel is reduced in the presence of calcium channel blockers, resulting in a fourfold increase in the risk of a composite outcome that included death related to cardiac causes, nonfatal myocardial infarction, stent thrombosis, and need for revascularization.¹⁰⁶

Digoxin

Calcium channel blockers increase the plasma concentration of digoxin, by decreasing its plasma clearance.¹⁰⁷

H₂ Antagonists

Cimetidine and ranitidine by altering hepatic enzyme activity and/or hepatic blood flow may increase the plasma concentrations of calcium channel blockers.

Cytoprotection

Drug-induced calcium channel blockade may provide cytoprotection against ischemic reperfusion injury.^{108,109} By decreasing calcium ion entry into cells and the conversion of xanthine dehydrogenase to xanthine oxidase (dependent on the calcium-calmodulin complex), calcium channel blockers may limit the accumulation of oxygen free radicals. Calcium channel blockers may attenuate renal injury from nephrotoxic drugs such as cisplatin and iodinated radiographic contrast media. The vasodilator effects of calcium channel blockers and resultant control of systemic hypertension may result in increases in renal blood flow and glomerular filtration rate, thus favoring natriuresis.

Vasodilators*

Updated by: Thomas J. Krall • James Ramsay

Introduction

This chapter addresses the anesthetic implications of elevated blood pressure and the medications used to reduce systemic and pulmonary vascular pressures. As described in [Chapter 14](#), control of vascular tone in the peripheral and pulmonary circulations is a complex interplay of local metabolism, endothelial function, and regulation by the sympathetic nervous and endocrine systems.

Systemic Hypertension

The threshold for diagnosing hypertension was lowered in the 2017 American College of Cardiology/American Heart Association guidelines so that systemic hypertension is currently defined as a blood pressure of 130/80 to 139/89 mm Hg (stage 1) or greater than or equal to 140/90 mm Hg (stage 2).¹ This will raise the prevalence of hypertension in American adults from 30% to 45%, including 75% of those over 65 years of age.^{1,2} By far, the most common type of hypertension is “essential” or “primary” for which there is no clear unifying pathophysiology despite decades of research. What is clear, however, is that hypertension is a major risk factor for cardiovascular disease including atherosclerosis, heart failure, stroke, renal disease, and overall decreased survival.^{3,4} “Secondary” hypertension is much less common and can be due to a variety of causes ([Table 20.1](#)). Antihypertensive medications are used to control both primary and secondary hypertension. If more than three medications are required for consistent control, a diagnosis of secondary hypertension should be strongly suspected.

TABLE 20.1	
Systemic hypertension	
Essential (primary)	
Secondary	
Obstructive sleep apnea	
Renal disease	
Renal parenchymal disease	
Renal artery stenosis	
Endocrine disease	
Pheochromocytoma	
Primary aldosteronism	
Cushing disease	
Hyperparathyroidism	
Hyper- and hypothyroidism	
Medications	
Oral contraceptives	
Chronic NSAID use	
Antidepressants	
Alcohol	
Aortic coarctation	

Abbreviation: NSAID, nonsteroidal antiinflammatory drug.

Management of essential hypertension includes alteration in lifestyle and diet (smoking cessation, weight reduction, increased physical activity, salt restriction) and use of medications. Most commonly, a thiazide diuretic is the initial therapy as increased sodium excretion results in decreased blood pressure; these medications are inexpensive and require infrequent dosing. However, their chronic use requires potassium monitoring and supplementation.

Alternatively, monotherapy with a dihydropyridine calcium channel antagonist, such as amlodipine, or an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB) may be used.⁵ Calcium channel blockade offers a direct vasodilator effect without the requirement of salt restriction and is associated with relatively few side effects. Use of an ACE inhibitor or ARB targets the renin-angiotensin system, a major contributor to blood pressure control. Decreased renal perfusion and increased sympathetic nervous system activity cause the release of renin, which then acts on “renin substrate” or angiotensin I at various sites in the body to release angiotensin II, a potent vasoconstrictor and promoter of sodium and water retention.⁶ Inhibition of angiotensin II production (with ACE inhibitor) or blockade of its receptor (with ARB) causes a reliable and potent antihypertensive effect, with very few side effects. In addition, in patients with most types of cardiac disease, these drugs have a well-known survival benefit. Although β -adrenergic blockade is also an option, they may be associated with inferior stroke protection (when compared to calcium channel blockade, ACE inhibitor, and ARB) in patients older than the age of 60 years⁷ and have a greater potential for systemic side effects.

Specific Antihypertensive Drugs and Anesthesia

Hypertensive patients are likely to be receiving one or more of thiazide diuretics, calcium channel blockers, ACE inhibitors/ARB medications, and β -adrenergic blockers. Less commonly, patients may be receiving other drugs, which antagonize the sympathetic nervous system (the centrally acting α_2 agonist clonidine, peripheral α_1 antagonists such as prazosin, α/β antagonists such as labetalol or carvedilol, nitrates, or hydralazine) (**Table 20.2**). Although many other drugs have been used in the past, they will not be discussed here. In general, antihypertensive therapy should be continued until the time of surgery, as managing poorly controlled hypertension is likely to be more difficult than managing the well-controlled hypertensive patient. Specific recommendations for withholding ACE inhibitors or angiotensin receptor blockers are discussed later. Severe or poorly controlled hypertension is a relatively common cause for postponement of surgery,⁸ although evidence supporting this practice comes from small studies mostly more than 20 years old. Although there is an association between uncontrolled blood pressure and adverse cardiovascular events, it remains unclear if postponing surgery for blood pressure control improves outcomes.⁹ Specific drugs and implications for perioperative management are discussed in the following text.

TABLE 20.2

Intravenous antihypertensive drugs commonly used in the perioperative setting

Drug	Mechanism	Intravenous dosing		Onset (minutes)	Duration plasma half-life clinical effect ^a
		Bolus	Infusion		
Metoprolol	β_1 Blocker	1-5 mg	N/A	1-5	Half-life: 3-7 hours Clinical: 1-4 hours
Labetalol	α_1 , β_1 , β_2 Blocker	5-20 mg	0.5-2 mg per minute	1-5	Half-life: 6 hours Clinical: 1-4 hours
Esmolol	β_1 Blocker	500-1,000 μ g/kg	50-300 μ g/kg per minute	1-2	Half-life: 9 minutes
Nicardipine	Dihydropyridine Ca blocker	100-400 μ g	5-15 mg per hour	2-10	Half-life: 2-4 hours Clinical: 30-60 minutes
Clevidipine (infusion only)	Dihydropyridine Ca blocker	N/A	1-16 mg per hour ^b	2-4	Half-life: 1 minute Clinical: 5-15 minutes
Hydralazine	Arteriolar dilator	5-20 mg	N/A	5-20	Half-life: 2-8 hours Clinical: 1-8 hours
Fenoldopam	Dopamine type 1 agonist	N/A	0.05-1.6 μ g/kg per minute	5-10	Half-life: 5 minutes Clinical: 30-60 minutes
Nitroprusside	NO donor	N/A	0.25-4 μ g/kg per minute	1-2	Half-life: <10 minutes Clinical: 1-10 minutes

Nitroglycerin	NO donor	20-400 µg	10-400 µg per minute	1-2	Half-life: 1-3 minutes Clinical: 5-10 minutes
---------------	----------	-----------	----------------------	-----	--

Abbreviations: Ca, calcium; NO, nitric oxide.

^aClinical effect commonly seen after bolus dose or stopping infusion.

^bUsual clinical range 4-6 mg per hour; see manufacturer's dosing algorithms.

β-Adrenergic Blockers

As mentioned earlier, β blockers are less commonly used as first-line agents in hypertension as other agents may have a better safety profile for this indication in those older than the age of 60 years. In addition, β blockers have a potential side effect profile, which limits their use in many patients including fatigue, depression, and impotence. However, β blockers are indicated for long-term treatment of patients with coronary artery disease and heart failure, in addition to their antihypertensive action.

Mechanism of Action

β Blockers can be classified according to whether they exhibit β₁ selective versus nonselective properties and whether they possess intrinsic sympathomimetic activity. A β blocker with selective properties binds primarily to β₁ (cardiac) receptors, whereas a β blocker with nonselective properties has equal affinity for β₁ and β₂ (vascular and bronchial smooth muscle, metabolic) receptors. The β blockers with intrinsic sympathomimetic activity (pindolol, acebutolol) tend to produce less bradycardia and thus are less likely to unmask left ventricular dysfunction. These drugs are also less likely to produce vasospasm and thus to exacerbate symptoms of peripheral vascular disease. The antihypertensive effect of β blockers and other vasodilators may be attenuated by nonsteroidal antiinflammatory drugs.¹⁰

In contrast to nonselective β blockers such as propranolol, cardioselective β₁ blockers (acebutolol, atenolol, metoprolol, bisoprolol) administered in low to moderate doses are unlikely to produce bronchospasm, decrease peripheral blood flow, or mask hypoglycemia. For these reasons, they are the preferred drugs for patients with pulmonary disease, insulin-dependent diabetes mellitus, or symptomatic peripheral vascular disease. The nonselective agent carvedilol, which also has α₁ blocking action, has been shown to improve survival in patients with systolic heart failure.¹¹⁻¹³ The cardioselective drugs metoprolol and bisoprolol have also been shown to provide a survival benefit in this population.¹⁴ A randomized trial of carvedilol versus metoprolol in heart failure suggested a mortality benefit for carvedilol, although the study was critiqued for potentially underdosing the metoprolol arm.¹⁵ Labetalol is another nonselective β blocker that also has significant α₁ blocking action. The presence of α-adrenergic blocking properties results in less bradycardia and negative inotropic effects compared with “pure” β blockers. These α properties, however, may result in orthostatic hypotension. The incidence of bronchospasm is similar to that seen with atenolol or metoprolol. Intravenous (IV) labetalol is used in hypertensive emergencies and is particularly useful in managing patients with type B aortic dissections, facilitating conversion from IV to oral medications.

Side Effects

Treatment of hypertension with β blockers involves certain risks, including bradycardia and heart block, congestive heart failure, bronchospasm, claudication, masking of hypoglycemia, sedation, and impotence, and when abruptly discontinued may precipitate angina pectoris or even myocardial infarction. Patients with any degree of congestive heart failure cannot generally tolerate more than modest doses of β blockers; yet, it is clear that when dosage is slowly increased and the drugs are given chronically, the antiadrenergic effect provides a significant benefit in chronic systolic heart failure.¹¹⁻¹⁵ Nonselective β blockers should likely be avoided in symptomatic asthma, although recent data suggests that selective β blockers are likely safe in asthma¹⁶ and chronic obstructive pulmonary disease^{17,18} and should be continued during chronic obstructive pulmonary disease exacerbations.¹⁹ β Blockers potentially increase the risk of serious hypoglycemia in diabetic patients because they blunt autonomic nervous system responses that would warn of hypoglycemia.

Nevertheless, the incidence of hypoglycemia has not been shown to be increased in diabetic patients being treated with β -adrenergic antagonists to control hypertension.²⁰

Intravenous β Blockers

The IV β blockers available in North America include metoprolol, propranolol, labetalol (an α_1 /nonselective β blocker), and esmolol, which is a very short-acting cardioselective agent, inactivated by plasma esterases. Perioperative β blockade can be used to continue preoperative therapy, but due to extensive first-pass activity for oral agents, the conversion to IV dosing is somewhat unpredictable. In the case of labetalol, its $\beta:\alpha$ ratio is 3:1 when taken orally and 7:1 when given IV.²¹

α_1 Receptor Blockers

Prazosin, terazosin, and doxazocin are oral, selective postsynaptic α_1 -adrenergic receptor antagonists resulting in vasodilating effects on both arterial and venous vasculature. Absence of presynaptic α_2 receptor antagonism leaves intact the normal inhibitory effect on norepinephrine release from nerve endings. These drugs are unlikely to elicit reflex increases in cardiac output and renin release. In contrast, oral phenoxybenzamine and IV phentolamine are nonselective α blockers, which also block presynaptic α_2 receptors. Both of these drugs are used almost exclusively in the management of pheochromocytoma and are not be discussed further. Urapidil is a potent α_1 antagonist and centrally acting serotonin antagonist, which is available outside the United States in both oral and IV formulations.

In addition to treating essential hypertension, prazosin may be of value for decreasing afterload in patients with congestive heart failure. Prazosin may also be a useful drug for the preoperative preparation of patients with pheochromocytoma. This drug has been used to relieve the vasospasm of Raynaud phenomenon. Another useful indication for prazosin in the treatment of essential hypertension is the presence of benign prostatic hypertrophy in older males, as this drug decreases the size of the gland.²²

Pharmacokinetics

Prazosin is nearly completely metabolized, and less than 60% bioavailability after oral administration suggests the occurrence of substantial first-pass hepatic metabolism. The elimination half-time is about 3 hours and is prolonged by congestive heart failure but not renal dysfunction. The fact that this drug is metabolized in the liver permits its use in patients with renal failure without altering the dose.

Cardiovascular Effects

Prazosin decreases systemic vascular resistance without causing reflex-induced tachycardia or increases in renin activity as occurs during treatment with hydralazine or minoxidil. Failure to alter plasma renin activity reflects continued activity of α_2 receptors that normally inhibit the release of renin. Vascular tone in both resistance and capacitance vessels is decreased, resulting in decreased venous return and cardiac output.

Side Effects

The side effects of prazosin include vertigo, fluid retention, and orthostatic hypotension. Nonsteroidal antiinflammatory drugs may interfere with the antihypertensive effect of prazosin. Dryness of the mouth, nasal congestion, nightmares, urinary frequency, lethargy, and sexual dysfunction may accompany treatment with this drug. Hypotension during epidural anesthesia may be exaggerated in the presence of prazosin, reflecting drug-induced α_1 blockade that prevents compensatory vasoconstriction in the unblocked portions of the body.²³ The resulting decrease in systemic vascular resistance results in hypotension that may not be responsive to the usual clinical doses of an α_1 -adrenergic agonist such as phenylephrine. In this situation, administration of epinephrine may be necessary to increase systemic vascular resistance and systemic blood pressure. Conceivably, the combination of prazosin and a β blocker could result in particularly refractory hypotension during regional anesthesia due to potentially blunted responses to β_1 as well as α_1 agonists.

α_2 Agonists

Clonidine is a centrally acting selective partial α_2 -adrenergic agonist (220:1 α_2 to α_1 activity) that acts as an antihypertensive drug by virtue of its ability to decrease sympathetic output from the central nervous system (CNS). This drug has proved to be particularly effective in the treatment of patients with severe hypertension or renin-dependent disease. The usual daily adult dose is 0.2 to 0.3 mg orally. The availability of a transdermal clonidine patch designed for weekly administration is a more convenient formulation but is not useful in the acute setting as the onset is slow (hours). Another drug of the same class is IV dexmedetomidine, a much more α_2 -selective drug that is approved for sedation rather than hypertension, although it does have a blood pressure–lowering action. Dexmedetomidine is discussed in [Chapter 5](#).

Mechanism of Action

α_2 -Adrenergic agonists produce clinical effects by binding to α_2 receptors of which there are three subtypes (α_{2A} , α_{2B} , α_{2C}) that are distributed ubiquitously, and each may be uniquely responsible for some, but not all, of the actions of α_2 agonists ([Figure 20.1](#)).²⁴ α_{2A} Receptors mediate sedation, analgesia, and sympatholysis, whereas α_{2B} receptors mediate vasoconstriction and possibly antishivering effects. The startle response may reflect activation of α_{2C} receptors.

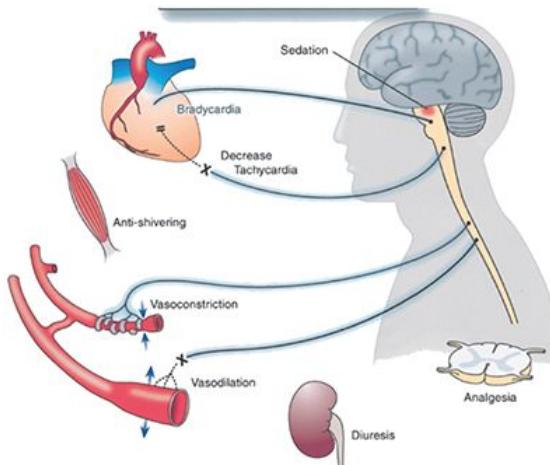

FIGURE 20.1 Schematic depiction of effects that are mediated by α_2 -adrenergic receptors. The site for sedation is the locus ceruleus of the brainstem, whereas the principal site of analgesia is most likely the spinal cord. In the heart, the dominant effect of α_2 stimulation is attenuation of tachycardia through block of the cardioaccelerator nerves and bradycardia through vagal stimulation. In the peripheral vasculature, there are vasodilatory effects reflecting sympatholysis and vasoconstriction mediated by α_2 receptors in smooth muscle cells. *Reprinted with permission from Kamibayashi T, Maze M. Clinical uses of alpha2-adrenergic agonists. Anesthesiology. 2000;93(5):1345-1349. Copyright © 2000 American Society of Anesthesiologists, Inc.*

Clonidine stimulates α_2 -adrenergic inhibitory neurons in the medullary vasomotor center. As a result, there is a decrease in sympathetic nervous system outflow from CNS to peripheral tissues. Decreased sympathetic nervous system activity is manifested as peripheral vasodilation and decreases in systemic blood pressure, heart rate, and cardiac output. The ability of clonidine to modify the function of potassium channels in the CNS (cell membranes become hyperpolarized) may be the mechanism for profound decreases in anesthetic requirements produced by clonidine and other even more selective α_2 -adrenergic agonists such as dexmedetomidine. α_2 Receptors on blood vessels mediate vasoconstriction and inhibit release of norepinephrine on peripheral sympathetic nervous system nerve endings. Neuraxial placement of clonidine inhibits spinal substance P release and nociceptive neuron firing produced by noxious stimulation.

Pharmacokinetics

Clonidine is rapidly absorbed after oral administration and reaches peak plasma concentrations within 60 to 90 minutes. The elimination half-time of clonidine is between 9 and 12 hours, with approximately 50% metabolized in the liver, whereas the rest is excreted unchanged in urine. The duration of hypotensive effect after a single oral dose is about 8 hours. The transdermal route requires about 48 hours to produce steady-state therapeutic plasma concentrations.

Cardiovascular Effects

The decrease in systolic blood pressure produced by clonidine is more prominent than the decrease in diastolic blood pressure. In patients treated chronically, systemic vascular resistance is little affected, and cardiac output, which is initially decreased, returns toward predrug levels. Homeostatic cardiovascular reflexes are maintained, thus avoiding the problems of orthostatic hypotension or hypotension during exercise. The ability of clonidine to decrease systemic blood pressure without paralysis of compensatory homeostatic reflexes is highly desirable. Renal blood flow and glomerular filtration rate are maintained in the presence of clonidine therapy.

Side Effects

The most common side effects produced by clonidine are sedation and xerostomia. Consistent with sedation and, perhaps more specifically, an agonist effect on postsynaptic α_2 receptors in the CNS are nearly 50% decreases in anesthetic requirements for inhaled anesthetics (minimum alveolar concentration) and injected drugs in patients pretreated with clonidine administered in the preanesthetic medication.²⁵ Patients pretreated with clonidine often manifest lower plasma concentrations of catecholamines in response to surgical stimulation and occasionally require treatment of bradycardia. As with other antihypertensive drugs, retention of sodium and water often occurs such that combination of clonidine with a diuretic is often necessary. Conversely, a diuretic effect during general anesthesia has been described after administration of oral clonidine, 2.5 to 5.0 $\mu\text{g}/\text{kg}$ as preanesthetic medication.²⁶ Skin rashes are frequent, impotence occurs occasionally, and orthostatic hypotension is rare. Despite the fact that clonidine prevents opioid-induced skeletal muscle rigidity and produces skeletal muscle flaccidity, α_2 agonists have no effect on the responses evoked by neuromuscular blocking drugs.²⁷

Rebound Hypertension

Abrupt discontinuation of clonidine therapy can result in rebound hypertension as soon as 8 hours and as late as 36 hours after the last dose.²⁸ Rebound hypertension is most likely to occur in patients who were receiving greater than 1.2 mg of clonidine daily. The increase in systemic blood pressure may be associated with a greater than 100% increase in circulating concentrations of catecholamines and intense peripheral vasoconstriction. Symptoms of nervousness, diaphoresis, headache, abdominal pain, and tachycardia often precede the actual increase in systemic blood pressure. β -Adrenergic blockade may exaggerate the magnitude of rebound hypertension by blocking the β_2 vasodilating effects of catecholamines and leaving unopposed their α vasoconstricting actions. Likewise, tricyclic antidepressant therapy may exaggerate rebound hypertension associated with abrupt discontinuation of clonidine therapy.²⁹ Tricyclic antidepressants can potentiate the pressor effects of norepinephrine.

Rebound hypertension can usually be controlled by reinstituting clonidine therapy or by administering a vasodilating drug such as hydralazine or nitroprusside. β -Adrenergic blocking drugs are useful but probably should be administered only in the presence of α -adrenergic blockade to avoid unopposed α vasoconstricting actions. In this regard, labetalol with α and β antagonist effects may be useful in the management of patients experiencing rebound hypertension. If oral clonidine therapy is interrupted because of surgery, use of transdermal clonidine provides a sustained therapeutic level of drug for as long as 7 days.³⁰ For a planned withdrawal, the clonidine dosage should be gradually decreased over 7 days or longer.

Rebound hypertension after abrupt discontinuation of chronic treatment with antihypertensive drugs is not unique to clonidine.²⁸ For example, abrupt discontinuation of β blocker therapy has been associated with

clinical evidence of excessive sympathetic nervous system activity. Antihypertensive drugs that act independently of central and peripheral sympathetic nervous system mechanisms (direct vasodilators, ACE inhibitors) do not seem to be associated with rebound hypertension after sudden discontinuation of therapy.

Other Clinical Uses

α -Adrenergic agonists (clonidine and dexmedetomidine) induce sedation, decrease anesthetic requirements, and improve perioperative hemodynamic (attenuate blood pressure and heart rate responses to surgical stimulation) and sympathoadrenal stability.²⁴ Although a number of small studies have demonstrated these benefits, the Perioperative Ischemic Evaluation 2 trial (2014) failed to demonstrate a cardioprotective effect when used perioperatively.³¹ The trial randomized patients in a 2-by-2 design to test the effect of low-dose clonidine (0.2 mg per day) versus placebo and low-dose aspirin (100 mg daily) versus placebo. The clonidine was started preoperative and continued for 72 hours after surgery. They found no change in the primary composite outcome of death and nonfatal myocardial infarction, but they found an increase in hypotension and nonfatal cardiac arrest in the clonidine group. Both clonidine and dexmedetomidine have been used to help reduce the sympathetic nervous system hyperactivity associated with alcohol and opioid withdrawal. α_2 Receptors within the spinal cord modulate pain pathways resulting in analgesia, and intrathecal clonidine has been studied as an effective adjuvant to neuraxial blockade both enhancing and prolonging sensory and motor block.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

The ACE inhibitors represented a major advance in the treatment of all forms of hypertension because of their potency and minimal side effects, resulting in improved patient compliance.³² The ARBs provide a similar mechanism of action with a slightly better side effect profile. These drugs are free of many of the CNS side effects associated with other antihypertensive drugs, including depression, insomnia, and sexual dysfunction. Other adverse effects, such as congestive heart failure, bronchospasm, bradycardia, and exacerbation of peripheral vascular disease, are not seen with ACE inhibitors/ARBs either. Similarly, metabolic changes induced by diuretic therapy, such as hypokalemia, hyponatremia, and hyperglycemia, are not observed. Rebound hypertension, as seen with clonidine, has also not been observed with ACE inhibitors/ARBs.

The ACE inhibitors are most effective in treating systemic hypertension secondary to increased renin production. These drugs have been established as first-line therapy in patients with systemic hypertension, congestive heart failure, and mitral regurgitation. The ACE inhibitors are more effective and possibly safer than other antihypertensive drugs in the treatment of hypertension in diabetics.³³ There is also evidence that ACE inhibitors delay the progression of diabetic renal disease.³⁴ As mentioned earlier, ACE inhibitors have been shown to provide a survival benefit in patients who have suffered a myocardial infarction and in patients with heart failure.³⁵

Mechanism of Action

Angiotensin II normally binds to a specific cell membrane receptor (AT_1) that ultimately leads to increased release of calcium from sarcoplasmic reticulum to produce vasoconstriction. Decreased generation of angiotensin II due to the administration of an ACE inhibitor results in reduced vasoconstrictive effects. In addition, plasma concentrations of aldosterone are decreased resulting in less sodium and water retention. The ACE inhibitors also block the breakdown of bradykinin, an endogenous vasodilator substance, which contributes to the antihypertensive effects of these drugs. The ACE inhibitors, like statins, reduce activation of low-density lipoprotein (LDL) receptors and thus decrease plasma concentrations of LDL cholesterol. If the concentration of LDL cholesterol is already sufficiently low, ACE inhibitors may no longer be effective in reducing the rate of cardiovascular events.³⁶

The ACE inhibitors can be classified according to the structural element that interacts with the zinc ion of the enzyme as well as the form in which the drug is administered (prodrug or active form). Administration of ACE inhibitors as prodrugs increases oral bioavailability prior to their hepatic metabolism to the active

drug. Enalapril is the prodrug of the active ACE inhibitor, enalaprilat, and conversion may be altered in patients with hepatic dysfunction. Captopril and lisinopril are not prodrugs. The major difference among clinically used ACE inhibitors is in duration of action.³⁷ The ARBs produce antihypertensive effects by blocking the vasoconstrictive actions of angiotensin II without affecting ACE activity.

Side Effects

Cough, upper respiratory congestion, rhinorrhea, and allergic-like symptoms seem to be the most common side effects of ACE inhibitors.³⁸ It is speculated that these airway responses reflect potentiation of the effects of kinins due to drug-induced inhibition of peptidyl-dipeptidase activity and subsequent breakdown of bradykinin. If respiratory distress develops, prompt injection of epinephrine (0.3-0.5 mL of a 1:1,000 dilution subcutaneously) is advised. Angioedema is a potentially life-threatening complication of treatment with ACE inhibitors. Decreases in glomerular filtration rate may occur in patients treated with ACE inhibitors. For this reason, ACE inhibitors are used with caution in patients with preexisting renal dysfunction and are not recommended for patients with renal artery stenosis. Hyperkalemia is possible due to decreased production of aldosterone. The risk of hyperkalemia is greatest in patients with recognized risk factors (congestive heart failure with renal insufficiency).³⁹ Measurement of plasma concentrations of potassium may be indicated in these patients.

The ARBs have similar side effect profile but do not inhibit breakdown of bradykinin, one of the benefits of ACE inhibitors and which may be a reason that ACE inhibitors are generally preferred as first-line therapy. A major difference between ACE inhibitors and ARBs is that ARBs do not cause cough, one of the reasons ACE inhibitors may not be tolerated (more than 10% of patients).

Preoperative Management

Adverse circulatory effects during anesthesia are recognized in patients chronically treated with ACE inhibitors/ARBs leading some to recommend that these drugs be discontinued 12 to 24 hours before anesthesia and surgery.⁴⁰ A retrospective study of more than 75,000 patients (9,900 taking ACE inhibitors) suggested that although continuation of these drugs until the time of surgery is associated with more intraoperative hypotension, there were no adverse consequences.⁴¹ A 2018 meta-analysis that included ACE inhibitors and ARBs also drew similar conclusions: Withholding ACE inhibitors/ARBs prior to surgery resulted in less intraoperative hypotension, but no change in mortality or major adverse cardiac events.⁴² However, a large data set of noncardiac surgery patients (Vascular Events in Non-cardiac Surgery Patients Cohort Evaluation Study [VISION]—a prospective study of 16,000 patients in eight countries) showed an association with same-day ACE inhibitors/ARB administration and increased mortality and major adverse events.⁴³ Currently, the 2014 American College of Cardiology/American Heart Association guidelines for perioperative management suggests it is “reasonable” to continue these drugs until the time of surgery, although many anesthesia practice groups hold them to avoid the hypotensive effects.⁴⁴ Exaggerated hypotension attributed to continued ACE inhibitor therapy has been responsive to crystalloid fluid infusion and/or administration of a catecholamine or vasopressin infusion. The ACE inhibitors may increase insulin sensitivity and hypoglycemia, which is a concern when these drugs are administered to patients with diabetes mellitus. Nevertheless, there is no evidence that the incidence of hypoglycemia is greater in diabetics being treated with ACE inhibitors for control of hypertension.²⁰

Specific Agents

Perioperative implications of different ACE inhibitors are similar; it is not clear that any one agent has more or less effect on perioperative blood pressure control. The only IV ACE inhibitor is enalaprilat; however, there is little published information to guide its use in this setting. It is not used as an infusion (ie, dosing recommendations are for intermittent injection) and has a less predictable onset and duration of action as well as antihypertensive action than short-acting direct vasodilators. Oral agents commonly seen are captopril, enalapril, lisinopril, and ramipril with the latter agents having a longer duration of action than captopril.

Common ARBs include losartan, irbesartan, candesartan, olmesartan, and valsartan, all of which have a relatively long duration of action (one or twice daily dosing). There is no IV agent available. These agents have similar antihypertensive actions and benefits in patients with heart failure as ACE inhibitors, although the evidence is somewhat less robust. A new combination of a neprilysin inhibitor with valsartan (sacubitril/valsartan) showed lower rates of death or hospitalization for heart failure in patients with ejection fraction less than 40%.⁴⁵ Neprilysin is a circulating enzyme that metabolizes vasoactive peptides, including bradykinin, enkephalins, substance P, and the natriuretic peptides. The increase in circulating natriuretic peptide levels may explain the clinical benefit in heart failure.⁴⁶ This medication will likely see increased utilization of the coming years for heart failure patients.

Calcium Channel Blocking Drugs

Calcium channel blocking drugs used as antihypertensives inhibit calcium influx through the voltage-sensitive L-type calcium channels in vascular smooth muscle. They are arterial specific, with little effect on venous circulation. The calcium channel drugs are broadly categorized into drugs of the dihydropyridine class (nifedipine, amlodipine, nicardipine, clevidipine) and those of the nondihydropyridine class (verapamil and diltiazem). Verapamil and diltiazem are less potent vasodilators and both have negative inotropic and chronotropic activity limiting their use in patients with cardiac disease. In current practice, these drugs are more used for their antiarrhythmic action than antihypertensive action (see [Chapter 21](#)).

The dihydropyridines are potent vasodilators and are relatively safe to use in patients with heart failure and cardiac conduction defects, with the exception of large doses of short-acting nifedipine, which may acutely lower the blood pressure and cause myocardial ischemia. The use of calcium channel blockers does not require concurrent sodium restriction, which makes these drugs unique antihypertensive drugs and perhaps the drugs of choice for patients who find sodium restriction unacceptable. The once-daily dosing of amlodipine is of particular appeal.

The parenteral dihydropyridine calcium channel blockers nicardipine and clevidipine are available as continuous IV infusions. They both offer rapid titration and short half-lives. The use of IV nicardipine in the perioperative setting is well studied, and it also has been used in the treatment of hypertensive emergencies.⁴⁷ Nicardipine undergoes hepatic metabolism and therefore showed elevated plasma concentrations and prolonged half-life in hepatic impairment. Clevidipine offers an advantage of being metabolized by plasma esterases to inactive metabolites. Its dosing does not require adjustment in the setting of hepatic or renal dysfunction. Its rapid titration, end-organ independent metabolism, and good safety profile has led to increased study of clevidipine in the critical care and perioperative environment, where it performs comparably to nicardipine.^{48–52} In a randomized trial of clevidipine compared to nitroglycerin, sodium nitroprusside (SNP), and nicardipine in perioperative cardiac surgery, patients spent statistically significantly less time outside of a prespecified blood pressure range with clevidipine than with SNP or nitroglycerin. The performance of clevidipine was equal to nicardipine on that metric. There was no significant difference in any adverse event rates for the four drugs.⁵¹ Clevidipine appears to be a potent and safe alternative to existing parenteral vasodilators.

Clevidipine and nicardipine share adverse effect profiles with the other dihydropyridine calcium channel blockers, including potential reflex tachycardia and negative inotropy. Potent vasodilators are known to inhibit hypoxic pulmonary vasoconstriction, and the parenteral calcium channel blockers are no exception.^{53,54} There are limited case reports of hypoxemia in the setting of nicardipine or clevidipine administration.^{55,56} This phenomenon is not completely understood but appears to involve inhibition of hypoxic pulmonary vasoconstriction in the setting of existing lung pathology leading to worsened ventilation-perfusion matching. The anesthesiologist should be aware of this phenomenon because of its rapid reversibility with discontinuation of these short-acting drugs. Clevidipine is an injectable lipid emulsion and is contraindicated in patients with defective lipid metabolism. Its similar visual appearance to propofol warrants special handling caution. Clevidipine is relatively contraindicated in severe aortic stenosis due to the potential for lowering coronary perfusion pressure and precipitating myocardial ischemia.⁵⁷

Phosphodiesterase Inhibitors

The phosphodiesterases (PDEs) are a broad family of 11 isoenzymes, which variably mediate the breakdown of intracellular cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP).⁵⁸ Although the many noncardiovascular actions of these enzymes are beyond the scope of this chapter, drugs of this class likely to be encountered by the anesthesiologist include the PDE3 inhibitors amrinone and milrinone and the PDE5 inhibitors sildenafil, tadalafil, and vardenafil. Inhibition of PDE causes vascular smooth muscle relaxation and, in the case of PDE3 inhibitors, positive inotropy from intracellular calcium mobilization.

The IV PDE3 inhibitor milrinone has replaced amrinone due to its reduced side effect profile. Breakdown of both cAMP and cGMP are inhibited in myocardial cells and vascular smooth muscle by this enzyme. Its combined inotropic and vasodilator actions make it a beneficial drug in the short-term treatment of heart failure, both in the intensive care and operative settings. An extensive literature documents its short-term hemodynamic benefits, whereas long-term oral use was associated with cardiovascular adverse effects and increased mortality. Although milrinone would not be a first-choice IV vasodilator in the absence of cardiac dysfunction, its vasodilation actions provide a significant benefit in the setting of heart failure. Milrinone is excreted by the kidneys mostly as unchanged drug. It has a half-life of 2 to 4 hours with normal renal function. The half-life increases in kidney injury, up to roughly 20 hours in a patient on continuous renal replacement therapy.⁵⁹

The PDE5 inhibitors selectively inhibit the breakdown of cGMP, more in vascular smooth muscle than in other cardiovascular sites. Due to a high level of PDE5 in the lungs, these drugs are effective pulmonary vasodilators, and they are also effective for erectile dysfunction. They are only available in oral formulations. Although peripheral (systemic) vascular effects are modest, when combined with other vasodilators, there can be significant lowering of blood pressure. Concurrent administration of nitroglycerin and erectile dysfunction drugs within 24 hours is not recommended as life-threatening hypotension from exaggerated systemic vasodilation may occur.⁶⁰

Nitric Oxide and Nitrovasodilators

Nitric Oxide

Nitric oxide (NO) is recognized as a chemical messenger in a multitude of biologic systems, with homeostatic activity in the modulation of cardiovascular tone (see [Chapter 14](#)), platelet regulation, and a neurotransmitter function in the CNS. In addition, it has roles in gastrointestinal smooth muscle relaxation and immune regulation. Therapeutically, NO is administered by inhalation to produce relaxation of the pulmonary arterial vasculature.

The NO is synthesized in endothelial cells from the amino acid L-arginine by NO synthetase, a constitutively expressed enzyme. It then diffuses into precapillary resistance arterioles where it induces guanylate cyclase to increase the cGMP concentration, which in turn results in vasodilation. It is formerly known as “endothelial-derived relaxing factor.” The NO production has a large role in regulation of vascular tone throughout the body. There is evidence to support deficiency in NO production being related to various vascular diseases including essential hypertension. As a result of stress, an inducible form of NO synthetase can produce large amounts of NO contributing to excessive vasodilation. The NO binds to the iron of heme-based proteins and thus is avidly bound and inactivated by hemoglobin leading to a half-time of less than 5 seconds under normal physiologic conditions.

As a therapeutic agent, inhaled NO affects the pulmonary circulation but not the systemic circulation due to its extremely rapid uptake by hemoglobin. Nitrovasodilators (nitrates and nitroprusside) work through generation of NO (see the following discussion) throughout the vasculature.

Nitric Oxide as a Pulmonary Vasodilator

Inhaled NO causes pulmonary arterial vasodilation that is proportional to the degree of pulmonary vasoconstriction ([Figure 20.2](#)). It has less effect on pulmonary vascular resistance if pulmonary vascular tone is not increased such as in types of pulmonary hypertension other than “primary.” By dilating vessels in

alveoli where it is locally delivered, inhaled NO usually improves oxygenation by improving ventilation-perfusion matching.

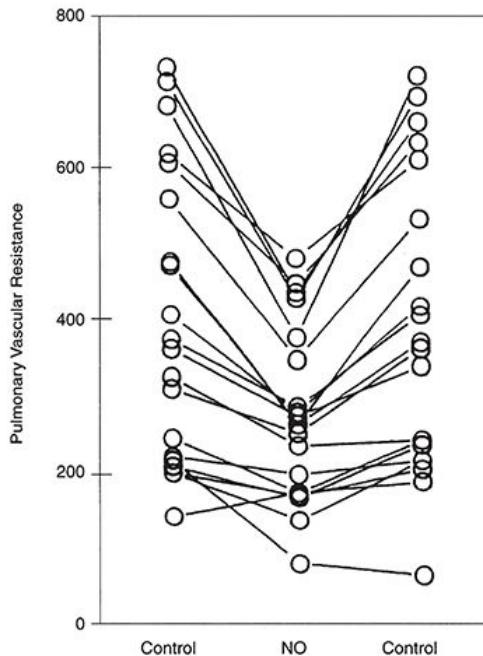

FIGURE 20.2 Inhalation of nitric oxide (NO). Pulmonary vascular resistance ($\text{dyne}/\text{cm}/\text{s}^{-5}$) before, during, and after inhalation of NO for each patient before cardiopulmonary bypass. Reprinted with permission from Rich GF, Murphy GD Jr, Roos CM, et al. Inhaled nitric oxide: selective pulmonary vasodilation in cardiac surgical patients. *Anesthesiology*. 1993;78(6):1028-1035. Copyright © 1993 American Society of Anesthesiologists, Inc.

In the United States, the only approved indication for inhaled NO is in pediatric lung injury. Inhaled NO, 10 to 20 ppm, has been used for therapy of persistent pulmonary hypertension of the newborn.^{61,62} Inhalation of NO in premature infants with respiratory distress syndrome decreases the incidence of chronic lung disease and death.⁶³

In the adult population, NO is used “off label” in managing severe pulmonary hypertension especially in the setting of acute right heart dysfunction or failure and in perioperative management of heart and lung transplant recipients. In acute lung injury and acute respiratory distress syndrome, inhaled NO will often provide a modest improvement in pulmonary hemodynamics and oxygenation, but clinical trials have failed to demonstrate an outcome benefit in this setting.⁶⁴

Toxicity

Inhaled NO increases methemoglobin levels as NO combines with hemoglobin. The increases in methemoglobin concentrations are usually modest. Life-threatening rebound arterial hypoxemia and pulmonary hypertension may accompany discontinuation of inhaled NO therapy.⁶⁵ Because of the variability in rebound pulmonary hypertension, it is important to wean patients from inhaled NO slowly. The NO is oxidized to nitrogen dioxide (NO_2) especially in the presence of high concentrations of oxygen. The NO_2 is a known pulmonary toxin (“silo-filler’s disease”) and is a possible product of the interaction of NO with oxygen. It is conceivable that NO_2 concentrations could produce pulmonary toxicity during treatment with NO. Continuous monitoring of inspired NO and NO_2 concentrations provided in the current delivery system is important to provide an early warning of possible pulmonary toxicity. In the presence of left heart dysfunction or failure, the increased pulmonary blood flow caused by inhaled NO can precipitate acute left heart failure and pulmonary edema.

Nitrodilators

The SNP and IV nitroglycerin are historically the vasodilators most widely used by anesthesiologists. As described earlier, these agents work through the generation of NO, which then augments cGMP in vascular smooth muscle, both arteries and veins, leading to vasodilation. The more recent availability of IV nicardipine and other arterial-specific dilators such as clevidipine and fenoldopam has to some degree replaced the use of the nitrodilators, especially nitroprusside due to its potential toxicities discussed later.

Sodium Nitroprusside

An SNP is a direct-acting, nonselective peripheral vasodilator that causes relaxation of arterial and venous vascular smooth muscle.⁶⁶ It is composed of a ferrous ion center complexed with five cyanide (CN^-) moieties and a nitrosyl group. The molecule is 44% cyanide by weight and is soluble in water. The SNP lacks significant effects on nonvascular smooth muscle and on cardiac muscle. Its onset of action is almost immediate, equipotent on arteries and veins, and its duration is transient, requiring continuous IV administration to maintain a therapeutic effect. The extreme potency of SNP necessitates careful titration of dosage as provided by continuous infusion devices and frequent monitoring of systemic blood pressure, often by intra-arterial monitoring.

Mechanism of Action

When infused IV, SNP interacts with oxyhemoglobin, dissociating immediately and forming methemoglobin while releasing cyanide and NO.⁶⁶ Once released, NO activates the enzyme guanylate cyclase present in vascular smooth muscle, resulting in increased intracellular concentrations of cGMP.⁶⁶ The cGMP inhibits calcium entry into vascular smooth muscle cells and may increase calcium uptake by the smooth endoplasmic reticulum to produce vasodilation.⁶⁷ As such, NO is the active mediator responsible for the direct vasodilating effect of SNP. In contrast to the organic nitrates (nitroglycerin), which require the presence of thio-containing compounds to generate NO, SPN spontaneously generates this product, thus functioning as a prodrug.

Metabolism

Metabolism of SNP begins with the transfer of an electron from the iron of oxyhemoglobin to SNP, yielding methemoglobin and an unstable SNP radical.⁶⁶ This electron transfer is independent of electron activity. The unstable SNP radical promptly breaks down, releasing all five cyanide ions, one of which reacts with methemoglobin to form cyanomethemoglobin. The remaining free cyanide ions are available to rhodanese enzymes in the liver and kidneys for conversion to thiocyanate. Rhodanese uses thiosulfate ions as sulfur donors, and most adults can detoxify approximately 50 mg of SNP using existing sulfur stores. Normal adult methemoglobin concentrations (about 0.5% of all hemoglobin) are capable of binding the cyanide released from 18 mg of SNP. Cyanomethemoglobin remains in dynamic equilibrium with free cyanide and is nontoxic. The nonenzymatic release of cyanide from SNP is not inhibited by hypothermia as may be present during cardiopulmonary bypass, whereas enzymatic conversion of cyanide to thiocyanate may be delayed.⁶⁸

Dose and Administration

Patients receiving SNP should have blood pressure monitored continuously via an arterial catheter. The recommended initial dose of SNP is 0.3 $\mu\text{g}/\text{kg}$ per minute IV titrated to a maximum rate of 10 $\mu\text{g}/\text{kg}$ per minute IV, with the maximum rate not to be infused longer than 10 minutes.⁶⁹ The SNP infusion rates of greater than 2 $\mu\text{g}/\text{kg}$ per minute IV result in dose-dependent accumulation of cyanide, and the risk of cyanide toxicity must be considered. Therefore, as other less toxic drugs are widely available, a reasonable approach might be to change to a different medication if the required dose approaches 2 $\mu\text{g}/\text{kg}$ per minute. Delivery of the SNP infusion as protected from light by aluminum foil is most often via an infusion pump.

Organ-Specific Effects

Cardiovascular

Baroreceptor-mediated reflex responses to SNP-induced decreases in systemic blood pressure manifest as tachycardia and increased myocardial contractility. These reflex-mediated responses may oppose the blood pressure-lowering effects of SNP. Although decreased venous return would tend to decrease cardiac output, the net effect is often an increase in cardiac output due to reflex-mediated increases in peripheral sympathetic nervous system activity combined with decreased impedance to left ventricular ejection. In the setting of left ventricular failure, SNP decreases systemic vascular resistance, pulmonary vascular resistance, and right atrial pressure, whereas the effect on cardiac output depends on the initial left ventricular end-diastolic pressure. There is no evidence that SNP exerts direct inotropic or chronotropic effects on the heart.

The SNP may increase the area of damage associated with a myocardial infarction through a phenomenon called “coronary steal.”⁷⁰ The SNP dilates resistance vessels in nonischemic myocardium, resulting in diversion of blood flow away from ischemic areas where collateral blood vessels are already maximally dilated. Decreases in diastolic blood pressure produced by SNP may also contribute to myocardial ischemia by decreasing coronary perfusion pressure and associated coronary blood flow.⁷¹

Renal

The SNP-induced decreases in systemic blood pressure may result in decreases in renal function. Release of renin may accompany blood pressure decreases produced by SNP and contribute to blood pressure overshoots when the drug is discontinued.⁷² Pretreatment with a competitive inhibitor of angiotensin II prevents blood pressure overshoots after discontinuation of SNP, thus confirming the participation of the renin-angiotensin system in this response.⁷³ Increased plasma concentrations of catecholamines also accompany hypotension produced by SNP.

Hepatic

In animals, SNP-induced decreases in systemic blood pressure do not result in hepatic hypoxia or changes in hepatic blood flow.⁷¹ Furthermore, hepatic blood flow does not change when cardiac output is maintained in anesthetized patients, despite 20% to 60% decreases in systemic blood pressure produced by SNP.⁷⁴

Cerebral

The SNP increases cerebral blood flow and cerebral blood volume. In patients with decreased intracranial compliance, this may increase intracranial pressure (greater than the increase produced by nitroglycerin). It is likely that the rapidity of systemic blood pressure decrease produced by SNP exceeds the capacity of the cerebral circulation to autoregulate its blood flow such that intracranial pressure and cerebral blood flow change simultaneously but in opposite directions.⁷⁵ Nevertheless, increases in intracranial pressure produced by SNP are maximal during modest decreases (<30%) in mean arterial pressure. When SNP-induced decreases in mean arterial pressure are greater than 30% of the awake level, the intracranial pressure decreases to below the awake level.⁷⁶ Furthermore, decreasing blood pressure slowly over 5 minutes with SNP in the presence of hypocapnia and hyperoxia negates the increase in intracranial pressure that accompanies the rapid infusion of nitroprusside.⁷⁷ Patients with known inadequate cerebral blood flow as associated with dangerously increased intracranial pressure or carotid artery stenosis should probably not be treated with SNP. During cardiopulmonary bypass, SNP has been shown to have no direct effect on cerebral vasculature and autoregulation is preserved.⁷⁸ The potential adverse effects of SNP on intracranial pressure are not present if the drug is administered after the dura has been surgically opened.

Pulmonary

Decreases in the partial pressure of arterial oxygen (PaO_2) may accompany the infusion of SNP and other peripheral vasodilators used to produce controlled hypotension. Attenuation of hypoxic pulmonary vasoconstriction by peripheral vasodilators is the presumed mechanism.⁵⁴ Addition of propranolol to the vasodilator regimen does not alter the magnitude of decrease in PaO_2 .⁷⁹ Furthermore, peripheral vasodilator-induced decreases in blood pressure are more likely to increase the shunt fraction in patients with normal lungs than in those with chronic obstructive pulmonary disease.⁸⁰ It is speculated that hypotension in normal

patients leads to decreased pulmonary artery pressure such that preferential perfusion of dependent but poorly ventilated alveoli occurs. In contrast, patients with chronic obstructive pulmonary disease may develop destructive vascular changes that prevent alterations in the distribution of pulmonary blood flow in response to vasodilation. The addition of positive end-expiratory pressure may reverse vasodilator-induced decreases in the PaO_2 .⁸¹

Hematologic

Increased intracellular concentrations of cGMP, as produced by SNP and nitroglycerin, have been shown to inhibit platelet aggregation.⁸² Infusion rates of SNP of greater than 3 $\mu\text{g}/\text{kg}$ per minute may result in decreases in platelet aggregation and increased bleeding time.⁸³ The postoperative stress-induced increase in platelet aggregation is absent in SNP-treated patients.⁸⁴ Increased bleeding time could also be the result of vasodilation secondary to a direct effect of SNP on vascular tone. However, clinical measures of intraoperative bleeding are not increased in SNP-treated patients, suggesting that decreased ability of platelets to aggregate during and after controlled hypotension does not have an adverse clinical effect.⁸⁴

Toxicity

Cyanide Toxicity

Clinical evidence of cyanide toxicity may occur when the rate of IV SNP infusion is greater than 2 $\mu\text{g}/\text{kg}$ per minute or when sulfur donors and methemoglobin are exhausted, thus allowing cyanide radicals to accumulate. Because any free cyanide radical may bind inactive tissue cytochrome oxidase and prevent oxidative phosphorylation, increased cyanide concentrations may precipitate tissue anoxia, anaerobic metabolism, and lactic acidosis. Children may be less able to mobilize thiosulfate stores despite increasing cyanide concentrations, leading to accelerated toxicity.

Regardless of the SNP infusion rate or total administered dose, cyanide toxicity should be suspected in any patient requiring an increasing dose especially more than 2 $\mu\text{g}/\text{kg}$ per minute or in a previously responsive patient who becomes less or unresponsive to the drug. Mixed venous partial pressure of oxygen (PvO_2) is increased in the presence of cyanide toxicity, indicating paralysis of cytochrome oxidase and inability of tissues to use oxygen. At the same time, metabolic acidosis (plasma lactate concentrations of >10 mM, which correlates with blood cyanide concentrations of >40 μM) develops as a reflection of anaerobic metabolism in the tissues. Decreased cerebral oxygen use is evidenced by the increased cerebral venous oxygen content. In awake patients, CNS dysfunction (mental status changes, seizures) may occur.

Treatment of Cyanide Toxicity. Appearance of tachyphylaxis in a previously sensitive patient in association with metabolic acidosis and increased mixed venous Po_2 mandates immediate discontinuation of SNP and administration of 100% oxygen despite normal oxygen saturation. Sodium bicarbonate is administered to correct metabolic acidosis. Sodium thiosulfate, 150 mg/kg IV administered over 15 minutes, has historically been the recommended first-line treatment for cyanide toxicity.⁶⁶ Thiosulfate acts as a sulfur donor to convert cyanide to thiocyanate, which is generally nontoxic (see following discussion). However, due to good side effect profile and increased availability, hydroxocobalamin has joined thiosulfate as part of the first-line treatment for cyanide toxicity, with both drugs frequently being used in conjunction.^{85,86} Hydroxocobalamin (vitamin B_{12a}), which binds cyanide to form cyanocobalamin (vitamin B₁₂), is administered as a 5-g initial dose, with the option for a second dose depending on clinical response.⁸⁷ In addition to being expensive, hydroxocobalamin may produce a reddish discoloration of the skin and mucous membranes. It may interfere with co-oximetry blood gas analysis, which is a relevant problem when coadministering drugs that are known to cause methemoglobinemia (ie, nitrates).⁸⁸ If cyanide toxicity is severe, with deteriorating hemodynamics and metabolic acidosis, the recommended treatment is slow IV administration of sodium nitrate, 5 mg/kg. Sodium nitrate converts hemoglobin to methemoglobin, which acts as an antidote by converting cyanide to cyanomethemoglobin.

Thiocyanate Toxicity

Thiocyanate is cleared slowly by the kidneys, with an elimination half-time of 3 to 7 days.⁶⁶ Clinical thiocyanate toxicity is rare, as thiocyanate is 100-fold less toxic than cyanide. In patients with normal renal function, 7 to 14 days of SNP infusion in the 2 to 5 µg/kg per minute range may be required to produce potentially toxic thiocyanate blood concentrations. The SNP infusions for 3 to 6 days may result in thiocyanate toxicity in patients with chronic renal failure who are not undergoing periodic hemodialysis.

Nonspecific symptoms of thiocyanate toxicity include fatigue, tinnitus, nausea, and vomiting. Clinical evidence of neurotoxicity produced by thiocyanate includes hyperreflexia, confusion, psychosis, and miosis. Toxicity may progress to seizures and coma. Increased thiocyanate concentrations competitively inhibit uptake and binding of iodine in the thyroid gland, sometimes producing clinical hypothyroidism. Thiocyanate clearance can be facilitated by dialysis. Oxyhemoglobin can slowly oxidize thiocyanate back to sulfate and cyanide, but this is insufficient to cause cyanide toxicity.

Methemoglobinemia

Adverse effects from methemoglobinemia produced by SNP breakdown are unlikely even in patients with a congenital inability to convert methemoglobin to hemoglobin (methemoglobin reductase deficiency).⁶⁶ The total SNP dose required to produce 10% methemoglobinemia exceeds 10 mg/kg. Patients receiving such high doses of SNP who present with evidence of impaired oxygenation despite an adequate cardiac output and arterial oxygenation should have methemoglobinemia included in the differential diagnosis. Measurement of methemoglobin via co-oximetry may be helpful in these patients.

Clinical Use

The use of SNP, as mentioned earlier, has significantly declined with the introduction of more selective arterial agents, which have a greater margin of safety and much less or absent toxicity. In addition, selective arterial agents do not generally have such a dramatic or acute effect on blood pressure due to preservation of venous tone. Before the availability of these drugs, SNP was used widely and well studied in the settings of controlled hypotension, hypertensive emergencies, aortic and cardiac surgery, and heart failure. In this latter population, the combined preload and afterload effect is still a possible advantage but at the cost of blood pressure lability and systemic toxicity. It is likely the use of SNP will continue to decline as experience grows with the newer agents.

Nitrates

Nitroglycerin is an organic nitrate that acts principally on venous capacitance vessels and large coronary arteries to produce peripheral pooling of blood and decreased cardiac ventricular wall tension.^{89,90} However, as the dose of nitroglycerin is increased, there is also relaxation of arterial vascular smooth muscle. Nitroglycerin can produce pulmonary vasodilation equivalent to the degree of systemic arterial vasodilation. The most common clinical use of nitroglycerin is sublingual or IV administration for the treatment of angina pectoris as a result of either atherosclerosis of the coronary arteries or intermittent vasospasm of these vessels. Controlled hypotension can also be achieved with the continuous infusion of nitroglycerin.

Mechanism of Action

Nitroglycerin, like SNP, generates NO, which stimulates production of cGMP to cause peripheral vasodilation (see earlier discussion). In contrast to SNP, which spontaneously produces NO, nitroglycerin requires the presence of thio-containing compounds. In this regard, the nitrate group of nitroglycerin is biotransformed to NO through a glutathione-dependent pathway involving both glutathione and glutathione S-transferase. Nitroglycerin is not recommended in patients with hypertrophic obstructive cardiomyopathy or in the presence of severe aortic stenosis, where venous pooling may lead to syncope.

Route of Administration

Nitroglycerin is most frequently administered by the sublingual route, but it is also available as an oral tablet, a buccal or transmucosal tablet, a sublingual spray, a transdermal ointment, or a continuous IV infusion. Sublingual administration of nitroglycerin results in peak plasma concentrations within 4 minutes. Only about

15% of the blood flow from the sublingual area passes through the liver, which limits the initial first-pass hepatic metabolism of nitroglycerin. In contrast, nitroglycerin is well absorbed after oral administration, but it is largely inactive because of first-pass hepatic metabolism.

Transdermal absorption of nitroglycerin, 5 to 10 mg over 24 hours, provides sustained protection against myocardial ischemia. The plasma concentration resulting from transdermal absorption of nitroglycerin is low, but tolerance to the drug effect occurs when the patches are left in place for longer than 24 hours. It is possible that removing the patches after 14 to 16 hours will prevent the development of tolerance.

Continuous infusion of nitroglycerin, via special delivery tubing to decrease absorption of the drug into plastic, is a useful approach to maintain a constant delivered concentration of nitroglycerin.

Pharmacokinetics

Nitroglycerin has an elimination half-time of about 1.5 minutes.⁹⁰ There is a large volume of distribution, reflecting tissue uptake, and it has been estimated that only 1% of total body nitroglycerin is present in the plasma. For this reason, plasma nitroglycerin concentrations may vary widely because of differences in tissue binding.

Methemoglobinemia

The nitrite metabolite of nitroglycerin is capable of oxidizing the ferrous ion in hemoglobin to the ferric state with the production of methemoglobin.^{91,92} In particular, high doses of nitroglycerin may produce methemoglobinemia in patients with hepatic dysfunction. Treatment of methemoglobinemia is as discussed earlier with SNP toxicity.

Tolerance

A limitation to the use of all nitrates is the development of tolerance to their vasodilating effects. Tolerance is dose dependent and duration dependent, usually manifesting within 24 hours of sustained treatment. If ischemia occurs during continuous administration of nitroglycerin, responsiveness to the anti-ischemic effects of the nitrate can usually be restored by increasing the dose. The mechanism of tolerance is not well understood but may reflect a change in the vasculature that limits the vasodilating effects of the nitrates. A drug-free interval of 12 to 14 hours is recommended to reverse tolerance to nitroglycerin and other nitrates. Rebound myocardial ischemia may occur during the drug-free interval.

Clinical Use

Perioperatively, nitroglycerin in all its forms is used to treat suspected myocardial ischemia as well as volume overload in the setting of heart failure (preload reduction). As a systemic antihypertensive, both for treatment and achieving controlled hypotension, nitroglycerin infusion can be effective, but its preferential effect on veins rather than arteries can make it less effective in severe hypertension than drugs, which preferentially act on the arteries. Although nitroglycerin has no “toxicity” (other than possible methemoglobinemia with high doses), its use for hypertension has declined with the availability of IV nicardipine and fenoldopam.

Isosorbide Dinitrate

Isosorbide dinitrate is a commonly administered oral nitrate for the prophylaxis of angina pectoris and for preload reduction in patients with heart failure. Its effects are very similar to that of nitroglycerin, but as an oral agent, isosorbide dinitrate is well absorbed from the gastrointestinal tract, and it is not subject to the extensive first-pass metabolism that limits oral use of nitroglycerin. It exerts a physiologic effect lasting up to 6 hours when taken in doses of 60 to 120 mg. The longer acting sustained release form provides a prolonged antianginal effect and improves exercise tolerance for up to 6 hours. Isosorbide dinitrate may also be administered sublingually, producing an effect lasting up to 2 hours. The metabolite of isosorbide dinitrate, isosorbide-5-mononitrate, is more active than the parent compound. Orthostatic hypotension accompanies acute administration of isosorbide dinitrate, but tolerance to this and other pharmacologic effects seems to develop with chronic therapy.

Hydralazine

Hydralazine is a direct systemic arterial vasodilator, which both hyperpolarizes smooth muscle cells and activates guanylate cyclase to produce vasorelaxation.⁹³ Arterial vasodilation by hydralazine produces reflex sympathetic nervous system stimulation with resulting increases in heart rate and myocardial contractility, so this drug is not generally recommended for patients with myocardial ischemia or coronary disease. It is an effective afterload-reducing agent and is still used in combination with nitrates for outpatient treatment of congestive heart failure and for intermittent IV dosing in the perioperative period or critical care setting. Although it has been widely used in hypertensive disorders associated with pregnancy, other agents may be associated with less adverse outcomes.⁹⁴ Long-term hydralazine use is limited due to an association with a systemic autoimmune syndrome that has features of drug-induced lupus and antineutrophil cytoplasmic antibody-associated vasculitis.⁹⁵ Acute IV administration has a slightly delayed onset, making it less appealing than other immediate-onset medications.

Fenoldopam

Fenoldopam is a dopamine type 1 receptor agonist, causing systemic arterial dilation through increasing cAMP. It has a particular action of increasing renal blood flow and increasing urine output and also increasing splanchnic blood flow due to the density of dopamine type 1 receptors in these beds.⁹⁶ Because of this action, it has been viewed by some as a possible “new renal dopamine,” which might have a renal protective effect, but evidence to support this hypothesis is weak. There is no question, however, that when compared to other IV antihypertensive drugs such as SNP or nicardipine, there is greater urine output with fenoldopam for the same degree of antihypertensive action. Fenoldopam is only available in an IV preparation, it has a rapid onset and 10-minute elimination half-life. As is the case with other arterial dilators, there is a baroreflex-mediated increase in heart rate and plasma catecholamine level associated with its use. Adverse effects are limited to an increase in intraocular pressure, making this drug unsuitable for patients with glaucoma.

Diuretics

As discussed earlier, diuretics continue to be first-line oral agents used for essential hypertension. Patients are most likely to be prescribed a thiazide drug, with more potent loop diuretics (furosemide, bumetanide) reserved for patients where thiazides are less effective such as patients with renal insufficiency or heart failure. Diuretics are not, strictly speaking, vasodilators, although there is evidence for a venodilating effect of IV furosemide.⁹⁷ Both thiazide and loop diuretics cause potassium loss, and their use generally mandates supplementation with potassium and often magnesium. This is true both for oral outpatient use and acute IV dosing in the perioperative or critical care setting.

Aldosterone antagonists or “potassium-sparing” agents are less potent than loop diuretics but have a clear role in patients with heart failure where their addition to other antihypertensive drugs (eg, ACE inhibitors) confers a survival benefit. This is possibly due to blocking aldosterone effects on the heart.

Drugs Not Discussed

The earlier discussion of antihypertensive drugs and vasodilators has not included a number of older agents, which are rarely used now for this indication in clinical practice in North America. These include trimethaphan, diazoxide, alpha-methyldopa, and adenosine. The reader is referred to old texts for a discussion of these agents.

Antiarrhythmic Drugs*

Updated by: Wendy Smith • James Ramsay

Cardiac arrhythmias occur commonly in the perioperative period, most of which are relatively benign and are due to transient changes in physiology, surgical stimuli, or the effect of anesthetic agents. Arrhythmias that require treatment are most commonly supraventricular, with atrial fibrillation being especially common after cardiac surgery.^{1,2} The chronic use of antiarrhythmic drugs for the treatment and prevention of cardiac arrhythmias is limited by the potential for these drugs to depress left ventricular contractility and the triggering of new arrhythmias (see the “[Proarrhythmic Effects](#)” section).³ For this reason, alternatives to pharmacologic therapy have been sought. Improved survival for those receiving implantable cardiac defibrillator devices compared with antiarrhythmic drugs has altered the treatment paradigms for patients with ventricular arrhythmias, although pharmacologic therapy remains first line in the case of structural heart disease.^{4,5} Similarly, catheter ablation techniques are preferred treatments for many supraventricular arrhythmias including atrial flutter and certain types of atrial fibrillation. As a result, pharmacologic treatment of cardiac arrhythmias is principally used to suppress atrial fibrillation and atrial flutter that is not responsive to catheter ablation treatment and for patients with implantable cardioverter-defibrillator devices who are receiving frequent indicated electrical shocks.

Pharmacologic treatment of cardiac arrhythmias and disturbances of the conduction of cardiac impulses with antiarrhythmic drugs is based on an understanding of the electrophysiologic basis of the abnormality and the mechanism of action of the therapeutic drug to be administered.^{1,6} The two major physiologic mechanisms that cause ectopic cardiac arrhythmias are reentry and enhanced automaticity. Factors encountered in the perioperative period that facilitate cardiac arrhythmias due to both mechanisms include hypoxemia, electrolyte and acid–base abnormalities, myocardial ischemia, altered sympathetic nervous system activity, bradycardia, and the administration of certain drugs. It is not commonly appreciated that alkalosis is even more likely than acidosis to trigger cardiac arrhythmias. Hypokalemia and hypomagnesemia predispose to ventricular arrhythmias and must be suspected in patients who are being treated with diuretics. Increased sympathetic nervous system activity, as may be encountered during laryngoscopy or surgical stimulation, lowers the threshold for ventricular fibrillation, a phenomenon that is attenuated by β blockade and vagal stimulation.⁷ Bradycardia predisposes to ventricular arrhythmias by causing a temporal dispersion of refractory periods among Purkinje fibers, creating an electrical gradient between adjacent cells. Enlargement of a failing left ventricle stretches individual myocardial cells and can thereby induce cardiac arrhythmias. Decreasing left ventricular volume with administration of digitalis, diuretics, or vasodilators helps to control cardiac arrhythmias that are precipitated by this mechanism.

In some patients, correction of identifiable precipitating events is not sufficient to suppress cardiac ectopic rhythms, and therefore, specific cardiac antiarrhythmic drugs may be indicated. Drugs administered for the chronic suppression of cardiac arrhythmias pose little threat to the uneventful course of anesthesia and should be continued up to the time of induction of anesthesia.^{1,8} As mentioned earlier, the majority of cardiac arrhythmias that occur during anesthesia do not require therapy. Cardiac arrhythmias, however, do require treatment when hemodynamic function is compromised or the disturbance predisposes to more serious cardiac arrhythmias.

General anesthetic-related cardiac arrhythmias have been ascribed to abnormal pacemaker activity characterized by suppression of the sinoatrial node, with the emergence of latent pacemakers within or below the atrioventricular tissues.⁶ Furthermore, development of reentry circuits is likely to be important in the mechanism of cardiac arrhythmias that occur during anesthesia. Certain anesthetics, particularly volatile drugs, may have effects on the specialized conduction system for cardiac impulses.

Mechanism of Action

It is well established that antiarrhythmic drugs produce pharmacologic effects by blocking passage of ions across sodium, potassium, and calcium ion channels present in the heart ([Figure 21.1](#)). The cardiac action potential results from the interplay of multiple inward and outward currents via specific ion channels responsible for each of the five phases. The duration of each phase of the action potential differs in atrial compared with ventricular myocardium and the specialized systems for conduction of cardiac impulses differ in ion channel density. Ion channels are large membrane-bound glycoproteins that provide a pathway across cell membranes for the passage of ions. Ion channels exist in different states (open, inactivated, closed). In the inactivated state, the ion channel is unresponsive to a continued or new stimulus. The resting state is more prevalent during diastole, the active state occurs during the upstroke of the action potential, and the inactivated state occurs during the plateau phase of repolarization.

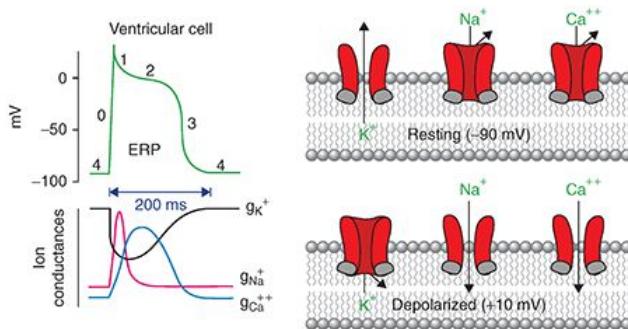

FIGURE 21.1 The physiologic basis of the cardiac action potential. Phase 0 represents rapid depolarization as a result of opening of Na^+ channels and closing of K^+ channels. Phase 1 is the period of initial repolarization that results from closure of Na^+ and opening of K^+ channels. Phase 2 is the plateau phase that results from the sustained Ca^{++} current that began with the initial depolarization. Phase 3 is repolarization due to opening of K^+ and closure of Ca^{++} channels. Phase 4 is the resting potential during which K^+ channels are open and Na^+ and Ca^{++} channels are closed. The effective refractory period (ERP) is the time during which the cell cannot be depolarized again. Redrawn based on Klabunde RE, ed. Cardiovascular Physiology Concepts. 2nd ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2011.

The effects of cardiac antiarrhythmic drugs on the action potential and effective refractory period of the cardiac action potential determine the clinical effect of these drugs. Drugs that primarily block inward sodium ion flow will slow conduction and result in suppression of the maximum upstroke velocity of the cardiac action potential. Potassium channel blocking drugs prolong repolarization by increasing the duration of the cardiac action potential and the effective refractory period resulting in prolongation of the QTc interval on the electrocardiogram (ECG). Calcium channels are present in myocardial cells, and the α subunit of L and T calcium ion channels is the site of action of some cardiac antiarrhythmic drugs.

Classification

Our knowledge of cardiac ion channels and the actions of antiarrhythmic drugs has greatly increased since the development of the original Vaughn-Williams classification ([Table 21.1](#)). One of the benefits and drawbacks of Vaughn-Williams is that it is simple and easy to understand; however, this simplicity prevents a thorough representation of the multifaceted effects of each drug. Alternate classification systems have been proposed, but a new gold standard has not yet been widely accepted. However, as our understanding and treatment of arrhythmias becomes more nuanced, there will likely be modifications to the original classification and the options bear mentioning. One of the first attempts is known as the **Sicilian Gambit** of 1991 in which the physiologic basis of the arrhythmia, rather than the predominant pharmacologic action of a drug, was the primary descriptor of each class.⁹ More recently, a proposal for a revision of Vaughn-Williams has been put forward.¹⁰ This updated system describes the existing classes with more granularity and has added several new classes for a more inclusive picture of the complex physiologic actions of antiarrhythmic

targets. For the purposes of this text, Vaughn-Williams continues to serve as an excellent scaffolding on which an anesthesiologist can build an introductory knowledge of antiarrhythmic drugs as long as the limitations of the system are acknowledged.

TABLE 21.1

Classification of cardiac antiarrhythmic drugs

Class I (inhibit fast sodium ion channels)
Class IA
Quinidine
Procainamide
Disopyramide
Moricizine
Class IB
Lidocaine
Tocainide
Mexiletine
Class IC
Flecainide
Propafenone
Class II (decrease rate of depolarization)
Esmolol
Propranolol
Acebutolol
Class III (inhibit potassium ion channels)
Amiodarone
Dronedarone
Sotalol
Ibutilide
Dofetilide
Class IV (inhibit slow calcium channels)
Verapamil
Diltiazem

According to the Vaughn-Williams classification, cardiac arrhythmic drugs are most commonly placed into four groups based primarily on the ability of the drug to control arrhythmias by blocking specific ion channels and currents during the cardiac action potential ([Tables 21.1](#) and [21.2](#)).^{11,12} Few cardiac antiarrhythmic drugs demonstrate completely specific effects on cardiac ion channels. It should be noted that other characteristics including the impact of the drug on autonomic nervous system activity and myocardial contractility may be more important clinically and should be taken into consideration when choosing a specific agent. Antiarrhythmic drugs also differ in their pharmacokinetics and efficacy in treating specific types of arrhythmias ([Tables 21.3](#) and [21.4](#)).⁸

TABLE 21.2

Electrophysiologic and electrocardiographic effects of cardiac antiarrhythmic drugs

	Class IA	Class IB	Class IC	Class II	Class III	Class IV
Depolarization rate (phase 0)	Decreased	No effect	Greatly decreased	No effect	No effect	No effect
Conduction velocity	Decreased	No effect	Greatly decreased	Decreased	Decreased	No effect
Effective refractory	Greatly	Decreased	Increased	Decreased	Greatly	No effect

period	increased				increased	
Action potential duration	Increased	Decreased	Increased	Increased	Greatly increased	Decreased

Class I Drugs

Class I drugs inhibit fast sodium channels during depolarization (phase 0) of the cardiac action potential with resultant decreases in depolarization rate and conduction velocity (see [Figure 21.1](#)).¹¹

Class IA Drugs

Class IA drugs (quinidine, procainamide, disopyramide, moricizine) lengthen both the action potential duration and the effective refractory period reflecting sodium channel inhibition and prolonged repolarization owing to potassium channel blockade.

Class IB Drugs

Class IB drugs (lidocaine, mexiletine, tocainide, phenytoin) are less powerful sodium channel blockers and, unlike class IA drugs, shorten the action potential duration and refractory period in normal cardiac ventricular muscle. In ischemic tissue, lidocaine may also block adenosine triphosphate-dependent channels, thus preventing ischemia-mediated shortening of ventricular depolarization.

Class IC Drugs

Class IC drugs (flecainide, propafenone) are potent sodium channel blockers and markedly decrease the rate of phase 0 depolarization and speed of conduction of cardiac impulses. These drugs have little effect on the duration of the cardiac action potential and the effective refractory period in ventricular myocardial cells but do shorten the duration of the action potential in Purkinje fibers. This inhomogeneity of effects on the rate of cardiac depolarization plus the slowing of cardiac conduction may contribute to the proarrhythmic effects of these drugs.

Class II Drugs

Class II drugs are primarily β -adrenergic antagonists. β -Adrenergic antagonists decrease the rate of spontaneous phase 4 depolarization resulting in decreased autonomic nervous system activity, which may be important in suppression of ventricular arrhythmia during myocardial ischemia and reperfusion. Drug-induced slowing of heart rate with resulting decreases in myocardial oxygen requirements is desirable in patients with coronary artery disease. β -Adrenergic antagonists slow the speed of conduction of cardiac impulses through atrial tissues resulting in prolongation of the P-R interval on the ECG, whereas the duration of action of the cardiac action potential in ventricular myocardium is not altered. These drugs are effective in decreasing the incidence of arrhythmia-related morbidity and mortality although the exact mechanism for this beneficial effect remains unclear.

Class III Drugs

Class III drugs (amiodarone, dronedarone, sotalol) primarily block potassium ion channels resulting in prolongation of cardiac depolarization, action potential duration, and the effective refractory period. These effects are beneficial in preventing cardiac arrhythmias by decreasing the proportion of the cardiac cycle during which myocardial cells are excitable and thus susceptible to a triggering event. Reentrant tachycardias may be suppressed if the action potential duration becomes longer than the cycle length of the tachycardia circuit.

In addition to class III effects, amiodarone exhibits sodium channel blockade (class I), β blockade (class II), and calcium channel blockade (class IV). Although this drug is US Food and Drug Administration (FDA)

approved for the treatment of refractory ventricular arrhythmias, it has become a widely used drug for the acute treatment and prevention of supraventricular and ventricular arrhythmias both in the operating room and the intensive care unit (see the following text).

Sotalol is a long-acting, noncardioselective β -blocking drug consisting of a racemic mixture of levorotatory and dextrorotatory isomers that possess similar class III effects. The levorotatory isomer of sotalol acts as a β -adrenergic antagonist, whereas the dextrorotatory isomer may increase mortality in patients with ventricular dysfunction and recent myocardial infarction. The reduced incidence of proarrhythmia effects seen with amiodarone or racemic sotalol treatment may be related to beneficial class II effects.

Another class III drug less commonly used is dofetilide, most likely to be prescribed by electrophysiologists in patients refractory to, or with side effects from other agents, but with a measurable incidence of proarrhythmia.

Class IV Drugs

Class IV drugs are the calcium blockers verapamil and diltiazem, which primarily act by inhibiting inward slow calcium ion currents that may contribute to the development of tachycardias. As such, these drugs may be useful in the treatment of both supraventricular tachyarrhythmias and idiopathic ventricular tachycardia. The dihydropyridine calcium blockers (nifedipine, nicardipine, nimodipine) do not have antiarrhythmic action.

Class 0 Drugs

As mentioned earlier, there are modern antiarrhythmic drug classifications, which recognize an expanded set of primary receptor targets.¹⁰ Although some new categories are theoretical, without corresponding pharmacologic agents, there is one “class 0” drug, which gained FDA approval in 2015 and is therefore worth discussing. Ivabradine is a novel drug that selectively inhibits the current in the sinoatrial node responsible for spontaneous slow depolarization and hence the heart rate. This has been termed the “funny current.” Ivabradine slows the heart rate, with greater effectiveness at higher heart rates.¹³ It has no hemodynamic effects other than on the heart rate and has been evaluated in clinical trials in patients with heart failure (normal and reduced ejection fraction) and coronary disease with heart failure, showing clinical benefit mostly in patients with heart failure and reduced ejection fraction with sinus rhythm >70 beats per minute and who are either on maximal doses of β blockers or are unable to take β blockers (the 2015 FDA-approved indication). The drug is only available in an oral formulation and is therefore unlikely to have utility in the acute perioperative setting; however, patients with heart failure may come to the operating room on this medication. Additionally, there is interest in its use as an isolated bradycardic agent in other settings such as the sinus tachycardia seen in sepsis.¹⁴

Proarrhythmic Effects

Proarrhythmia effects describe bradyarrhythmias or tachyarrhythmias that represent new cardiac arrhythmias associated with antiarrhythmic drug treatment.³ These include torsades de pointes (most common), incessant ventricular tachycardia, and wide complex ventricular rhythm.¹¹

Torsades de Pointes

Torsades de pointes is triggered by early afterdepolarizations in a setting of delayed repolarization and increased duration of refractoriness manifesting as prolongation of the QTc interval on the ECG. Class IA (quinidine and disopyramide) and class III drugs (amiodarone) prolong the QTc interval by potassium channel blockade providing the setting for torsades de pointes. Drug-induced torsades de pointes is often associated with bradycardia because the QTc interval is longer at slower heart rates. Exacerbating factors such as hypokalemia, hypomagnesemia, poor left ventricular function, and concomitant administration of other QT-prolonging drugs are important predisposing factors in the development of this life-threatening rhythm.

Incessant Ventricular Tachycardia

Incessant ventricular tachycardia may be precipitated by drugs that slow conduction of cardiac impulses (class IA and IC drugs) sufficiently to create a continuous ventricular tachycardia circuit (reentry). Incessant ventricular tachycardia is more likely to occur with high doses of class IC drugs and in patients with a prior history of sustained ventricular tachycardia and poor left ventricular function. Ventricular tachycardia due to this mechanism is generally slower because of the drug effect but may be resistant to drugs or electrical therapy. This rhythm is rarely associated with class IB drugs, which have a weaker blocking effect of sodium channels.

Wide Complex Ventricular Rhythm

Wide complex ventricular rhythm is usually associated with class IC drugs in the setting of structural heart disease. Excessive plasma concentrations of the drug or an abrupt change in the dose may result in this arrhythmia. Wide complex ventricular rhythm is thought to reflect a reentrant tachycardia and easily degenerates to ventricular fibrillation.

Efficacy and Results of Treatment With Cardiac Antiarrhythmic Drugs

Chronic suppression of ventricular ectopy with an antiarrhythmic drug other than amiodarone does not prevent future life-threatening arrhythmias and may increase mortality.¹¹ In fact, patients treated with class IC drugs experienced a higher incidence of sudden cardiac arrest reflecting the proarrhythmia effects of these drugs. Conversely, β-adrenergic antagonists that do not typically suppress ventricular arrhythmias appear to decrease mortality and the risk of life-threatening ventricular arrhythmias. In patients with a history of myocardial infarction and ventricular arrhythmias, mortality was increased in those who received class IA and IC drugs, whereas mortality was decreased with amiodarone and β-adrenergic antagonists.¹⁵ Survivors of cardiac arrest have a high risk of subsequent ventricular fibrillation and treatment of these patients with amiodarone results in fewer life-threatening cardiac events. The proarrhythmic and negative inotropic effects of class IA and IC drugs precludes their administration to patients with congestive heart failure. In these patients, administration of amiodarone appears to be safe and effective.

Prophylactic Antiarrhythmic Drug Therapy

Although commonly used in the past, lidocaine is no longer recommended as prophylactic treatment for patients in the early stages of acute myocardial infarction and without malignant ventricular ectopy.¹⁶ In fact, lidocaine does not decrease and may increase mortality because of an increase in the occurrence of fatal bradyarrhythmias and asystole.

Calcium channel antagonists are not recommended as routine treatment of patients with acute myocardial infarction because mortality is not decreased by these drugs. Calcium channel blockers may be administered to patients in whom myocardial ischemia persists despite treatment with aspirin, heparin, nitroglycerin, and β-adrenergic antagonists.

Magnesium is involved in many enzymatic reactions, produces systemic and coronary vasodilation, inhibits platelet aggregation, and decreases myocardial reperfusion injury. Data on the ability of magnesium to decrease mortality following myocardial infarction are conflicting.¹⁷ Treatment with magnesium is indicated in patients following an acute myocardial infarction who develop torsades de pointes ventricular tachycardia.¹⁸

In patients with heart failure, amiodarone reduces the risk of sudden cardiac death by 29% and therefore represents a viable alternative in patients who are not eligible for or who do not have access to implanted cardiac defibrillator therapy for the prevention of sudden cardiac death from arrhythmias.¹⁹ Amiodarone can be considered as an adjuvant therapy to implanted cardiac defibrillator in preventing recurrent shocks. However, amiodarone therapy is neutral with respect to all-cause mortality and is associated with a two- and fivefold increased risk of pulmonary and thyroid toxicity, respectively.¹⁹ Prophylactic dofetilide did not demonstrate a mortality benefit either.²⁰ In summary, there is little role for prophylactic antiarrhythmic medications for the primary prevention of sudden cardiac death in patients with heart failure with the exception of amiodarone.

Atrial fibrillation after heart surgery is a common complication that has been associated with prolonged hospitalization and cardiovascular morbidity. Prophylactic therapy with amiodarone, β blockers, sotalol, and magnesium has been effective in reducing the occurrence of atrial fibrillation, length of hospital stay, and cost of hospital treatment and may be effective in reducing the risk of stroke.²¹

Decision to Treat Cardiac Arrhythmias

Drug treatment of cardiac arrhythmias is not uniformly effective and frequently causes side effects (see the “[Proarrhythmic Effects](#)” section).^{1,22} The benefit of antiarrhythmic drugs is clearest when it results in the immediate termination of a sustained tachycardia. There is no doubt that the termination of ventricular tachycardia by lidocaine or supraventricular tachycardia by adenosine or verapamil is a true benefit of antiarrhythmic therapy. Furthermore, when given for a limited period, side effects are less likely. Conversely, it has been difficult to demonstrate that antiarrhythmic drugs alleviate symptoms related to chronic cardiac arrhythmias, a situation in which the risk of side effects is greater. The increase in long-term mortality associated with certain drugs (Cardiac Arrhythmia Suppression Trial and other trials) raises the possibility that some antiarrhythmics result in sensitization of the myocardium to concurrent triggering factors (myocardial ischemia, neurohumoral activation, myocardial stretch, slow healing process after a myocardial infarction) that then elicit cardiac arrhythmias.^{15,22} The mechanism by which β -adrenergic antagonists decrease mortality after an acute myocardial infarction is not known.

The value of monitoring plasma drug concentrations in minimizing the risks associated with therapy is not established. In fact, many side effects appear to depend as much on the nature and extent of the underlying heart disease as on increased plasma drug concentrations.²²

Antiarrhythmic Drug Pharmacology

Quinidine

Quinidine is a class IA drug that is effective in the treatment of acute and chronic supraventricular arrhythmias ([Figure 21.2](#)).²³ Due to its side effect profile and low therapeutic index (see the following text), and the availability of newer agents, quinidine is rarely used. It can prevent recurrence of supraventricular tachyarrhythmias or suppress premature ventricular contractions and can slow the ventricular rate in the presence of atrial fibrillation, and about 25% of patients with new-onset atrial fibrillation will convert to normal sinus rhythm when treated with quinidine. Supraventricular tachyarrhythmias associated with Wolff-Parkinson-White syndrome are effectively suppressed by quinidine.

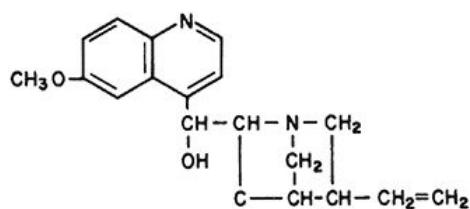

FIGURE 21.2 Quinidine.

Quinidine is most often administered orally in a dose of 200 to 400 mg four times daily. Oral absorption of quinidine is rapid, with peak concentrations in the plasma attained in 60 to 90 minutes and an elimination half-time of 5 to 12 hours. The therapeutic blood level of quinidine is 1.2 to 4.0 μ g/mL. Intravenous (IV) quinidine is rarely used due to vasodilation and myocardial depression.

Mechanism of Action

Quinidine is the dextroisomer of quinine and, like quinine, has antimalarial and antipyretic effects. Unlike quinine, however, quinidine has intense effects on the heart. For example, quinidine decreases the slope of phase 4 depolarization, which explains its effectiveness in suppressing cardiac arrhythmias caused by enhanced automaticity. Quinidine increases the fibrillation threshold in the atria and ventricles. Quinidine-

induced slowing of the conduction of cardiac impulses through normal and abnormal fibers may be responsible for the ability of quinidine to occasionally convert atrial flutter or fibrillation to normal sinus rhythm. This drug can abolish reentry arrhythmias by prolonging conduction of cardiac impulses in an area of injury, thus converting one-way conduction blockade to two-way conduction blockade. A decrease in the atrial rate during atrial flutter or fibrillation may reflect slowed conduction velocity, a prolonged effective refractory period in the atria, or both.

Metabolism and Excretion

Quinidine is hydroxylated in the liver to inactive metabolites, which are excreted in the urine. About 20% of quinidine is excreted unchanged in the urine. Enzyme induction significantly shortens the duration of action of quinidine. The concurrent administration of phenytoin, phenobarbital, or rifampin may lower blood levels of quinidine by enhancing liver clearance. Because of its dependence on renal excretion and hepatic metabolism for clearance from the body, accumulation of quinidine or its metabolites may occur in the presence of impaired function of these organs. About 80% to 90% of quinidine in plasma is bound to albumin. Quinidine accumulates rapidly in most tissues except the brain.

Side Effects

Quinidine has a low therapeutic ratio, with heart block, hypotension, and proarrhythmia being potential adverse side effects. As the plasma concentration increases to more than 2 $\mu\text{g}/\text{mL}$, the P-R interval, QRS complex, and QTc interval on the ECG are prolonged. Patients with preexisting prolongation of the QTc interval or evidence of atrioventricular heart block on the ECG should not be treated with quinidine.

Patients in normal sinus rhythm treated with quinidine may show an increase in heart rate that is a result of presumably either an anticholinergic action and/or a reflex increase in sympathetic nervous system activity. This atropine-like action of quinidine opposes its direct depressant actions on the sinoatrial and atrioventricular nodes and is why digitalis is often given before quinidine therapy is initiated.

Allergic reactions may include drug rash or a drug fever that is occasionally associated with leukocytosis. Thrombocytopenia is a rare occurrence that is caused by drug-platelet complexes that evoke production of antibodies. Discontinuation of quinidine results in return of the platelet count to normal in 2 to 7 days. Nausea, vomiting, and diarrhea occur in about one-third of treated patients.

Like other cinchona alkaloids and salicylates, quinidine can cause cinchonism. Symptoms of cinchonism include tinnitus, decreased hearing acuity, blurring of vision, and gastrointestinal upset. In severe cases, there may be abdominal pain and mental confusion.

Because quinidine is an α -adrenergic blocking drug, it can interact in an additive manner with drugs that cause vasodilation. Quinidine also interferes with normal neuromuscular transmission and may accentuate the effect of neuromuscular blocking drugs. Recurrence of skeletal muscle paralysis in the immediate postoperative period has been observed in association with the administration of quinidine.²⁴

Procainamide

Procainamide is as effective as quinidine for the treatment of ventricular tachyarrhythmias but less effective in abolishing atrial tachyarrhythmias ([Figure 21.3](#)). Premature ventricular contractions and paroxysmal ventricular tachycardia are suppressed in most patients within a few minutes after IV administration, which is better tolerated than IV quinidine but may still cause hypotension. Procainamide can be administered IV at a rate not exceeding 100 mg every 5 minutes until the rhythm is controlled (maximum 15 mg/kg). When the cardiac arrhythmia is controlled, a constant rate of infusion (2-6 mg per minute) is used to maintain a therapeutic concentration of procainamide. The systemic blood pressure and ECG (QRS complex) are monitored continuously during infusion of this drug. The therapeutic blood level of procainamide is 4 to 8 $\mu\text{g}/\text{mL}$.

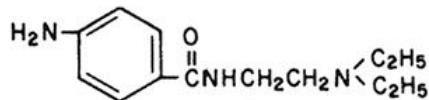

FIGURE 21.3 Procainamide.

Mechanism of Action

Procainamide is an analogue of the local anesthetic procaine. Procainamide possesses an electrophysiologic action similar to that of quinidine but produces less prolongation of the QTc interval on the ECG. As a result, paradoxical ventricular tachycardia is a rare feature of procainamide therapy. Procainamide has no vagolytic effect and can be used in patients with atrial fibrillation to suppress ventricular irritability without increasing the ventricular rate. Like quinidine, procainamide may prolong the QRS complex and cause ST-T wave changes on the ECG.

Metabolism and Excretion

Procainamide is eliminated by renal excretion and hepatic metabolism. In humans, 40% to 60% of procainamide is excreted unchanged by the kidneys. The dose of procainamide must be decreased when renal function is abnormal. In the liver, procainamide that has not been excreted unchanged by the kidneys is acetylated to *N*-acetyl procainamide (NAPA), which is also eliminated by the kidneys. This metabolite is cardioactive and probably contributes to the antiarrhythmic effects of procainamide. In the presence of renal failure, plasma concentrations of NAPA may reach dangerous levels. Eventually, 90% of an administered dose of procainamide is recovered as unchanged drug or its metabolites.

The activity of the *N*-acetyltransferase enzyme response for the acetylation of procainamide is genetically determined. In patients who are rapid acetylators, the elimination half-time of procainamide is 2.5 hours compared with 5 hours in slow acetylators. The blood level of NAPA exceeds that of procainamide in rapid but not slow acetylators. Unlike its analogue, procaine, procainamide is highly resistant to hydrolysis by plasma cholinesterase. Evidence of this resistance is the fact that only 2% to 10% of an administered dose of procainamide is recovered unchanged in the urine as para-aminobenzoic acid.

Only about 15% of procainamide is bound to plasma proteins. Despite this limited binding in plasma, procainamide is avidly bound to tissue proteins with the exception of the brain.

Side Effects

Similar to quinidine, use of procainamide has dramatically decreased due to its side effect profile and availability of newer agents. Hypotension that results from procainamide is more likely to be caused by direct myocardial depression than peripheral vasodilation. Indeed, rapid IV injection of procainamide is associated with hypotension, whereas higher plasma concentrations slow conduction of cardiac impulses through the atrioventricular node and intraventricular conduction system. Ventricular asystole or fibrillation may occur when procainamide is administered in the presence of heart block, as associated with digitalis toxicity. Direct myocardial depression that occurs at high plasma concentrations of procainamide is exaggerated by hyperkalemia. As with quinidine, ventricular arrhythmias may accompany excessive plasma concentrations of procainamide.

Chronic administration of procainamide may be associated with a syndrome that resembles systemic lupus erythematosus. Serositis, arthritis, pleurisy, or pericarditis may develop, but unlike systemic lupus erythematosus, vasculitis is not usually present. Patients with this lupus-like syndrome often develop antinuclear antibodies (positive antinuclear antibody test). Slow acetylators are more likely than rapid acetylators to develop antinuclear antibodies. Symptoms disappear when procainamide is discontinued.

As with many drugs, procainamide may cause drug fever or an allergic rash. Although agranulocytosis is rare, leukopenia and thrombocytopenia may be seen after chronic use of procainamide, often in association with the lupus-like syndrome. The most common early, noncardiac complications of procainamide are gastrointestinal disturbances, including nausea and vomiting.

Disopyramide

Disopyramide is comparable to quinidine in effectively suppressing atrial and ventricular tachyarrhythmias (**Figure 21.4**). Absorption of oral disopyramide is almost complete, resulting in peak blood levels within 2

hours of administration. Therapeutic plasma concentrations of disopyramide are 2 to 4 $\mu\text{g}/\text{mL}$. About 50% of the drug is excreted unchanged by the kidneys. As a result, the typical elimination half-time of 8 to 12 hours is prolonged in the presence of renal dysfunction. A dealkylated metabolite with less antiarrhythmic and atropine-like activity than the parent drug accounts for about 20% of the drug's elimination. Disopyramide is not available in an IV formulation.

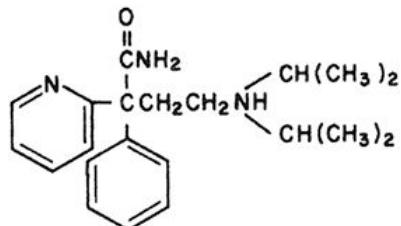

FIGURE 21.4 Disopyramide.

Side Effects

The most common side effects of disopyramide are dry mouth and urinary hesitancy, both of which are caused by the drug's anticholinergic activity. Some patients taking disopyramide also experience blurred vision or nausea. Prolongation of the QTc interval on the ECG and paradoxical ventricular tachycardia (similar to quinidine) may occur. For this reason, disopyramide should be administered cautiously if patients have known cardiac conduction effects. Disopyramide has significant myocardial depressant effects and can precipitate congestive heart failure and hypotension. The potential for direct myocardial depression, especially in patients with preexisting left ventricular dysfunction, seems to be greater with this drug than with quinidine and procainamide.

Moricizine

Moricizine is a phenothiazine derivative with modest efficacy in the treatment of sustained ventricular arrhythmias. In view of its proarrhythmic effects, this drug is reserved for the treatment of life-threatening ventricular arrhythmias when other drugs such as amiodarone are not available or contraindicated (eg, allergy). It is not effective in the treatment of atrial arrhythmias. Moricizine decreases the fast inward sodium ion current and also decreases automaticity.

Side Effects

Proarrhythmic effects occur in 3% to 15% of patients treated chronically with moricizine. Patients with poor left ventricular function tolerate moricizine and small increases in systemic blood pressure and heart rate may accompany therapy. Plasma concentrations of theophylline may increase in patients treated with moricizine.

Lidocaine

Lidocaine is used principally for suppression of ventricular arrhythmias, having minimal if any effect on supraventricular tachyarrhythmias (see [Chapter 10](#)). This drug is particularly effective in suppressing reentry cardiac arrhythmias, such as premature ventricular contractions and ventricular tachycardia. The efficacy of prophylactic lidocaine therapy for preventing early ventricular fibrillation after acute myocardial infarction has not been documented and is no longer recommended (see earlier discussion).

In adult patients with a normal cardiac output, hepatic function, and hepatic blood flow, an initial administration of lidocaine, 2 mg/kg IV, followed by a continuous infusion of 1 to 4 mg per minute should provide therapeutic plasma lidocaine concentrations of 1 to 5 $\mu\text{g}/\text{mL}$. Decreased cardiac output and/or hepatic blood flow, as produced by anesthesia, acute myocardial infarction, or congestive heart failure, may decrease by 50% or more of the initial dose and the rate of lidocaine infusion necessary to maintain therapeutic plasma levels. Concomitant administration of drugs such as propranolol and cimetidine can result in decreased hepatic clearance of lidocaine. Advantages of lidocaine over quinidine or procainamide are the more rapid onset and prompt disappearance of effects when the continuous infusion is terminated, greater therapeutic

index, and a much reduced side effect profile. Lidocaine for IV administration differs from that used for local anesthesia because it does not contain a preservative. Lidocaine is also well absorbed after oral administration but is subject to extensive hepatic first-pass metabolism. As a result, only about one-third of an oral dose of lidocaine reaches the circulation. Mexiletine (see the following text) is an oral analogue of lidocaine. Intramuscular (IM) absorption of lidocaine is nearly complete. In an emergency situation, lidocaine, 4 to 5 mg/kg IM, will produce a therapeutic plasma concentration in about 15 minutes. This level is maintained for about 90 minutes.

Mechanism of Action

Lidocaine delays the rate of spontaneous phase 4 depolarization by preventing or diminishing the gradual decrease in potassium ion permeability that normally occurs during this phase. The effectiveness of lidocaine in suppressing premature ventricular contractions reflects its ability to decrease the rate of spontaneous phase 4 depolarization. The ineffectiveness of lidocaine against supraventricular tachyarrhythmias presumably reflects its inability to alter the rate of spontaneous phase 4 depolarization in atrial cardiac cells.

In usual therapeutic doses, lidocaine has no significant effect on either the QRS or QTc interval on the ECG or on atrioventricular conduction. In high doses, however, lidocaine can decrease conduction in the atrioventricular node as well as in the His-Purkinje system.

Metabolism and Excretion

Lidocaine is metabolized in the liver, and resulting metabolites may possess cardiac antiarrhythmic activity.

Side Effects

Lidocaine is essentially devoid of effects on the ECG or cardiovascular system when the plasma concentration remains less than 5 µg/mL. In contrast to quinidine and procainamide, lidocaine does not alter the duration of the QRS complex on the ECG, and activity of the sympathetic nervous system is not changed. Lidocaine depresses cardiac contractility less than any other antiarrhythmic drug used to suppress ventricular arrhythmias. Toxic plasma concentrations of lidocaine (>5-10 µg/mL) produce peripheral vasodilation and direct myocardial depression, resulting in hypotension. In addition, slowing of conduction of cardiac impulses may manifest as bradycardia, a prolonged P-R interval, and widened QRS complex on the ECG. Stimulation of the central nervous system (CNS) occurs in a dose-related manner, with symptoms appearing when plasma concentrations of lidocaine are greater than 5 µg/mL. Seizures are possible at plasma concentrations of 5 to 10 µg/mL. The CNS depression, apnea, and cardiac arrest are possible when plasma lidocaine concentrations are greater than 10 µg/mL. The convulsive threshold for lidocaine is decreased during arterial hypoxemia, hyperkalemia, or acidosis, emphasizing the importance of monitoring these parameters during continuous infusion of lidocaine to patients for suppression of ventricular arrhythmias.

Mexiletine

Mexiletine is an orally effective amine analogue of lidocaine that is used for the chronic suppression of ventricular cardiac tachyarrhythmias. Combination with a β blocker or another antiarrhythmic drug such as quinidine or procainamide results in a synergistic effect that permits a decrease in the dose of mexiletine and an associated decrease in the incidence of side effects. Electrophysiologically, mexiletine is similar to lidocaine. The addition of the amine side group enables mexiletine to avoid significant hepatic first-pass metabolism that limits the effectiveness of orally administered lidocaine. The usual adult dose is 150 to 200 mg every 8 hours. As it is a lidocaine analogue, mexiletine may be effective in decreasing neuropathic pain for patients in whom alternative pain medications have been unsatisfactory.²⁵

Side Effects

Epigastric burning may occur and is often relieved by taking the drug with meals. Neurologic side effects include tremulousness, diplopia, vertigo, and occasionally slurred speech. Cardiovascular side effects resemble lidocaine. Increases in liver enzymes may occur especially in patients manifesting congestive heart

failure. Blood dyscrasias occur rarely. Proarrhythmic effects may manifest in occasionally treated patients. Toxic effects may develop at plasma concentrations only slightly above therapeutic levels.

Tocainide

Tocainide, like mexiletine, is an orally effective amine analogue of lidocaine that was formerly used for the chronic suppression of ventricular cardiac tachyarrhythmias but is no longer available in the United States. Its side effects resemble those of mexiletine, but in rare patients, this drug has caused severe bone marrow depression (leukopenia, anemia, thrombocytopenia) and pulmonary fibrosis.²⁵ The usual adult dose is 400 to 800 mg administered every 8 hours. As with mexiletine, the combination of tocainide with a β -adrenergic blocker or another antiarrhythmic drug has a synergistic effect.

Phenytoin

Phenytoin is particularly effective in suppression of ventricular arrhythmias associated with digitalis toxicity. This drug is effective, although to a lesser extent than quinidine, procainamide, and lidocaine, in the treatment of ventricular arrhythmias due to other causes. Phenytoin may be useful in the treatment of paradoxical ventricular tachycardia or torsades de pointes that is associated with a prolonged QTc interval on the ECG. Treatment of atrial tachyarrhythmias with phenytoin is not very effective.

Phenytoin can be administered orally or IV. The IM administration is too unreliable to treat cardiac arrhythmias. The IV dose is 100 mg (1.5 mg/kg) every 5 minutes until the cardiac arrhythmia is controlled or 10 to 15 mg/kg (maximum 1,000 mg) has been administered. Because phenytoin can precipitate in 5% dextrose in water, it is preferable to give the drug via a delivery tubing containing normal saline. Slow IV injection into a large peripheral or central vein is recommended to minimize the likelihood of discomfort or thrombosis at the injection site. Therapeutic blood levels range from 10 to 18 μ g/mL.

Mechanism of Action

The effects of phenytoin on automaticity and velocity of conduction of cardiac impulses resemble those of lidocaine. Phenytoin exerts a greater effect on the electrocardiographic QTc interval than does lidocaine and shortens the QTc interval more than any of the other antiarrhythmic drugs. Phenytoin has no significant effect on the ST-T waves or the QRS complex. It does not significantly depress the myocardium in usual doses but can cause hypotension when administered in high doses rapidly. Conduction of cardiac impulses through the atrioventricular node is improved, but activity of the sinus node may be depressed. The ability of some volatile anesthetics to depress the sinoatrial node is a consideration if administration of phenytoin during general anesthesia is planned.

Metabolism and Excretion

Phenytoin is hydroxylated and then conjugated with glucuronic acid for excretion in the urine. The elimination half-time is about 24 hours. Because phenytoin is metabolized by the liver, impaired hepatic function may result in higher than normal blood levels of the drug. Blood levels of phenytoin can be lowered by drugs, such as barbiturates, that enhance its rate of metabolism. Warfarin, phenylbutazone, and isoniazid may inhibit metabolism and increase phenytoin blood levels. Uremia increases the unbound fraction of phenytoin relative to the plasma-bound portion.

Side Effects

Phenytoin toxicity most commonly manifests as CNS disturbances, especially cerebellar disturbances. Symptoms include ataxia, nystagmus, vertigo, slurred speech, sedation, and mental confusion. Cerebellar symptoms correlate with phenytoin blood levels of greater than 18 μ g/mL. Cardiac arrhythmias that have not been suppressed at this concentration are unlikely to respond favorably to further increases in the dosage of phenytoin. Phenytoin partially inhibits insulin secretion and may lead to increased blood glucose levels in patients who are hyperglycemic. Leukopenia, granulocytopenia, and thrombocytopenia may occur as a manifestation of drug-induced bone marrow depression. Nausea, skin rash, and megaloblastic anemia may occur.

Flecainide

Flecainide is a fluorinated local anesthetic analogue of procainamide that is more effective in suppressing ventricular premature beats and ventricular tachycardia than quinidine and disopyramide ([Figure 21.5](#)). Flecainide is also effective for the treatment of atrial tachyarrhythmias. Because it delays conduction in the bypass tracts, flecainide can be effective for the treatment of tachyarrhythmias due to reentry mechanisms as associated with the Wolff-Parkinson-White syndrome. Chronic treatment of ventricular arrhythmias with flecainide after myocardial infarction is not recommended due to an increased incidence of sudden death in treated patients.²⁶ Thus, flecainide should be reserved for the treatment of life-threatening arrhythmias.²⁷ This drug is sometimes used to treat arrhythmias in the fetus as it crosses the placenta.²⁷

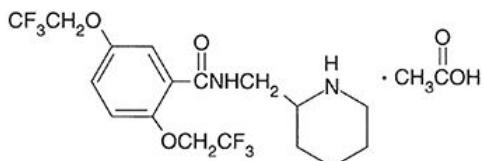

FIGURE 21.5 Flecainide.

Metabolism and Excretion

Oral absorption of flecainide is excellent, and a prolonged elimination half-time (about 20 hours) makes a twice daily dose of 100 to 200 mg acceptable. This drug is not available in an IV formulation. About 25% of flecainide is excreted unchanged by the kidneys, and the remainder appears as weakly active metabolites. Elimination of flecainide is decreased in patients with congestive heart failure or renal failure. Flecainide competes with metabolic pathways used by other drugs and as a result may increase the plasma concentrations of digoxin and propranolol. Coadministration of amiodarone and flecainide can double plasma flecainide concentrations. Phenytoin and other drugs that stimulate hepatic P450 enzymes may speed the elimination of flecainide. The therapeutic plasma concentration of flecainide ranges from 0.2 to 1.0 µg/mL. Flecainide has a moderate negative inotropic effect and a proarrhythmic effect, especially in patients with preexisting decreased left ventricular function. Vertigo and difficulty in visual accommodation are common dose-related side effects of flecainide therapy.

Side Effects

Proarrhythmic effects occur in a significant number of treated patients especially in the presence of left ventricular dysfunction. Flecainide prolongs the QRS complex by 25% or more and, to a lesser extent, prolongs the P-R interval on the ECG. These changes suggest the possibility of atrioventricular or infranodal conduction block of cardiac impulses. Flecainide may depress sinoatrial node function as do β-adrenergic antagonists and calcium channel blockers. For these reasons, flecainide is not administered to patients with second- and third-degree atrioventricular heart block. The most common noncardiac adverse effect of flecainide is dose-related blurred vision. Flecainide increases the capture thresholds of pacemakers. This is the amount of current required to electrically capture cardiac tissue. Therefore, capture thresholds should be remeasured in individuals with pacemakers after the steady-state flecainide dosage is changed.²⁸

Propafenone

Propafenone, like flecainide, is an effective oral antiarrhythmic drug for suppression of ventricular and atrial tachyarrhythmias. This drug possesses weak β-adrenergic blocking and calcium blocking effects. Propafenone may be proarrhythmic, especially in patients with poor left ventricular function and sustained ventricular tachycardia.

Absorption after oral administration is excellent, and peak plasma levels occur in about 3 hours. The rate of metabolism is genetically determined with about 90% of patients able to metabolize propafenone efficiently in the liver. The principal metabolites in those who metabolize the drug rapidly are

pharmacologically active and equivalent in antiarrhythmic potency to the parent drug. Because of extensive metabolism, the availability of propafenone increases significantly in the presence of liver disease.

Side Effects

Proarrhythmic effects are more likely to occur in patients with preexisting ventricular arrhythmias. Propafenone depresses the myocardium and may cause conduction abnormalities such as sinoatrial node slowing, atrioventricular block, and bundle-branch block. Small doses of quinidine inhibit the metabolism of propafenone, whereas propafenone interferes with the metabolism of propranolol and metoprolol resulting in increased plasma concentrations of these β blockers. This drug also increases the plasma concentration of warfarin and may prolong the prothrombin time. Vertigo, disturbances in taste, and blurred vision are the common side effects. Nausea and vomiting may occur, and, rarely, cholestatic hepatitis or worsening of asthma manifests.

β -Adrenergic Antagonists

β -Adrenergic antagonists are effective for treatment of cardiac arrhythmias related to enhanced activity of the sympathetic nervous system (perioperative stress, thyrotoxicosis, pheochromocytoma). Propranolol and esmolol are effective for controlling the rate of ventricular response in patients with atrial fibrillation and atrial flutter. Multifocal atrial tachycardia may respond to esmolol or metoprolol but is best treated with amiodarone. Comparable doses of metoprolol (5-15 mg IV over 20 minutes, which lasts 5-7 hours) produces antiarrhythmic effects similar to those of propranolol as well as the same potential side effects. Acebutolol is effective in the treatment of frequent premature ventricular contractions. β -Adrenergic antagonists, especially propranolol, may be effective in controlling torsades de pointes for patients with prolonged QTc intervals. Acebutolol, propranolol, and metoprolol are approved for prevention of sudden death following myocardial infarction. For example, in contrast to class I antiarrhythmic drugs, propranolol decreases sudden death as well as reinfarction rates in the first year after acute myocardial infarction.¹⁶

Mechanism of Action

The antiarrhythmic effects of β -adrenergic antagonists most likely reflect blockade of the responses of β receptors in the heart to sympathetic nervous system stimulation as well as the effects of circulating catecholamines. As a result, the rate of spontaneous phase 4 depolarization and sinoatrial node discharge is decreased. The rate of conduction of cardiac impulses through the atrioventricular node is slowed as reflected by a prolonged P-R interval on the ECG. This drug has little effect on the ST-T wave, although it may shorten the overall QTc interval. β -Adrenergic antagonists can depress the myocardium not only by β blockade but also by direct depressant effects on cardiac muscle. In addition to β -adrenergic blockade, these drugs cause alterations in the electrical activity of myocardial cells. This cell membrane effect is probably responsible for some of the antidysrhythmic effects of β -adrenergic antagonists. Indeed, dextropropranolol, which lacks β -adrenergic antagonist activity, is an effective cardiac antiarrhythmic.

The usual oral dose of propranolol for chronic suppression of ventricular arrhythmias is 10 to 80 mg every 6 to 8 hours. The total daily dose is determined by the physiologic effects of propranolol on the heart rate and systemic blood pressure. Effective β blockade is usually achieved in an otherwise normal person when the resting heart rate is 55 to 60 beats per minute. For emergency suppression of cardiac arrhythmias in an adult, propranolol may be administered IV in a dose of 1 mg per minute (3-6 mg). The onset of action after IV administration is within 2 to 5 minutes, the peak effect at the atrioventricular node is within 10 to 15 minutes, and the duration of action is 3 to 4 hours. Administration at 1-minute intervals is intended to minimize the likelihood of excessive pharmacologic effects on the conduction of cardiac impulses. In patients with marginal systemic blood pressure or left ventricular dysfunction, the rate of administration may need to be slowed and the total dose limited to less than 3 mg.

Metabolism and Excretion

Orally administered propranolol is extensively metabolized in the liver, and a hepatic first-pass effect is responsible for the variation in plasma concentration; the therapeutic plasma concentration of propranolol

may vary from 10 to 30 ng/mL. Propranolol readily crosses the blood–brain barrier. The principal metabolite of propranolol is 4-hydroxypropranolol, which possesses weak β -adrenergic antagonist activity. This active metabolite most likely contributes to the antiarrhythmic activity after the oral administration of propranolol. The elimination half-time of propranolol is 2 to 4 hours, although the antiarrhythmic activity usually persists for 6 to 8 hours.

Side Effects

Bradycardia, hypotension, myocardial depression, and bronchospasm are side effects of β -adrenergic antagonists that reflect the ability of these drugs to inhibit sympathetic nervous system activity. Patients with any degree of congestive heart failure are highly dependent on increased sympathetic nervous system activity as a compensatory mechanism. Attenuation of this compensatory response may accentuate congestive heart failure. In addition, the direct depressant effects of propranolol on myocardial contractility may further accentuate congestive heart failure. The use of propranolol in patients with preexisting atrioventricular heart block is not recommended. Propranolol may cause drug fever, an allergic rash, or nausea and may increase esophageal reflux. Cold extremities and worsening of Raynaud disease may occur. Interference with glucose metabolism may manifest as hypoglycemia in patients being treated for diabetes mellitus. The most common CNS side effects are mental depression and fatigue. Reversible alopecia may occur. Upregulation of β -adrenergic receptors occurs with chronic administration of β -adrenergic antagonists such that abrupt discontinuation of treatment may lead to supraventricular tachycardia that is particularly undesirable in patients with coronary artery disease. Slowly tapering the dose of β -adrenergic antagonist will prevent withdrawal responses.

Amiodarone

Amiodarone is a potent antiarrhythmic drug with a wide spectrum of activity against refractory supraventricular and ventricular tachyarrhythmias. In the presence of ventricular tachycardia or fibrillation that is resistant to electrical defibrillation, amiodarone 300 mg IV is recommended. Preoperative oral administration of amiodarone decreases the incidence of atrial fibrillation after cardiac surgery.²⁹ It is also effective for suppression of tachyarrhythmias associated with Wolff-Parkinson-White syndrome because it depresses conduction in the atrioventricular node and the accessory bypass tracts. Similar to β blockers and unlike class I drugs, amiodarone decreases mortality after myocardial infarction.³⁰

After initiation of oral therapy, a decrease in ventricular tachyarrhythmias occurs within 72 hours. The maintenance dose can usually be gradually decreased to about 400 mg daily for suppression of ventricular tachyarrhythmias and 200 mg daily for suppression of supraventricular tachyarrhythmias. Administered IV over 2 to 5 minutes, a dose of 5 mg/kg produces a prompt antiarrhythmic effect that lasts up to 4 hours. Therapeutic blood concentrations of amiodarone are 1.0 to 3.5 $\mu\text{g}/\text{mL}$. After discontinuation of chronic oral therapy, the pharmacologic effect of amiodarone lasts for a prolonged period (up to 60 days), reflecting the prolonged elimination half-time of this drug.

Mechanism of Action

Amiodarone, a benzofuran derivative, is 37% iodine by weight and structurally resembles thyroxine ([Figure 21.6](#)). It prolongs the effective refractory period in all cardiac tissues, including the sinoatrial node, atrium, atrioventricular node, His-Purkinje system, ventricle, and, in the case of Wolff-Parkinson-White syndrome, accessory bypass tracts. Amiodarone has an antiadrenergic effect (noncompetitive blockade of α and β receptors) and a minor negative inotropic effect, which may be offset by the drug's potent vasodilating properties.³¹ Amiodarone acts as an antianginal drug by dilating coronary arteries and increasing coronary blood flow.

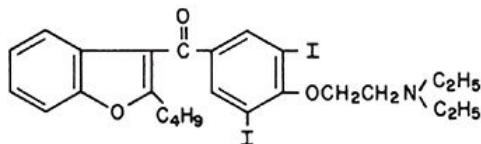

FIGURE 21.6 Amiodarone.

Metabolism and Excretion

Amiodarone has a prolonged elimination half-time (29 days) and large volume of distribution ([Figure 21.7](#)).³² This drug is minimally dependent on renal excretion as evidenced by an unchanged elimination half-time in the absence of renal function.³² The principal metabolite, desethylamiodarone, is pharmacologically active and has a longer elimination half-time than the parent drug, resulting in accumulation of this metabolite with chronic therapy. Protein binding of amiodarone is extensive, and the drug is not easily removed by hemodialysis. There is an inconsistent relationship between the plasma concentration of amiodarone and its pharmacologic effects as the ultimate concentration of drug in the myocardium is 10 to 50 times that present in the plasma.

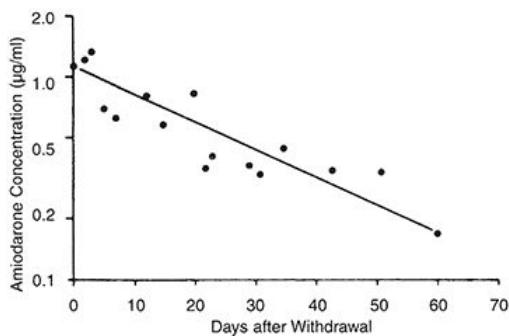

FIGURE 21.7 After discontinuation of amiodarone, the plasma concentration decreases slowly, resulting in a prolonged elimination half-time. *From Kannan R, Nademanee K, Hendrickson JA, et al. Amiodarone kinetics after oral doses. Clin Pharmacol Ther. 1982;31(4):438-444. Copyright © 1982 American Society for Clinical Pharmacology and Therapeutics. Reprinted by permission of John Wiley & Sons, Inc.*

Side Effects

Side effects in patients treated chronically with amiodarone are common, especially when the daily maintenance dose exceeds 400 mg.³³ Screening tests, such as chest radiographs and tests for pulmonary function, thyroid-stimulating hormone, and liver function, are recommended. Other than the pulmonary function tests, these studies should be repeated at 3, 6, and 12 months and annually thereafter.³⁴

Pulmonary Toxicity

The most serious side effect of amiodarone is pulmonary alveolitis (pneumonitis).^{35,36} The overall incidence of amiodarone-induced pulmonary toxicity is estimated at 5% to 15% of treated patients, with a reported mortality of 5% to 10%. The cause of this drug-induced pulmonary toxicity is not known but may reflect the ability of amiodarone to enhance production of free oxygen radicals in the lungs that in turn oxidize cellular proteins, membrane lipids, and nucleic acids. It is suggested that high-inspired oxygen concentrations may accelerate these reactions.³⁷ For this reason, it may be prudent to restrict the inspired concentration of oxygen in patients receiving amiodarone and undergoing general anesthesia to the lowest level capable of maintaining adequate systemic oxygenation.³⁸ Indeed, postoperative pulmonary edema has been reported in patients being treated chronically with amiodarone.³⁸ Furthermore, there is evidence that patients with preexisting evidence of amiodarone-induced pulmonary toxicity are at increased risk for developing adult respiratory distress syndrome after surgery that requires cardiopulmonary bypass.^{39,40} It must be recognized, however, that no animal model has established a cause-and-effect relationship between oral amiodarone administration and secondary oxygen-enhanced pulmonary toxicity.

There are two distinct types of presentation of patients with amiodarone-induced pulmonary toxicity.³⁶ The more common form of pulmonary toxicity consists of a slow insidious onset of progressive dyspnea,

cough, weight loss, and pulmonary infiltrates on the chest x-ray. The second form of pulmonary toxicity has a much more acute onset of dyspnea, cough, arterial hypoxemia, and occasionally fever that may mimic an infectious pneumonia. Postoperative pulmonary edema attributed to amiodarone-induced pulmonary toxicity reflects this acute form of onset.

Cardiovascular

Like quinidine and disopyramide, amiodarone may prolong the QTc interval on the ECG, which may lead to an increased incidence of ventricular tachyarrhythmias, including torsades de pointes (proarrhythmic effect). Heart rate often slows and is resistant to treatment with atropine. Responsiveness to catecholamines and sympathetic nervous system stimulation is decreased as a result of drug-induced inhibition of α - and β -adrenergic receptors. Direct myocardial depressant effects are presumed to be minimal.⁴¹ The IV administration of amiodarone may result in hypotension, most likely reflecting the peripheral vasodilating effects of this drug. Atrioventricular heart block may also occur when the drug is administered IV. The negative inotropic effects of amiodarone may be enhanced in the presence of general anesthesia, β -adrenergic blockers, and calcium channel blockers.⁴² Drugs that inhibit automaticity of the sinoatrial node (lidocaine) could accentuate the effects of amiodarone and increase the likelihood of sinus arrest. The potential need for a temporary artificial cardiac (ventricular) pacemaker and administration of a sympathomimetic such as isoproterenol may be a consideration in patients being treated with this drug and scheduled to undergo surgery.⁴³

Ocular, Dermatologic, Neurologic, and Hepatic

Corneal microdeposits occur in most patients during amiodarone therapy, but visual impairment is unlikely. Optic neuropathy has been found in 1.8% of patients treated with amiodarone compared to 0.3% of the general population.⁴⁴ Optic neuropathy from amiodarone typically has a more insidious onset, milder degree of visual loss, longer duration of disc edema, and more often bilateral. Discontinuation often leads to slow improvement in visual acuity. Photosensitivity and rash develop in up to 10% of patients. Rarely, there may be a cyanotic discoloration (slate-gray pigmentation) of the face that persists even after the drug is discontinued. Neurologic toxicity may manifest as peripheral neuropathy, tremors, sleep disturbance, headache, or proximal skeletal muscle weakness.⁴⁵ Transient, mild increases in plasma transaminase concentrations may occur, and fatty liver infiltration has been observed.⁴⁵

Pharmacokinetic

Amiodarone inhibits hepatic P450 enzymes resulting in increased plasma concentrations of digoxin, procainamide, quinidine, warfarin, and cyclosporine. Amiodarone also displaces digoxin from protein-binding sites. The digoxin dose may be decreased as much as 50% when administered in the presence of amiodarone. Amiodarone also increases the plasma concentrations of quinidine, procainamide, and phenytoin. The anticoagulant effects of warfarin are potentiated because amiodarone may directly depress vitamin K-dependent clotting factors.

Endocrine

Amiodarone contains iodine and has effects on thyroid metabolism, causing either hypothyroidism or hyperthyroidism in 2% to 4% of patients. Thyroid dysfunction may develop insidiously in these patients. Hyperthyroidism has occurred up to 5 months after discontinuation of amiodarone. Patients with preexisting thyroid dysfunction seem more likely to develop amiodarone-related alterations in thyroid function. Hyperthyroidism is best detected by finding an increased plasma concentration of triiodothyronine. Hypothyroidism is best detected by finding an increased plasma concentration of thyroid-stimulating hormone.

Amiodarone-induced hyperthyroidism reflecting the release of iodine from the parent drug is often refractory to conventional therapy. These patients may be intolerant of β -adrenergic blockade because of their underlying cardiomyopathies. When medical management fails, the performance of surgical thyroidectomy

provides prompt metabolic control. Bilateral superficial cervical plexus blocks have been described for anesthetic management of subtotal thyroidectomy in these patients.⁴⁶

Dronedarone

Dronedarone is a noniodinated benzofuran derivative of amiodarone that has been developed as an alternative for the treatment of atrial fibrillation and atrial flutter. Similar to amiodarone, dronedarone is a potent blocker of multiple ion currents and is currently recommended for treatment of atrial fibrillation and atrial flutter in people whose hearts have either returned to normal rhythm or who undergo drug therapy or direct current cardioversion to maintain normal rhythm. Dronedarone reduced the rate of hospitalization in atrial fibrillation patients but did not demonstrate a reduction in mortality.⁴⁷ A trial of the drug in heart failure was stopped as an interim analysis showed a possible increase in heart failure deaths in patients with moderate to severe congestive heart failure.⁴⁸ As a result, the clinical utility of dronedarone is significantly limited by its efficacy and contraindication in patients with permanent atrial fibrillation or patients with advanced or recent congestive heart failure exacerbations.

Mechanism of Action

Dronedarone blocks the L-type calcium current, the inward sodium current, and multiple potassium currents. It also has sympatholytic effects.⁴⁹ However, it is a more potent blocker of peak sodium current and has stronger in vitro antiadrenergic effects compared with amiodarone.

Metabolism and Excretion

Dronedarone is well absorbed (70%-94%) after oral administration, and absorption increases two- to threefold when it is taken with food. Dronedarone undergoes significant first-pass metabolism that reduces its net bioavailability to 15%. With sustained administration of 400 mg twice daily, steady-state plasma concentrations of 84 to 167 ng/mL are reached in 7 days. The clearance of dronedarone is principally nonrenal, with a terminal half-life of 20 to 40 hours. Dronedarone is a substrate for and a moderate inhibitor of CYP3A4. Consequently, dronedarone should not be coadministered with other CYP3A4 inhibitors such as antifungals, macrolide antibiotics, or protease inhibitors. When coadministered with moderate CYP3A4 inhibitors such as verapamil and diltiazem, lower doses of concomitant drugs should be used to avoid severe bradycardia and conduction block.⁴⁹

Side Effects

The most frequently reported adverse effect of dronedarone is nausea and diarrhea. As compared to placebo, patients in the treatment group of the ATHENA trial had significantly increased rates of bradycardia, QT interval prolongation, diarrhea, nausea, and serum creatinine increase. In the ATHENA trial, patients in the treatment group did not have increased rates of interstitial lung disease, hyperthyroid, or hypothyroidism.⁵⁰

Sotalol

Sotalol is a nonselective β-adrenergic antagonist drug at low doses, and at higher doses, it prolongs the cardiac action potential in the atria, ventricles, and accessory bypass tracts. Sotalol is administered for the treatment of sustained ventricular tachycardia or ventricular fibrillation.⁵¹ This drug is also approved for the treatment of atrial tachyarrhythmia including atrial fibrillation as may follow cardiac surgery. Sotalol is not recommended in patients with asthma, left ventricular dysfunction, and cardiac conduction abnormalities including prolonged QTc intervals on the ECG. Because of its proarrhythmic effects, this drug is usually restricted for use in patients with life-threatening ventricular arrhythmias.

The daily oral dose of sotalol is 240 to 320 mg administered twice daily. Because sotalol is excreted mainly by the kidneys, the dosing intervals should be lengthened in patients with renal dysfunction. Sotalol does not bind to plasma proteins, is not metabolized, and does not cross the blood-brain barrier to any extent. β-Adrenergic blocking effects of this drug primarily reflect activity of the levorotatory isomer.

Side Effects

The most dangerous side effect of sotalol is torsades de pointes, reflecting prolongation of the QTc interval on the ECG. Torsades de pointes is dose related, occurring in 0.5% of patients receiving 80 mg of sotalol daily and in 5.8% of patients receiving more than 320 mg daily. The β -blocking effects of sotalol result in decreased myocardial contractility, bradycardia, and delayed conduction of cardiac impulses through the atrioventricular node. Other side effects of sotalol include fatigue, dyspnea, vertigo, and nausea.

Ibutilide

Ibutilide is effective for the conversion of recent onset atrial fibrillation or atrial flutter to normal sinus rhythm. Hepatic metabolism is extensive with production of inactive metabolites with the exception of hydroxy metabolites that possess weak antiarrhythmic effects. Polymorphic ventricular tachycardia with or without prolongation of the QTc interval on the ECG may occur during ibutilide treatment, especially in patient with predisposing factors (impaired left ventricular function, preexisting prolonged QTc intervals, hypokalemia, hypomagnesemia).

Dofetilide

Dofetilide is a potent, pure potassium channel blocking drug of the class III antiarrhythmic drugs. Dofetilide causes a dose-dependent prolongation of the action potential duration and hence the QT interval. Dofetilide is effective for the conversion of recent onset atrial fibrillation or atrial flutter to normal sinus rhythm as well as the maintenance of normal sinus rhythm in patients who have been successfully cardioverted. Oral absorption is greater than 90%, and 80% of the drug is excreted unchanged in the urine. The starting dose of 0.5 mg twice daily is the highest acceptable dose. Dosage adjustments are indicated based on renal function. Trimethoprim, cimetidine, and prochlorperazine can inhibit renal clearance of dofetilide. Proarrhythmic effects of dofetilide may occur when it is coadministered with calcium channel blocking drugs. Dofetilide does not depress myocardial contractility. Torsades de pointes occurs in a dose-related manner, especially in patients with preexisting left ventricular dysfunction. By FDA mandate, a patient must be admitted to a certified hospital for at least 72 hours for cardiac monitoring during initiation of dofetilide. Such monitoring is necessary to determine the presence of QT prolongation.

Verapamil and Diltiazem

Among the calcium channel blockers, verapamil and diltiazem have the greatest efficacy for the treatment of cardiac arrhythmias.¹ Verapamil is highly effective in terminating paroxysmal supraventricular tachycardia, a reentrant tachycardia whose pathway usually includes the atrioventricular node. This drug also effectively controls the ventricular rate in most patients who develop atrial fibrillation or flutter. Verapamil, however, does not have a depressant effect on accessory tracts and thus will not slow the ventricular response rate in patients with Wolff-Parkinson-White syndrome. In fact, verapamil may cause reflex sympathetic nervous system activity that enhances conduction of cardiac impulses over accessory tracts and thus increases the ventricular response rate similar to digitalis. Verapamil has little efficacy in the therapy for ventricular ectopic beats.

The usual dose of verapamil for suppression of paroxysmal supraventricular tachycardia is 5 to 10 mg IV (75-150 μ g/kg) over 1 to 3 minutes followed by a continuous infusion of about 5 μ g/kg per minute to maintain a sustained effect. The administration of calcium gluconate, 1 g IV, approximately 5 minutes before administration of verapamil may decrease verapamil-induced hypotension without altering the drug's antiarrhythmic effects.⁵² Chronic treatment with oral verapamil, 80 to 120 mg every 6 to 8 hours, may be useful for prevention of paroxysmal supraventricular tachycardia and for control of the ventricular response rate in atrial fibrillation or atrial flutter. Diltiazem, 20 mg IV, produces antiarrhythmic effects similar to those of diazepam, and the potential side effects are similar.

Mechanism of Action

Verapamil and the other calcium channel blockers inhibit the flux of calcium ions across the slow channels of vascular smooth muscle and cardiac cells. This effect on calcium ion flux manifests as a decreased rate of spontaneous phase 4 depolarization. Verapamil has a substantial depressant effect on the atrioventricular node

and a negative chronotropic effect on the sinoatrial node. This drug exerts a negative inotropic effect on cardiac muscle and produces a moderate degree of vasodilation of the coronary arteries and systemic arteries.

Metabolism and Excretion

An estimated 70% of an injected dose of verapamil is eliminated by the kidneys, whereas up to 15% may be present in the bile. A metabolite, norverapamil, may contribute to the parent drug's antiarrhythmic effects. The need for a large oral dose is related to the extensive hepatic first-pass effect that occurs with the oral route of administration.

Side Effects

The side effects of verapamil used to treat cardiac arrhythmias reflect its effects on calcium ion flux into cardiac cells. Atrioventricular heart block is more likely in patients with preexisting defects in the conduction of cardiac impulses. Direct myocardial depression and decreased cardiac output are likely to be exaggerated in patients with poor left ventricular function. Peripheral vasodilation may contribute to hypotension. There may be potentiation of anesthetic-produced myocardial depression, and the effects of neuromuscular blocking drugs may be exaggerated.

By decreasing hepatic blood flow, cimetidine may increase the plasma concentration of verapamil. Verapamil, like quinidine, may increase the plasma concentration of digoxin by 50% to 75%. Excessive bradycardia has been observed when verapamil and propranolol are administered simultaneously.

Other Cardiac Antiarrhythmic Drugs

Digitalis

Digitalis preparations such as digoxin are effective cardiac antiarrhythmics for stabilization of atrial electrical activity and the treatment and prevention of atrial tachyarrhythmias. Because of their vagolytic effects, these drugs can also slow conduction of cardiac impulses through the atrioventricular node and thus slow the ventricular response rate in patients with atrial fibrillation. Conversely, digitalis preparations enhance conduction of cardiac impulses through accessory bypass tracts and can dangerously increase the ventricular response rate in patients with Wolff-Parkinson-White syndrome. The usual oral dose of digoxin is 0.5 to 1.0 mg in divided doses over 12 to 24 hours. Digitalis toxicity is a risk and may manifest as virtually any cardiac arrhythmia (most commonly atrial tachycardia with block).

Adenosine

Adenosine is an endogenous nucleoside that slows conduction of cardiac impulses through the atrioventricular node, making it an effective alternative to calcium channel blockers (verapamil) for the acute treatment of paroxysmal supraventricular tachycardia, including that due to conduction through accessory pathways in patients with Wolff-Parkinson-White syndrome.⁵³ This drug is not effective in the treatment of atrial fibrillation, atrial flutter, or ventricular tachycardia. The usual dose of adenosine is 6 mg IV followed, if necessary, by a repeat injection of 6 to 12 mg IV about 3 minutes later.

Adenosine receptors represent a logical target for treatment of pain. Adenosine agonists result in blockade of acute nociception and reduce hypersensitivity to thermal or mechanical stimuli in the presence of sensitization after peripheral inflammation or nerve injury. This response most likely reflects actions on extracellular G protein-coupled receptors present in the periphery nervous system and CNS, primarily in the spinal cord. Intrathecal administration of adenosine produces selective inhibition of hypersensitivity presumed to be due to central sensitization.⁵⁴

Mechanism of Action

Adenosine has cardiac electrophysiologic effects similar to those of the calcium channel blockers verapamil and diltiazem.¹ It stimulates cardiac adenosine₁ receptors to increase potassium ion currents, shorten the action potential duration, and hyperpolarize cardiac cell membranes. In addition, adenosine decreases cyclic adenosine monophosphate concentrations. Its short-lived cardiac effects (elimination half-time 10 seconds)

are due to carrier-mediated cellular uptake and metabolism to inosine by adenosine deaminase. Methylxanthines inhibit the actions of adenosine by binding to adenosine₁ receptors. Conversely, dipyridamole (adenosine uptake inhibitor) and cardiac transplantation (denervation hypersensitivity) potentiate the effects of adenosine.

Side Effects

The side effects associated with the rapid IV administration of adenosine include facial flushing, headache, dyspnea, chest discomfort, and nausea. Adenosine may produce transient atrioventricular heart block. Bronchospasm, although an uncommon complication, has been observed after the IV administration of adenosine, even in the absence of preexisting symptoms.^{55,56} It is recommended that adenosine be used with caution, if at all, in patients known to have active wheezing. Several theories have been proposed to account for adenosine's bronchoconstrictor effect, including activation of adenosine receptors on the bronchial smooth muscle, mast cell degranulation, and stimulation of prostaglandin formation.⁵⁷ The pharmacologic effects of adenosine are antagonized by methylxanthines (theophylline, caffeine) and potentiated by dipyridamole.

Ranolazine

Although developed as treatment for angina, ranolazine has been noted to have efficacy in treatment of atrial arrhythmias and suppression of nonsustained ventricular tachycardia. Ranolazine is a piperazine derivative with a chemical structure similar to lidocaine. The cellular effects of ranolazine are attributed to binding at the local anesthetic binding site of the voltage-gated sodium channel. It is currently approved for the adjunctive treatment of chronic stable angina; however, multiple ongoing studies are evaluating the efficacy and safety of ranolazine in treatment of atrial fibrillation.

Diuretics*

Updated by: Vikram V. Saxena • Maya Jalbout Hastie

Diuretics, commonly used in the treatment of hypertension and heart failure, consist of a group of drugs with different pharmacokinetic and pharmacodynamic properties. Their primary effect is to increase urine flow. Most diuretics produce their clinical effect by blocking sodium (Na) reabsorption in different locations of the nephron.¹ This results in increased Na delivery to the distal tubules. The normal driving force for potassium (K) excretion by distal renal tubules is the transtubular electrical potential difference created by Na reabsorption. The presence of Na in the distal tubules promotes the reabsorption of Na in exchange for secretion of K, therefore resulting in hypokalemia. Individual sites of action of the different diuretics are illustrated in [Figure 22.1](#). In general, diuretics with a site of action upstream of the collecting duct result in hyponatremia, hypokalemia, and metabolic alkalosis. In contrast, collecting duct diuretics result in hyperkalemia and metabolic acidosis.²

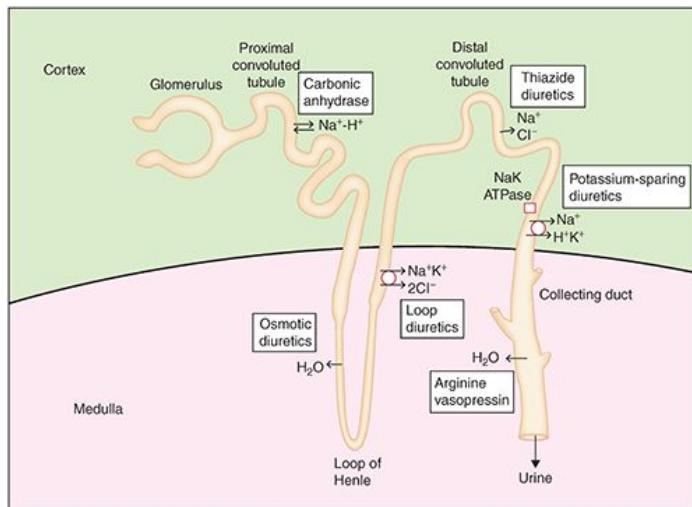

FIGURE 22.1 The sites of action of the different diuretics.

Carbonic Anhydride Inhibitors

Acetazolamide is the prototype of a class of sulfonamide drugs that bind avidly to carbonic anhydrase enzyme, producing noncompetitive inhibition of enzyme activity, principally in the proximal renal tubules, as well as the collecting ducts (see [Figure 22.1](#); [Table 22.1](#)).³ A Na-hydrogen (H) exchanger allows absorption of Na in exchange for secretion of H+ into the renal tubule.

TABLE 22.1

Diuretics and their sites of action

	Receptors	Main site of action	Clinical uses	Notable side effects
Carbonic anhydrase	Carbonic anhydrase	Proximal convoluted tubule	Altitude sickness Glaucoma	Metabolic acidosis
Loop diuretics	Na-K-2Cl cotransport	Medullary thick ascending loop of Henle	First-line diuretics in renal impairment	Ototoxicity Alkalosis Hypokalemia

Thiazides	Na-Cl cotransport	Cortical ascending loop of Henle	First-line therapy of hypertension	Alkalosis Hypokalemia Diabetes and dyslipidemia Hyperuricemia
Osmotic diuretics		Proximal convoluted tubule and loop of Henle	Increased intracranial pressure Oxygen free radical scavenging	Volume overload in CHF patients Hypokalemia, hyponatremia, hypomagnesemia
Potassium-sparing diuretics	Epithelial Na channel	Collecting duct	Adjuncts to loop diuretics or thiazides	Hyperkalemia
Aldosterone blockers	Na-K-ATPase	Collecting duct	Heart failure with low ejection fraction	Hyperkalemia
Dopamine and fenoldopam	D ₁	Proximal tubule and loop of Henle	Renal protection and hypertension treatment in critically ill patients	Effectiveness not substantiated
Brain natriuretic peptide	Na-K-ATPase	Collecting duct	Management of decompensated heart failure	
Vasopressin	V ₂	Collecting duct	SIADH, CHF, cirrhosis	Osmotic demyelination
Aquaporins	AQP	Collecting duct		

Abbreviations: AQP, aquaporin; ATPase, adenosine triphosphatase; CHF, congestive heart failure; Cl, chlorine; 2Cl, 2 units of chlorine ions; K, potassium; Na, sodium; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Bicarbonate (HCO_3^-) and H^+ combine in the proximal tubule lumen to produce carbonic acid. Carbonic anhydrase enzyme catalyzes the otherwise slow breakdown of carbonic acid into carbon dioxide (CO_2) and water; CO_2 diffuses readily into the tubular cells, where cytoplasmic carbonic anhydrase catalyzes the reverse reaction leading to HCO_3^- , which then follows an electrochemical gradient across the basal membrane into the interstitium. The net result is absorption of HCO_3^- . Inhibition of carbonic anhydrase in the proximal renal tubule results in decreased reabsorption of Na^+ , HCO_3^- , and water.³

Pharmacokinetics and Pharmacodynamics

After oral administration, acetazolamide is excreted unchanged by the kidneys. The dose should be adjusted in patients with renal failure and the elderly.⁴

Acetazolamide completely blocks membrane-bound and cytoplasmic carbonic anhydrase in the proximal tubule and to a lesser extent, in the collecting ducts, preventing Na and HCO_3^- absorption.³ This increased excretion of HCO_3^- results in an alkaline urine with metabolic acidosis. Natriuresis associated with carbonic anhydrase inhibitors is modest, with a fractional Na excretion of up to 5%.³ The increased delivery of Na to the distal tubules leads to K loss. Most of the chloride is reabsorbed in the loop of Henle.³ This leads to the excretion of an alkaline urine in the presence of hyperchloremic metabolic acidosis.

Clinical Uses

In addition to its diuretic properties, acetazolamide is administered to decrease intraocular pressure in the treatment of glaucoma. There is a high concentration of carbonic anhydrase enzyme in the ciliary process; inhibition of the enzyme activity by acetazolamide results in decreased formation of aqueous humor and, consequently, decreased intraocular pressure.² Similarly, formation of cerebrospinal fluid is also inhibited by

acetazolamide. Accordingly, acetazolamide has been used in the treatment of idiopathic intracranial hypertension.² Idiopathic intracranial hypertension, previously referred to as **benign intracranial hypertension** or **pseudotumor cerebri**, is caused by increased intracranial pressure in the absence of tumors or other causes. It manifests with headaches, pulsatile tinnitus, and visual changes secondary to papilledema, which could progress to vision loss. Women are more likely affected, especially women with obesity, in their third decade of life. When treatment with acetazolamide fails, surgical treatment is an option. In addition, lumbar punctures, in addition to being diagnostic, provide symptomatic relief.

Acetazolamide may be beneficial in the management of familial periodic paralysis because the drug-induced metabolic acidosis increases the local concentration of K in skeletal muscles.² Similarly, acetazolamide, by producing metabolic acidosis, may stimulate the respiratory drive in patients who are hypoventilating in a compensatory response to respiratory alkalosis, such as altitude sickness. Altitude sickness, which can be prevented by a slow acclimatization process, develops following rapid ascent to high altitudes.² The hypoxia at high altitudes is counteracted by hyperventilation, which leads to respiratory alkalosis. This in turn depresses ventilation. Acetazolamide-induced metabolic acidosis can reverse the hypoventilation.² Conversely, the loss of HCO₃⁻ ions necessary to buffer CO₂ may result in the exacerbation of respiratory acidosis in patients with chronic obstructive airway disease, leading to central nervous system depression.

Side Effects

There is a high incidence of systemic side effects associated with the use of acetazolamide such as fatigue, decreased appetite, depression, and paresthesias,⁴ which could be secondary to the development of acidosis.⁴

Acetazolamide dose should be reduced in patients with chronic renal insufficiency and avoided in patients with severe chronic renal insufficiency because of the increased risk of metabolic acidosis.²

Loop Diuretics

Furosemide, torsemide, azosemide, bumetanide, and ethacrynic acid are diuretics that inhibit reabsorption of Na, K, and chloride by impairing activity of the Na-K-2Cl transport protein in the medullary portions of the thick ascending limb of the loop of Henle. This area of the nephron accounts for the reabsorption of 20% to 30% of filtered Na while being impermeable to water.^{1,2} Because of their site of action, loop diuretics are the most potent diuretics, with a dose-dependent response.² Diuretics in general, and loop diuretics in particular, are first-line therapy in patients with fluid retention resulting from heart failure.²

Pharmacokinetics and Pharmacodynamics

Ethacrynic Acid

Ethacrynic acid is the only nonsulfonamide in the group and can therefore be used in those allergic to other drugs in this class. It has 70% the relative potency of furosemide.³ Ototoxicity, a common dose-dependent side effect of loop diuretics, is notable with the use of ethacrynic acid.² In addition, nausea is common following administration of ethacrynic acid.

Furosemide

Furosemide is effective when administered orally or intravenously (IV). However, absorption of orally administered furosemide varies between patients from 10% to 100%, with an average of 50%.^{2,5} Protein binding is extensive, with approximately 90% of the drug bound to albumin. Glomerular filtration and renal tubular secretion account for approximately 50% to 60% of furosemide excretion. The remaining 40% to 50% is conjugated to glucuronide in the kidneys.^{2,5,6} The elimination half-life is 1 to 2 hours, resulting in the short duration of action of furosemide. Furosemide has a fast onset of action, producing diuresis within 5 to 10 minutes of administration, with a peak effect at 30 minutes and duration of action of 2 to 6 hours. In order to achieve natriuresis, a specific dose of the diuretic should reach the site of action within the kidneys. In patients with normal renal function, 40 mg of IV furosemide will produce maximal natriuresis.⁵ Because of decreased drug delivery to the tubule in chronic renal insufficiency, the dosing of loop diuretics should be

increased.^{2,5} In these patients, maximal diuresis can be achieved with an IV bolus of 160 to 200 mg, administered slowly to avoid the occurrence of tinnitus.⁵ Doses larger than 200 mg will not result in increased natriuresis.⁵ In addition, in patients with chronic renal insufficiency, a loading dose followed by a continuous infusion of furosemide could be considered instead of repeated bolus administration.^{1,5} However, the Diuretic Optimization Strategies Evaluation trial, a prospective randomized study of the use of loop diuretics in patients admitted with acute heart failure, did not find a significant difference in symptomatic relief or significant improvement of renal function with the use of high-dose diuretics or with continuous diuretic infusion compared to low-dose or repeated diuretic boluses, respectively.⁷ Alternatively, the addition of a different class of diuretics, such as thiazide diuretics can help in this setting.⁵

Bumetanide and Torsemide

Bumetanide has a bioavailability of 80% to 100% after oral administration. It can be administered orally, IV, or intramuscularly. It is 40 times more potent than furosemide except in its effect on K excretion.² Similar to bumetanide, torsemide's metabolism is mostly by the liver,² and in patients with liver failure, there is increased drug delivery to the kidneys.⁵ Torsemide is 3 times as potent as furosemide and has a longer duration of action, with a plasma half-life of 3 to 4 hours,³ allowing for a once-a-day dosing regimen.⁸

Clinical Uses

Loop diuretics are not first-line treatment for hypertension in patients with normal kidney function. However, they are first-line diuretics in patients with renal insufficiency.^{1,5,8} The antihypertensive effect of loop diuretics is due to their ability to decrease intravascular fluid volume and eliminate salt. Compared to furosemide, the long-acting drug azosemide produces better blood pressure control, especially at nighttime.¹ This effect is desirable since the lack of nocturnal fall in blood pressure (nondipping) is associated with end-organ damage.¹

Loop diuretics are commonly used in patients admitted with acute exacerbation of heart failure.^{7,8} Diuresis leads to loss of water and salt with a resulting decrease in intravascular volume thus decreasing ventricular filling pressure and reducing pulmonary edema.⁶ In addition, loop diuretics mediate peripheral vasodilation via prostaglandins, further decreasing venous return and pulmonary edema.⁶ Treatment with torsemide was found to decrease readmissions related to heart failure when compared to furosemide.¹

Furosemide decreases intracranial pressure by inducing systemic diuresis and by decreasing cerebrospinal fluid production. This diuretic-induced decrease in intracranial pressure is not accompanied by changes in cerebral blood flow or plasma osmolarity. Furosemide can be administered as single-drug therapy (0.5-1.0 mg/kg IV) or as a lower dose (0.1-0.3 mg/kg IV) in combination with mannitol. Alterations in the blood-brain barrier do not influence the immediate or subsequent effects of furosemide on intracranial pressure. This characteristic contrasts with that of mannitol, which may produce rebound intracranial hypertension if a disrupted blood-brain barrier allows mannitol to enter the central nervous system. A combination of furosemide and mannitol is more effective in decreasing intracranial pressure than either drug alone, but severe dehydration and electrolyte imbalance are also more likely. In the presence of symptomatic hypercalcemia, furosemide may lower the plasma concentration of calcium by stimulating urine output.

Side Effects

Side effects of loop diuretics most often manifest as abnormalities of fluid and electrolyte balance. Loop diuretic use can lead to hypokalemia thus increasing the likelihood toxicity with multiple drugs including digitalis. As with thiazide diuretics, loop diuretics may cause hyperuricemia, but this is rarely clinically significant. Likewise, hyperglycemia, although possible, is less likely to occur than with thiazide diuretics.

Acute or chronic treatment of patients with diuretics, including loop diuretics, may result in tolerance to the diuretic effect ("braking phenomenon"). Acute tolerance is presumed to reflect Na and water retention (activation of the renin-angiotensin system) in the presence of contracted extracellular fluid volume.⁵ Treatment of this acute tolerance is extracellular volume repletion. With chronic use of diuretics, there is evidence of a compensatory hypertrophy of those portions of the renal tubule (especially distal convoluted

tubules) responsible for Na retention, leading to decreased diuretic effectiveness.⁵ When tolerance develops in a patient treated chronically with furosemide, it may be possible to reestablish a diuretic effect with the administration of a thiazide diuretic, to block the hypertrophied Na reabsorption sites.⁵

Loop diuretics should only be administered to patients with a normal or increased intravascular fluid volume. Acute hypovolemia may result from administration of loop diuretics to hypovolemic patients or from over treatment and the resulting hypotension may further exacerbate renal ischemic injury and concentrate nephrotoxins in the renal tubules. Accordingly, loop diuretics should be avoided in patients with acute renal insufficiency.^{2,9}

Furosemide increases renal tissue concentrations of aminoglycosides and enhances the nephrotoxicity. Cephalosporin nephrotoxicity may also be increased by furosemide. In addition, loop diuretics potentiate nondepolarizing neuromuscular blockade.² Furosemide has been associated with allergic interstitial nephritis similar to that occasionally produced by penicillin. Cross-sensitivity may exist when a patient allergic to other sulfonamides is given furosemide. The renal clearance of lithium is decreased in the presence of diuretic-induced decreases in Na reabsorption. Consequently, plasma concentrations of lithium may be acutely increased by the IV administration of furosemide in the perioperative period.

Development of ototoxicity, either transient or permanent, is a rare dose-dependent complication associated with the use of loop diuretics. This side effect is most likely to occur with prolonged increases in the plasma concentration of these drugs in the presence of other ototoxic drugs such as aminoglycosides or in the presence of chronic renal insufficiency.²

Thiazide Diuretics

Thiazide diuretics are most often administered for maintenance treatment of essential hypertension in which the combination of diuresis, natriuresis, and vasodilation are synergistic. Included in this class of drugs are hydrochlorothiazide and thiazide-like drugs, such as chlorthalidone and indapamide. Hydrochlorothiazide is the second most frequently prescribed antihypertensive medication, and thiazides are usually administered in combination with other antihypertensives.¹⁰ Also, a thiazide diuretic may be utilized to mobilize edema fluid associated with renal, hepatic, or cardiac dysfunction. Less common uses of thiazide diuretics include management of diabetes insipidus and treatment of hypocalcemia.

Pharmacokinetics and Pharmacodynamics

Thiazide diuretics produce diuresis by inhibiting reabsorption of Na and chloride ions, in the cortical portion of the ascending loop of Henle and the distal convoluted tube, by blocking the Na-chlorine cotransporter, thereby blocking 5% to 10% of the filtered Na (see [Figure 22.1](#)).² Enhanced distal delivery of Na results in increased excretion of K into the renal tubules. The result is an increase in the urinary excretion of Na, chloride, and K ions. In addition, thiazide diuretics stimulate the reabsorption of calcium in the distal convoluted tube.¹

Thiazide diuretics are readily absorbed when administered orally; hydrochlorothiazide has a 60% to 70% bioavailability.⁸ They are extensively protein bound.⁸ Most thiazides are eliminated unchanged in the kidney; indapamide, however, is metabolized by the liver.⁵ Thiazides' effectiveness is markedly reduced in patients with renal insufficiency.⁵ Thiazide diuretics have a long half-life of 8 to 12 hours, allowing for a convenient once-a-day dosing.⁸ Chlorthalidone has the longest elimination half-life of 50 to 60 hours.⁸

Indapamide, xipamide, and metolazone are structurally related to furosemide but share a thiazide-like mechanism of action with differences in their clinical effects.² Thiazide diuretics, with the exception of metolazone, are ineffective in patients with severe renal insufficiency, and the use of loop diuretics in these patients is recommended.⁸

Clinical Uses

Thiazide diuretics are recommended as first-line therapy for essential hypertension, and the use of chlorthalidone specifically has been shown to decrease the risk of major cardiovascular events when

compared to calcium channel blockers or angiotensin-converting enzyme inhibitors in a large randomized control trial, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial.¹¹

The antihypertensive effect of thiazide diuretics is due initially to a decrease in extracellular fluid volume, often with a decrease in cardiac output, which normalizes after several weeks.¹ The sustained antihypertensive effect of thiazide diuretics, however, is due to peripheral vasodilation, which requires several weeks to develop. It is unclear whether the resulting decrease in systemic vascular resistance after chronic thiazide therapy results from direct or indirect vasodilatory effect.¹⁰

Because they stimulate calcium reabsorption, thiazide diuretics are used in the treatment of calcium-containing renal calculi.¹ Although unlikely to cause hypercalcemia, thiazide diuretics should be used cautiously in patients with conditions that predispose to hypercalcemia, such as hyperparathyroidism and sarcoidosis.²

Chlorthalidone, a longer acting thiazide-like diuretic, is recommended for use in resistant hypertension, achieving better nighttime control of the blood pressure.¹ In addition, treatment with chlorthalidone resulted in decreased cardiovascular events when compared to treatment with lisinopril or amlodipine.¹¹

Indapamide, a weak diuretic, decreases blood pressure by causing vasodilation.² Xipamide on the other hand is a potent diuretic and kaliuretic, and frequent measurement of K levels are recommended.² Metolazone can promote diuresis in patients with renal insufficiency, when other thiazides are not effective, and it is usually administered with a loop diuretic. Their concomitant use should be monitored closely because of their synergism and because of metolazone's propensity to accumulate because of its prolonged elimination half-life.^{2,5,8}

Side Effects

Thiazide diuretic-induced hypokalemic, hypochloremic, or metabolic alkalosis is a common side effect when these drugs are administered chronically for maintenance treatment of essential hypertension. However, these side effects are usually tolerated at low doses.⁸ Hypokalemia may manifest as skeletal muscle weakness and gastrointestinal ileus, and it may increase the likelihood of developing digitalis toxicity. Depletion of Na and magnesium ions may accompany kaliuresis. Cardiac dysrhythmias may occur as the result of diuretic-induced hypokalemia or hypomagnesemia. In addition, hypercalcemia may result, especially in patients receiving calcium supplements or vitamin D therapy.² The use of thiazide diuretics can potentiate nondepolarizing neuromuscular blockade.² The effectiveness of thiazides is decreased in patients receiving nonsteroidal antiinflammatory drugs.⁸ In addition, thiazide diuretics may promote lithium reabsorption in the proximal tubule by a compensatory mechanism, thereby potentiating toxicity.²

Inhibition of renal tubular secretion of urate by thiazide diuretics can result in hyperuricemia in 50% of treated patients, and a small percentage of patients might develop clinical gout.^{2,10}

Thiazide diuretics may cause glucose intolerance and aggravate glucose control in diabetic patients,² especially when used in combination with β-blockers. The mechanism of hyperglycemia is unknown but may result from a drug-induced decrease of insulin release from the pancreas and peripheral resistance to the effects of insulin.¹⁰ In addition, thiazide-induced hypokalemia may be associated with glucose intolerance and treating the hypokalemia may protect from developing diabetes.⁸ Thiazide treatment may cause hyperlipidemia, affecting cholesterol and triglyceride levels.¹⁰

Intravascular fluid volume status should be considered in all patients treated with thiazide diuretics and scheduled for surgery. The presence of orthostatic hypotension in such patients should arouse suspicion that intravascular fluid volume is decreased.

Because of the structural similarities between sulfonamide antibiotics and thiazide and loop diuretics, it has been suggested that patients with sulfa allergy may demonstrate cross-reactivity to these classes of diuretics.²

Osmotic Diuretics

Osmotic diuretics such as mannitol, urea, isosorbide, and glycerin are inert substances that do not undergo metabolism and are filtered freely at the glomerulus. Their administration causes increased plasma and renal tubular fluid osmolality, with resulting osmotic diuresis.³ Portions of the renal tubules that are highly permeable to water, namely, the proximal renal tubules and more importantly, the loop of Henle, represent the principal site of action of osmotic diuretics.³

Mannitol

Mannitol is the only osmotic diuretic in current use. Structurally, mannitol is a six-carbon sugar alcohol that does not undergo metabolism. It is not absorbed from the gastrointestinal tract, which necessitates its exclusive use by IV injection to achieve a diuretic effect. Mannitol does not enter cells, and its only means of clearance from the plasma is by glomerular filtration.

Pharmacokinetics and Pharmacodynamics

After administration, mannitol is completely filtered at the glomeruli, and none of the filtered drug is subsequently reabsorbed from the renal tubules.³ By increasing tubular fluid osmolality, it decreases water reabsorption and promotes water diuresis.² The Na is diluted in this retained water in the renal tubules, leading to less reabsorption of this ion. However, hypernatremia may result from the water diuresis.²

In addition to causing renal tubular effects, IV administration of mannitol also increases plasma osmolarity, thus drawing fluid from intracellular to extracellular spaces. This increased plasma osmolarity may result in an acute expansion of the intravascular fluid volume, which could be poorly tolerated in patients with borderline cardiac function. Increased plasma osmolarity allows water to move along an osmotic gradient from tissues, including the brain, into the intravascular space, leading to decreased intracranial pressure. Mannitol is a scavenger of oxygen-free radicals, which may prevent cellular injury.

Clinical Uses

Mannitol is mainly used in the acute management of elevated intracranial pressures and in the treatment of glaucoma.

Mannitol decreases intracranial pressure by increasing plasma osmolarity, which draws water from tissues, including the brain, along an osmotic gradient. Mannitol begins to exert an effect within 10 to 15 minutes, with a peak effect at 30 to 45 minutes and a duration of 6 hours.¹² The effect on ICP is dose dependent within this dosing range, and the larger dose may last longer.¹² However, larger doses, up to 2 g/kg and repeated administration can result in metabolic derangements.¹² An intact blood–brain barrier is necessary for the cerebral effects of mannitol. If the blood–brain barrier is not intact, mannitol may enter the brain, drawing fluid with it and causing worsening of the cerebral edema.¹² In addition, a rebound increase in ICP may occur following mannitol use.¹²

Mannitol has been used to prevent perioperative kidney failure in the setting of acute tubular necrosis. It is thought to provide renal protection by several mechanisms. As an osmotic diuretic, it is not reabsorbed by the tubules and results in osmotic diuresis that forces casts and necrotic debris out of the renal tubules.¹² In addition, mannitol has been shown to cause vasodilation of vascular smooth muscle mediated by the release of prostaglandins,¹² which is dependent on the dose and rate of administration. This vasodilation leads to improved renal blood flow, thereby protecting the kidneys from acute failure following renal tubular necrosis.^{2,12} Also, mannitol has free radical scavenging properties, which could protect the transplanted kidneys following reperfusion.^{2,12} Despite its common use during cardiac and major vascular surgery for renal protection, and although mannitol increases urine output, it has not been shown to prevent perioperative acute renal failure.¹²

Side Effects

The initial increase in intravascular volume associated with the administration of mannitol may be poorly tolerated in patients with left ventricular dysfunction, leading to pulmonary edema. For this reason, furosemide may be a preferred drug for treatment of increased intracranial pressure in patients with left

ventricular dysfunction. In addition, in patients with renal insufficiency, mannitol is not filtered and will cause increase in the intravascular volume.⁵ Prolonged use of mannitol may cause hypovolemia, electrolyte disturbances with hypokalemic hypochloremia alkalosis, and plasma hyperosmolarity due to excessive excretion of water and Na.

Potassium-Sparing Diuretics

The K-sparing diuretics act on the collecting ducts and are grouped in two categories: pteridine analogues and aldosterone receptor blockers.¹ Pteridine analogues, such as triamterene and amiloride, prevent Na reabsorption in the cortical collecting duct by blocking the epithelial Na channels, independent of aldosterone. Aldosterone receptor blockers on the other hand, such as spironolactone and eplerenone, prevent the synthesis and the activation of the aldosterone-dependent basal cell Na-K-ATPase pump. Both mechanisms result in decreased Na reabsorption without the increased K secretion that would otherwise be expected.¹ The collecting duct accounts for <3% of Na reabsorption. Accordingly, K-sparing diuretics do not cause substantial diuresis and are not used as single antihypertensive therapy.^{1,13} They are used in conjunction with thiazide diuretics to prevent the associated loss of K and magnesium.⁸

Pharmacokinetics and Pharmacodynamics

Oral absorption of amiloride and triamterene is limited (25% and 50%, respectively).³ Amiloride is more potent than triamterene and is not metabolized but excreted in the kidneys.⁵ Triamterene is a pteridine with a structural resemblance to folic acid. The metabolism of triamterene by the liver is extensive, and its metabolite, secreted into the renal tubule, has diuretic activity.⁵ Accordingly, both kidney and liver disease will affect the pharmacokinetics of triamterene.⁵ The elimination half-time for triamterene is 4 hours and for amiloride is about 20 hours.³

Clinical Uses

The K-sparing diuretics are most often used in combination with loop diuretics or thiazide diuretics to augment diuresis and limit renal loss of K, and they are rarely used as monotherapy.¹³

Side Effects

Hyperkalemia is the principal side effect of therapy with K-sparing diuretics, especially when combined with angiotensin-converting enzyme inhibitor or angiotensin II receptor blockers or in presence of nonsteroidal antiinflammatory drugs (see [Table 22.1](#)).^{2,13} Although triamterene can block folic acid, it rarely causes megaloblastic anemia.¹³

Aldosterone Antagonists

Spironolactone is a synthetic steroid analogue and a nonspecific mineralocorticoid receptor antagonist.⁸ This drug bears a close structural resemblance to aldosterone and results in K-sparing diuresis. Spironolactone binds to the cytoplasmic mineralocorticoid receptors in the collecting ducts, preventing Na reabsorption via the Na-K pump. Eplerenone is a selective aldosterone receptor blocker and has less affinity for other mineralocorticoid receptors. It is, however, less potent than spironolactone.¹³ It was previously believed that spironolactone effects were solely the result of competitive antagonism of aldosterone binding to the mineralocorticoid receptors. However, it has been shown that blocking the effects of other ligands, such as cortisol, on the mineralocorticoid receptors contributes to spironolactone and eplerenone clinical effects as well.¹³ Conversely, blockade of aldosterone produces beneficial end-organ effects, independently of blood pressure control.¹³ Spironolactone, when added to conventional therapy, was shown to effectively reduce morbidity and mortality in patients with heart failure with poor ejection fraction in the Randomized Aldactone Evaluation Study.¹⁴ This is thought to be the result of prevention of aldosterone-induced cardiac remodeling and fibrosis.¹³ However, spironolactone therapy was not found to significantly improve outcomes in patients with heart failure and preserved ejection fraction (diastolic heart failure).¹⁵ Similarly, eplerenone, a selective mineralocorticoid receptor blocker, has been shown to improve morbidity and mortality compared

to optimal medical treatment in patients with acute myocardial infarction and left heart failure, in the Eplerenone in Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study.^{13,16}

Pharmacokinetics and Pharmacodynamics

Spironolactone and eplerenone exert their effect on the aldosterone receptor of the tubular cell and reach the tubular cells from the plasma and not from the tubular fluid² and are the only diuretics that do not require to reach the renal tubule to exert their effect.³ They provide competitive blockade of epithelial aldosterone receptors in the distal tubule and the collecting duct, preventing Na-K-ATPase activation and resulting in decreased Na reabsorption and in decreased K excretion.^{3,13} Oral absorption of spironolactone approaches 70% of the administered dose. Spironolactone undergoes extensive hepatic first-pass metabolism with multiple active metabolites,⁵ which account for spironolactone's long half-life of 20 hours.⁸ Spironolactone and its metabolites are extensively bound to plasma proteins and excreted by the kidneys. Similarly, eplerenone undergoes hepatic metabolism and its half-life is prolonged in the presence of CYTP3A4 inhibitors, such as ketoconazole and verapamil.¹³

Clinical Uses

Spironolactone and eplerenone are often prescribed for the treatment of essential hypertension, in combination with thiazides, particularly in patients with low renin state (such as black, elderly, and diabetic patients) or those with metabolic syndrome.¹³ Aldosterone antagonist diuretics are also used in patients with refractory hypertension, whose blood pressure remains difficult to control despite therapy with several medications, including a diuretic.¹³ Furthermore, thiazide therapy might promote increased aldosterone levels because of decreased intravascular volume.¹³ The combination of spironolactone with a thiazide diuretic results in improved diuresis and blood pressure control, in addition to prevention of the thiazide-induced hypokalemia and hypomagnesemia.⁸

In addition, spironolactone and eplerenone are indicated in the treatment of patients demonstrating "aldosterone escape." This results from incomplete aldosterone blockade during antihypertensive therapy with blockers of the renin-angiotensin-aldosterone system.^{8,13}

Aldosterone antagonists are used to promote diuresis in patients with edema and fluid overload associated with hyperaldosteronism, such as liver cirrhosis, nephrotic syndrome, and heart failure. As discussed earlier, the administration of spironolactone along with an angiotensin-converting enzyme inhibitor in the treatment of patients with heart failure with poor ejection fraction results in a decrease in cardiovascular morbidity and mortality.¹⁴

Side Effects

Hyperkalemia, especially in the presence of impaired renal function, is the most serious side effect of treatment with spironolactone. The combination of spironolactone with angiotensin-converting enzyme inhibitors can exacerbate hyperkalemia.² Because it is a nonspecific mineralocorticoid receptor antagonist, spironolactone can block androgen and progesterone receptors, leading to gynecomastia and breast tenderness⁸ that may prompt patients to seek cessation of therapy.¹⁴

Dopamine Receptor Agonists

Dopamine receptor agonists, such as dopamine and fenoldopam, result in natriuresis and increased renal blood flow, via their actions on renal tubular dopamine-1 (D₁) receptors.

Pharmacokinetics and Pharmacodynamics

Endogenous dopamine is synthesized locally in the epithelial cells of the renal tubules and exerts its effect directly.³ At low concentrations, dopamine exerts its clinical effect via activation of dopamine receptors. Activation of D₁ receptors in the proximal renal tubule and in the loop of Henle increases cyclic adenosine monophosphate formation, resulting in inhibition of the Na-H exchange and Na-K-ATPase pump.³ In

addition, D₁ receptors mediate an increase in renal blood flow leading to a small increase in glomerular filtration rate.³ With increasing doses of dopamine, sympathetic activation begins to predominate. The β activation results in increased inotropy, increased cardiac output, and elevation in systemic blood pressure. At even higher doses, α activation prevails, leading to vasoconstriction.

Fenoldopam is a fast-acting IV antihypertensive with a short half-life of 10 minutes,³ used in the short-term treatment of patients with severe hypertension. Fenoldopam is a relatively selective D₁-receptor agonist with moderate affinity to α₂ receptors. It has no effect on D₂, β, or α₁ receptors.³ Accordingly, it results in increased renal blood flow and decreased systemic vascular resistance.¹⁷ Both dopamine and fenoldopam have poor bioavailability after oral intake and are thus administered IV.

Clinical Uses

Dopamine is used to maintain renal blood flow in patients with cardiogenic shock with low or normal systemic vascular resistance.³ Similarly, fenoldopam is used for its renal vasodilation properties and because it lacks sympathetic activity, even at higher doses, it is used to treat resistant hypertension.³ Both drugs have been used at very low doses to provide renal protection in high-risk patients, such as after cardiac or major vascular surgery, or following radio contrast iodine injection.¹⁷ However, postoperative renal protection and the reduction in the incidence of perioperative acute renal failure have not been substantiated in large randomized control studies.¹⁷⁻¹⁹

Natriuretic Peptides

Atrial natriuretic peptide and brain natriuretic peptide are normally produced in the atria and ventricles of the heart, respectively, in response to myocardial wall stretch.³ They exert their diuretic effect on the collecting duct of the kidneys, by blocking the basal Na-K-ATPase channel. In the United States, nesiritide, a recombinant brain natriuretic peptide, is the only natriuretic peptide currently available. It is suggested in the management of patients with decompensated congestive heart failure,²⁰ although data on its effect on long-term morbidity and mortality are lacking.²¹ It is administered IV as a continuous infusion and has a short half-life of 18 minutes.³

Vasopressin Receptor Antagonists

Vasopressin receptor antagonists, or vaptans, competitively inhibit the V₂ receptor in the renal collecting duct, thereby leading to decreased water reabsorption. Currently, tolvaptan is the only US Food and Drug Administration-approved selective V₂ receptor antagonist for the treatment of euvolemic and hypervolemic hyponatremia associated with syndrome of inappropriate antidiuretic hormone secretion, congestive heart failure, or liver cirrhosis.²²

Pharmacokinetics and Pharmacodynamics

Tolvaptan may be orally administered in order to antagonize the effects of arginine vasopressin.²³ As a highly selective agent, it binds the V₂ receptor with an affinity 29 times stronger than that for V₁. Endogenous stimulation of the V₂ receptor by vasopressin leads to luminal translocation of the aquaporin receptor in the collecting duct.

Tolvaptan therefore blocks this action leading to enhanced aquaresis without loss of electrolytes. Onset of aquaresis occurs 2 to 4 hours after administration, with peak effect occurring within 4 to 8 hours. Tolvaptan is highly protein bound and metabolized by nonrenal routes, mainly the CYP3A system, with a half-life of about 12 hours. Moderate to severe liver impairment decreases clearance of tolvaptan, which should be avoided in patients with preexisting disease.²⁴

Clinical Uses

Tolvaptan is US Food and Drug Administration approved for the treatment of clinically significant hyponatremia, which can be seen in some patients with decompensated heart failure or syndrome of

inappropriate antidiuretic hormone secretion.³ While several studies have noted greater weight and fluid loss when tolvaptan was added to loop diuretic therapy for patients in congestive heart failure, this has not resulted in improvements in clinical measures such as symptoms, length of stay, heart failure, or postdischarge outcomes.²⁵ There have been inconsistent results regarding the improvement of dyspnea in heart failure patients treated with tolvaptan.²⁶

Side Effects

Due to Tolvaptan's ability to increase free water excretion, it is labeled with a black box warning against rapid correction of hyponatremia that could lead to potentially fatal osmotic demyelination.³ Less serious side effects include those related to polyuria, which may result in dehydration, hypotension, dizziness, pyrexia, thirst, and xerostomia. There is also potential for hyperglycemia. Treatment should be limited to 30 days due to the potential for liver damage.²⁴ Coadministration with CYP3A inducers may reduce the plasma concentration of tolvaptan, whereas CYP3A inhibitors raise the potential for toxicity.

Aquaporin Modulators

Aquaporins are recently described membrane channels that facilitate water movement across cells in response to osmotic gradient.²⁷ Subtypes of aquaporin respond to the antidiuretic hormone in the collecting duct of the kidney, and mutations in those channels can result in hereditary nephrogenic diabetes insipidus.^{2,27} Other subunits located in the cerebral perivascular astrocyte end foot may be involved in cerebral edema and in the pathogenesis of neuromyelitis optica.^{2,27} Nephrogenic diabetes insipidus (NDI), which is characterized by polyuria and polydypsia, results from an inappropriate response to the antidiuretic hormone. The most common form of NDI is acquired, usually secondary to lithium toxicity, hypercalcemia, or polycystic kidney disease. Hereditary NDI on the other hand is rare and can result either from an X-linked defect in V₂ receptors or from an autosomal recessive AQP2 mutation.²⁷ Treatment with thiazide diuretics in these patients helps decrease the kidney's diluting ability.²⁷

Lipid-Lowering Drugs*

Updated by: Peter C. Schmidt

Lipoprotein Metabolism

Lipoproteins are macromolecular lipid protein complexes responsible for the transport of lipids to and from the peripheral tissues. Lipoproteins are classified based on their relative density as (1) chylomicrons, (2) very low-density lipoproteins (VLDLs), (3) intermediate-density lipoproteins, (4) low-density lipoproteins (LDLs), and (5) high-density lipoproteins (HDLs) ([Table 23.1](#)). Lipoprotein metabolism can be divided into the exogenous and endogenous pathways ([Figure 23.1](#)). The exogenous pathway refers to the processing of dietary fats, cholesterol, and lipid-soluble vitamins, whereas the endogenous pathway describes hepatic cholesterol synthesis and its distribution to the peripheral tissues.

TABLE 23.1

Classification of lipoproteins

Lipoprotein	Density (g/mL)	Diameter (nm)
Chylomicrons	<0.95	75-1,200
Very low-density lipoproteins	0.95-1.006	30-90
Intermediate-density lipoproteins	1.006-1.019	~30
Low-density lipoproteins	1.019-1.063	~20
High-density lipoproteins	1.063-1.21	8-12

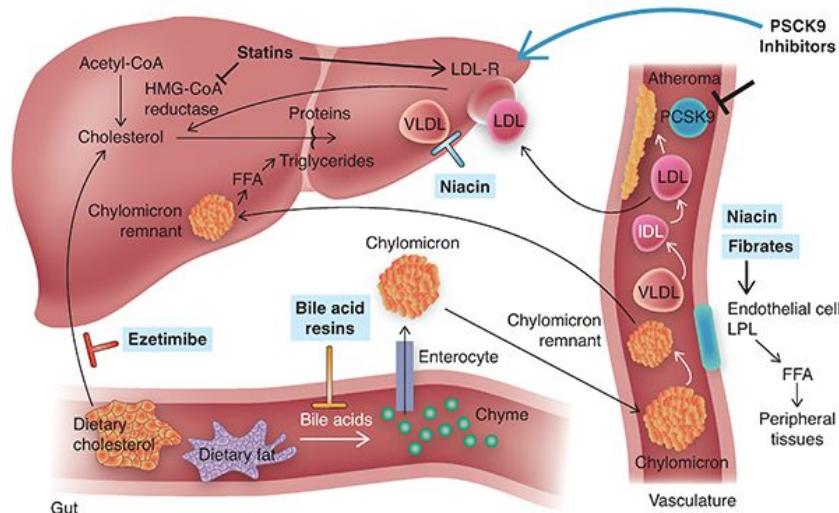

FIGURE 23.1 A diagrammatic representation of lipid metabolism. T-shaped markers indicate inhibition, and arrow-shaped markers indicate enhancement. Abbreviations: FFA, free fatty acid; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-R, low-density lipoprotein receptors; LPL, lipoprotein lipase; PCSK9, proprotein convertase subtilisin/kexin type 9; VLDL, very low-density lipoprotein.

Exogenous Pathway

In the small intestine, bile emulsifies dietary fat and cholesterol, and lipase excreted by the pancreas hydrolyzes triglycerides. The intestinal endothelium takes up these products by endocytosis and packages lipids into large chylomicrons, which then enter the lymphatic system. After traveling through the thoracic duct, the chylomicrons enter the bloodstream where they interact with lipoprotein lipase in vascular endothelial cells, yielding glycerol and free fatty acids, which can be used by the peripheral tissues for fuel or storage. During this process, the chylomicrons shrink and become chylomicron remnants. These remnants are transported to the liver where they are taken up by hepatocytes via endocytosis and subsequently hydrolyzed.

Endogenous Pathway

In the liver, hepatocytes synthesize cholesterol, lipids, and proteins, which are assembled into VLDL and excreted into the bloodstream. Similar to the processing of chylomicrons, endothelial cell lipoprotein lipase hydrolyzes the fats in VLDL particles, which then shrink to form intermediate-density lipoprotein and LDL. The LDL particles contain most of the cholesterol in plasma and are cleared from the blood by binding to LDL receptors (LDL-R) on hepatocytes. Apolipoproteins C and E are essential cofactors of the hydrolysis of VLDL and are contributed by HDL particles. The HDL also transfers apolipoprotein C2 to chylomicrons in the exogenous pathway and is responsible for reverse cholesterol transport, in which excess cholesterol is delivered from the peripheral tissues to the liver for excretion in the bile.¹

Lipid Disorders

A minority of lipid disorders arise from genetic defects in lipoprotein metabolism, which may present in the pediatric period or early adulthood. One such disorder, familial hypercholesterolemia, arises from a defect in the gene for LDL-R. Heterozygotes for this defect experience accelerated atherosclerosis and represent about 1 in 500 persons. Homozygotes are much rarer, have total and LDL cholesterol levels 4 times normal, and have an extreme propensity for atherosclerosis. Hyperlipidemia may also arise from secondary causes including obesity, diabetes, alcohol abuse, hypothyroidism, glucocorticoid excess, and hepatic or renal dysfunction.¹ Most cases of hyperlipidemia in adults arise from a combination of secondary causes, genetic predisposition, and environmental factors, including poor diet and a lack of exercise.²

It has been recognized for several decades that increased plasma concentrations of total and LDL cholesterol are associated with an increased risk of cardiovascular disease.^{3,4} Conversely, higher HDL cholesterol levels appear to reduce the risk of atherosclerosis and cardiovascular events because of the critical role of HDL in reverse cholesterol transport.⁵⁻⁷ Furthermore, lowering plasma concentrations of total and LDL cholesterol with pharmacologic agents decreases the risk of coronary events in patients with and without coronary artery disease.^{8,9} Hypertriglyceridemia is known to cause pancreatitis, but its causal relationship to atherosclerosis is less well established.²

The safety and efficacy of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, have been particularly well established and have become the mainstay of treatment of hyperlipidemia,^{9,10} as reflected in current guidelines issued by the American College of Cardiology and the American Heart Association. These guidelines advocate statin use in five risk-stratified groups (**Table 23.2**) for the primary or secondary prevention of atherosclerotic cardiovascular disease and in other groups dependent on the presence of associated risk factors. In fact, American College of Cardiology and the American Heart Association guidelines no longer recommend the use of drugs other than statins for the treatment of hyperlipidemia.¹¹ Based on these guidelines, well over 50 million adults in the United States are eligible for statin therapy.¹² Therefore, anesthesiologists can expect to routinely encounter patients taking statins in the perioperative period. However, alternative agents to statins are still used in clinical practice for the treatment of familial lipid disorders, for those with very high LDL levels, and for those who are intolerant of statins.

Drugs for Treatment of Hyperlipidemia

Statins have become the mainstay of and sole agents recommended for the treatment of hyperlipidemia; however, there are multiple other agents still used for patients intolerant of statins or those with genetic lipid disorders. The effects of these different classes of medications on LDL, HDL, and triglycerides are summarized in [Table 23.3](#).

TABLE 23.3

Drugs for treatment of hyperlipidemia

	LDL	HDL	Triglycerides
Diet change	↓ 10%-15%	Variable increase	↓ 10%-20%
Statins	↓ 20%-60%	↑ 5%-10%	↓ 10%-20%
Bile acid resins	↓ 15%-30%	↑ 3%-5%	No change or mild increase
Fibrates	↓ 5%-20% or increase	↑ 10%-35%	↓ 40%-50%
Ezetimibe	↓ 18%	↑ 1%	↓ 8%
Niacin	↓ 15%-30%	↑ 20%-30%	↓ 20%-50%
PCSK9 inhibitors	↓ 38%-72%	↑ 4%-9%	↑ 2%-23%

Abbreviations: ↑, increase; ↓, decrease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PCSK9, proprotein convertase subtilisin/kexin type 9.

Statins

Statins act as inhibitors of HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step of cholesterol biosynthesis in which HMG-CoA is converted to mevalonate (see [Figure 23.1](#)). Statins are structurally related to HMG-CoA, and competitive inhibition of the enzyme causes an increase in hepatic LDL-R. The combined effect of decreased cholesterol synthesis and increased LDL uptake by the liver by statins results in a decrease in LDL concentration of 20% to 60%. Statins also increase HDL by approximately 10%, possibly from increased synthesis of apolipoprotein A1. Plasma triglyceride concentrations decrease 10% to 20% in statin-treated patients, although this is usually insufficient as the sole treatment of hypertriglyceridemia.²

The drugs in this class (atorvastatin, fluvastatin, lovastatin, pravastatin, simvastatin, pitavastatin and rosuvastatin) are considered largely equivalent. Randomized clinical trials have shown that statins lower cardiac events (total mortality, death from myocardial infarction, revascularization procedures, stroke, and peripheral vascular disease) in patients with or without atherosclerosis.^{13,14} Furthermore, angiographic studies have shown benefit on coronary stenosis in native vessels or grafts in patients treated with statins as

well as in patients experiencing acute coronary syndromes.¹⁵ Early initiation of statin therapy following an acute myocardial infarction is recommended.^{16,17}

The reduction in cardiac events observed with statin use may not be solely due to LDL-lowering effects. Statins are thought to stabilize existing atherosclerotic plaques, and there is evidence that statins have many pleiotropic effects, including antiinflammatory, antioxidant, and vasodilatory properties. Reduced perioperative morbidity and mortality has even been reported in observational studies following perioperative statin administration, although this is not yet widely advocated.¹⁸

Pharmacokinetics

Statins are variably absorbed from the gastrointestinal tract following oral ingestion. Bile acid–binding resins can decrease the absorption of these drugs. Lovastatin and simvastatin are prodrugs that require metabolism to the open β -hydroxy acid form to be pharmacologically active. Food intake increases plasma concentrations of lovastatin but has minimal effects on the other statins. All of the statins are highly protein bound with the exception of pravastatin. Also with the exception of pravastatin, all of the statins undergo extensive metabolism by hepatic P450 enzymes. Elimination half-times vary widely, from 30 minutes to 30 hours, depending on drug and formulation (immediate release vs extended release).

Despite the short elimination half-times, the duration of pharmacodynamic effects is about 24 hours. This is a consideration in the perioperative period when patients may not be able to ingest oral medications. Atorvastatin and fluvastatin undergo minimal renal excretion and likely do not require dosage adjustments in patients with renal insufficiency. Statins are teratogenic in animals and thus are not recommended for use during pregnancy.¹⁹

Side Effects

Statins are generally well-tolerated, with common complaints being gastrointestinal upset, fatigue, and headache. A meta-analysis of 22 placebo-controlled statin trials revealed slightly more subjects discontinued dosing in the placebo groups (13.9%) than in the active groups (13.3%) over a mean duration of 4.1 years.²⁰ In clinical trials, less than 5% of patients treated with statins experienced adverse effects, similar to the rates in placebo-treated groups. However, in clinical practice, there are several side effects of concern, most notably muscle-related effects and liver abnormalities.

Muscle-Related Side Effects

The most common adverse events requiring discontinuation or switching of statins in clinical practice are skeletal muscle related. Statin-associated muscle symptoms can range in severity from simple myalgias to myositis with mild creatine kinase elevation to life-threatening rhabdomyolysis characterized by a greater than 10-fold elevation in creatine kinase. Myositis and rhabdomyolysis are quite rare and in clinical trials occur with similar frequency in placebo-treated groups. Conversely, myalgias are reported in as many as a third of statin-treated patients in clinical practice and more commonly in patients with certain risk factors (**Table 23.4**).²¹ The mechanisms underlying statin-related myotoxicity are incompletely understood. It is possible that by inhibiting HMG-CoA reductase, statins decrease not only cholesterol synthesis but also the formation of ubiquinone (otherwise known as coenzyme Q10), which is important for mitochondrial function and cell membrane integrity.²² Alternatively, decreased cholesterol levels in skeletal muscle cell membranes may increase membrane fluidity, leading to unstable sarcolemma, myotonic discharges, and, in advanced but rare situations, rhabdomyolysis.²³

TABLE 23.4

Statin myotoxicity risk factors

- Age >80 years
- Female sex
- Very low vitamin D
- Asian ethnicity
- Renal/hepatic failure

Low body mass index, small frame
Preexisting neuromuscular or muscular disorders
Diabetes mellitus
Certain genetic polymorphisms
Poorly controlled hypothyroidism

Adapted from Mancini GB, Baker S, Bergeron J, et al. Diagnosis, prevention, and management of statin adverse effects and intolerance: Canadian Consensus Working Group update (2016). *Can J Cardiol.* 2016;32(7 suppl):S35-S65.

Severe muscle-related adverse events associated with statin use are often secondary to drug interactions with agents that are also metabolized by the hepatocyte cytochrome P450 (CYP) system. Myopathy appears to be most frequent in patients treated with atorvastatin, simvastatin, and lovastatin, as these are metabolized by CYP3A4 and their concentrations are increased by CYP3A4 inhibitors, including warfarin, protease inhibitors, macrolide antibiotics, and azole antifungals. Fluvastatin, pravastatin, and pitavastatin have the lowest rate of events. Drugs likely to be administered during anesthesia, including succinylcholine, have not been shown to increase the incidence of statin-induced myopathy.²²⁻²⁴

Hepatic Dysfunction

Persistent increases in plasma aminotransferase concentrations occur in 0.5% to 3% of treated patients and are dose-dependent. This commonly manifests during the first 3 months of therapy. Discontinuation of the drug is recommended if plasma aminotransferase concentrations increase to more than 3 times normal. Progression to hepatic failure is extremely rare.²

Proprotein Convertase Subtilisin/Kexin Type 9 Inhibitors

Two proprotein convertase subtilisin/kexin type 9 (PCSK9) antibodies are currently available: evolocumab and alirocumab. Both act by binding PCSK9 in the blood, leading to increased hepatic expression of LDL-R and increased clearance of LDL from the blood.^{25,26}

Evolocumab is indicated for the reduction of myocardial infarction, stroke, and coronary artery revascularization in adults with existing cardiovascular disease, and as an adjunct to diet, alone or in combination with other lipid-lowering therapies, for treatment of adults with primary hyperlipidemia. It is also indicated for the treatment of patients with homozygous familial hypercholesterolemia.

Alirocumab carries a similar indication and includes the treatment of heterozygous familial hypercholesterolemia.

Pharmacokinetics

Both drugs are administered subcutaneously, every 2 weeks. Evolocumab can also be administered monthly with a higher dose. Maximum suppression of PCSK9 occurs between 4 to 8 hours after injection. As these drugs are proteins, elimination is through target binding and proteolysis. Evolocumab has a half-life of 11 to 17 days and alirocumab has a slightly longer half-life of 17 to 20 days. The half-lives of both drugs are prolonged with the coadministration of a statin, but this is not to be considered clinically relevant.

Side Effects

The PCSK9 inhibitors are generally well tolerated, with the most common adverse events being upper respiratory tract infections, influenza, and injection site reactions.

Bile Acid Resins

Bile acid resins may be effective for the treatment of lipid disorders in which the primary abnormality is an increased plasma LDL cholesterol concentration with a normal or near-normal triglyceride level. The three drugs in this class, colestevam, cholestyramine, and colestipol, have a low potential for toxicity, but gastrointestinal side effects are often dose-limiting. There is no systemic absorption of these resins.

Administered as monotherapy, bile acid-binding resins decrease plasma concentrations of LDL cholesterol

by 15% to 30%. Plasma concentrations of triglycerides may increase 5% to 20% in treated patients owing to increased production of VLDLs.

Bile acid resins bind bile in the intestine, interrupting enterohepatic circulation and increasing fecal excretion that increases hepatic bile acid synthesis from cholesterol stores (see [Figure 23.1](#)). This increases the production of hepatic LDL-R and increases the uptake of LDL cholesterol from blood, lowering plasma concentrations of LDL cholesterol. The HMG-CoA reductase activity also increases.

Side Effects

Palatability and constipation are common complaints in patients being treated with cholestyramine. A high fluid intake is useful in minimizing constipation. Colesevelam has fewer gastrointestinal side effects and is approved for use in adolescents with familial hypercholesterolemia. There may be transient increases in the plasma concentrations of alkaline phosphatase and transaminases.

Because cholestyramine is a chloride form of an ion exchange resin, hyperchloremic acidosis can occur, especially in younger and smaller patients in whom the relative dose is larger. Absorption of fat-soluble vitamins as well as other pharmacologic agents may be impaired. For this reason, other drugs should be given at least 1 hour before or 4 hours after administration of cholestyramine.

Niacin

Niacin (nicotinic acid) is a water-soluble B complex vitamin that inhibits synthesis of VLDLs in the liver by an unknown mechanism (see [Figure 23.1](#)). In addition, niacin inhibits release of free fatty acids from adipose tissue and increases the activity of lipoprotein lipase. The result of these effects is a dose-related 15% to 30% decrease in plasma LDL cholesterol concentrations, a 20% to 50% decrease in triglycerides, and a 20% to 30% increase in HDL. Niacin does not produce any detectable changes in synthesis of cholesterol, nor does it alter excretion of bile acids.²⁷

Pharmacokinetics

Niacin is readily absorbed from the gastrointestinal tract and undergoes extensive hepatic first-pass metabolism. The primary route of metabolism is methylation to *N*-methyl-nicotinamide. Niacin also undergoes conjugation with glycine to produce nicotinuric acid. Metabolites undergo renal excretion and at high doses, niacin undergoes renal excretion unchanged.

Side Effects

Niacin is often poorly tolerated, which may limit its usefulness. The most common side effect is intense prostaglandin-induced cutaneous flushing that occurs in about 10% of patients. Aspirin administered 30 minutes before ingestion of niacin decreases flushing, whereas alcohol ingestion potentiates flushing. Abdominal pain, nausea and vomiting, diarrhea, and malaise are common complaints in treated patients. Hepatic dysfunction manifesting as increased plasma transaminase activity and cholestatic jaundice may be associated with large doses of niacin. Therefore, niacin is not recommended for administration to patients with liver disease. Hyperglycemia and abnormal glucose tolerance may occur in nondiabetic patients treated with niacin. Plasma concentrations of uric acid are increased, increasing the incidence of gouty arthritis. Niacin may exaggerate the orthostatic hypotension associated with antihypertensive drugs and the myopathy associated with statins. Peptic ulcer disease may be reactivated by niacin.

Fibrates

Fibrates are derivatives of fibric acid and are effective drugs for decreasing plasma concentrations of triglycerides. In the postoperative period, treatment with fibrates is restarted when the patient is well hydrated and able to ingest oral medications. There are three fibric acid derivatives commonly used for the treatment of hyperlipidemia: gemfibrozil, fenofibrate, and bezafibrate. Clofibrate was the original fibric acid derivative for treatment of increased plasma triglyceride concentrations. This drug is no longer considered the drug of choice, principally because of concern that noncardiovascular adverse events may be increased in treated patients.²⁸ Fibrates produce a dose dependent 40% to 50% decrease in plasma triglycerides and 10% to 35%

increase in HDL concentrations, whereas the effect on LDL concentrations is variable. Drug-induced increase in the activity of lipoprotein lipase is the likely mechanism for the triglyceride-lowering effects of these drugs (see [Figure 23.1](#)). This action of fibrates may reflect activation of specific transcription factors (peroxisome proliferator-activated receptors), which result in upregulation of genes for lipoprotein lipase and fatty acid oxidation. Induction of lipoprotein lipase contributes to lipolysis of triglyceride-rich lipoproteins, VLDL, and chylomicrons. When the LDL concentration increases, it is presumed to reflect improved catabolism of VLDLs and, hence, increased production of LDLs. Bezafibrate is also thought to improve insulin sensitivity.²⁹

Pharmacokinetics

Gemfibrozil is well absorbed from the gastrointestinal tract following oral administration. Metabolism is by oxidation of a methyl group to form a hydroxymethyl and then a carboxyl metabolite. Protein binding is extensive. The elimination half-time of gemfibrozil is approximately 15 hours, with an estimated 70% of a single dose appearing unchanged in the urine. Fenofibrate is a prodrug that is hydrolyzed by esterases to the active metabolite, fenofibric acid. Fenofibric acid is metabolized by conjugation with glucuronic acid that undergoes extensive renal excretion. The elimination half-time of fenofibrate is about 20 hours. Absorption of fenofibrate is increased when the drug is administered with food. Protein binding is approximately 99%. Increased plasma concentrations of liver transaminase enzymes are more likely to occur with fenofibrate than with the other fibrates.

Side Effects

The most common side effects of the fibrates are gastrointestinal (abdominal pain, nausea) and headache. Gemfibrozil increases the cholesterol content of bile (lithogenicity) and may increase the formation of gallstones. The incidence of skeletal muscle myopathy and risk of rhabdomyolysis is increased when this drug is administered in combination with statins, especially lovastatin. The anticoagulant effect of warfarin is potentiated by gemfibrozil, presumably reflecting its displacement from binding sites on albumin. A mild increase in plasma transaminase enzymes may occur in treated patients. Considering the dependence on renal excretion for elimination and occasional increases in liver function tests, it may be prudent to avoid administration of this drug to patients with preexisting renal or hepatic disease. The increase in noncardiovascular mortality observed with clofibrate²⁸ may be due to low plasma cholesterol concentrations, which predispose patients to hemorrhagic stroke, particularly when systemic hypertension is present.³⁰

Ezetimibe

Ezetimibe acts as a selective inhibitor of cholesterol absorption, which leads to a secondary upregulation of LDL-R (see [Figure 23.1](#)). Cholesterol absorption is inhibited because of ezetimibe's ability to disrupt a complex between the annexin-2 and caveolin-1 proteins in the brush border of the small intestine. Used as monotherapy, ezetimibe decreases LDL cholesterol levels by 8% to 22%, and it can potentiate the effect of statins by an additional 17%. It modestly influences triglyceride levels and has a negligible effect on HDL cholesterol levels.²⁷ Clinical trials addressing the efficacy of ezetimibe in improving cardiovascular endpoints have been conflicting, with some showing a decreased risk of atherosclerotic events when used in conjunction with statins, whereas others have had negative results.^{31,32} It may be helpful in avoiding high-dose statin therapy.

Side Effects

Ezetimibe is very well tolerated, with adverse event rates similar to placebo in clinical trials.

Omega-3 Fatty Acids (Fish Oil)

One type of fat present in marine fish oils is highly unsaturated omega-3 fatty acid. The primary effect of this fatty acid is to decrease plasma concentrations of triglycerides, whereas the effect on the plasma LDL cholesterol concentrations is variable. It is not clear what dose is necessary to cause desirable effects on the plasma concentrations of triglycerides. Fish oil supplements are not regarded as drugs and thus are not

regulated by the U.S. Food and Drug Administration. The long-term safety of taking fish oil capsules is not known, and there is no evidence that fish oil supplementation prevents heart disease. The use of this supplement is of primary concern to the anesthesiologist due to the increased risk of bleeding.³³

Other Agents

Lomitapide is an inhibitor of microsomal triglyceride transfer protein, an intracellular lipid transport protein that is thought to be important for the production of chylomicrons in the intestine and VLDL by hepatocytes. It is indicated for homozygous familial hypercholesterolemia and carries a boxed warning for risk of hepatotoxicity and is only available through a restricted-access program.³⁴

Mipomersen is an oligonucleotide inhibitor of apolipoprotein B100 that is similarly approved for the treatment of patients with homozygous familial hyperlipidemia. Like lomitapide, mipomersen frequently causes elevations in liver enzymes as well as steatosis and is subject to a boxed warning and a restricted access program. It is not currently being marketed in the United States.³⁵

PART IV Pulmonary System

Gas Exchange

Alexander Huang • Peter Slinger

*The essentials of anesthesia are applied physiology,
pharmacology, and clinical monitoring
with a little bit of internal medicine.*

John Sandison, 1980

*Respiratory physiology is difficult; if the answer
is simple you don't understand the question.*

Peter Slinger, 2013

During surgery, the anesthesiologist becomes, in part, an applied respiratory physiologist, and an understanding of the physiology and pharmacology pertaining to the respiratory system is fundamental to anesthetic management. Understanding gas exchange is particularly challenging because respiratory physiology is not an exact science. Anesthesiologists work mainly with concepts that allow them to treat and predict the alterations in respiration associated with anesthesia and a variety of diseases. However, these concepts are all specific to the context of a patient's gas exchange at a specific time and in a specific situation and often cannot be extrapolated precisely to a situation of altered physiology. As discussed, even fundamental basics of respiratory physiology such as **dead space** and **functional residual capacity** (FRC) are never absolute values but are dynamic and always changing.

Functional Anatomy

Upper Airway Anatomy and Gas Flow

Oropharynx and Nasopharynx

The air passages extending from the nares and lips through the nasopharynx and oropharynx, through the larynx to the cricoid cartilage make up the functional upper airway. The upper airway serves a host of functions: warming and humidifying passing air, filtering particulate matter, and preventing aspiration.¹

During normal quiet breathing, air enters via the nose, a chamber separated in the midline along its entire length by a cartilaginous and bony septum. It is bounded laterally by the inferior, middle, and superior turbinates overlying the sinus ostia and inferiorly by the hard and soft palates and joining the nasopharynx posteriorly. The mucosa covering these structures is highly vascular and well innervated, facts that must be appreciated when performing nasopharyngeal intubation with endotracheal tubes, nasogastric sumps or feeding tubes, or fiberoptic bronchoscopes. This tissue is sensitive to even modest stimulation and is easily torn, leading to significant bleeding. The nasal passages represent a significant resistance to airflow, normally double that found in mouth breathing. Hence, normal subjects or patients will revert to mouth breathing during exercise or respiratory failure.

The pharynx is 12 to 15 cm long and is divided into the nasopharynx, the oropharynx, and the laryngopharynx (lying posterior to the larynx). The oropharynx is further subdivided into the velopharynx (posterior to the soft palate) and the retroglossal pharynx (posterior to the base of the tongue) ([Figure 24.1](#)).² The supine position, sleep, and general anesthesia may promote obstruction of the oropharynx by the tongue, soft palate, and pharyngeal musculature as their tone decreases.³ Flexion of the cervical spine generally increases upper airway resistance. During inspiration, a nonsedated, spontaneously breathing patient dilates

the oropharyngeal pharynx by contracting the genioglossus muscle and elevating the tongue off the pharyngeal wall in a coordinated reflex. This subconscious phasic inspiratory dilation opposes the tendency of the upper airway to collapse due to the negative airway pressure generated by the diaphragm during inspiration. Unfortunately, this reflex genioglossus activity is easily abolished by low doses of most anesthetics, with the exception of ketamine.⁴

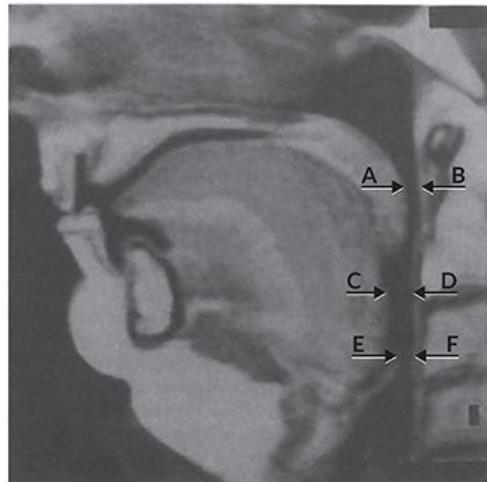

FIGURE 24.1 Sagittal magnetic resonance imaging of the upper airway of an awake patient. A-B is the junction of nasopharynx with velopharynx, C-D is the retroglossal pharynx, and E-F is the minimum anteroposterior upper airway diameter at the tip of the epiglottis. The laryngopharynx extends downward from E-F to the cricoid cartilage. *Reprinted with permission from Shorten GD, Opie NJ, Graziotti P, et al. Assessment of upper airway anatomy in awake, sedated and anaesthetised patients using magnetic resonance imaging. Anaesth Intensive Care. 1994;22(2):165-169. Copyright © 1994 SAGE Publications.*

Larynx

The larynx is a complex structure that lies anterior to the 4th to the 6th cervical vertebrae and consists of several muscles, their ligaments, and associated cartilaginous structures (**Figure 24.2**). The inlet of the larynx is bordered by the epiglottis, aryepiglottic folds, and the arytenoids. The larynx itself bulges into the pharynx posteriorly creating a deep pharyngeal recess anterolaterally on either side, the pyriform fossae. The pyriform fossae, which lie to each side of midline, are clinically relevant because of their tendency to trap food or foreign objects in the pharynx and as potential sites for the application of topical anesthesia to block the internal branch of the superior laryngeal nerve. The larynx serves as the organ of phonation and plays an important role in coughing and in protection of the airway from entrainment of solids and liquids during swallowing.⁵

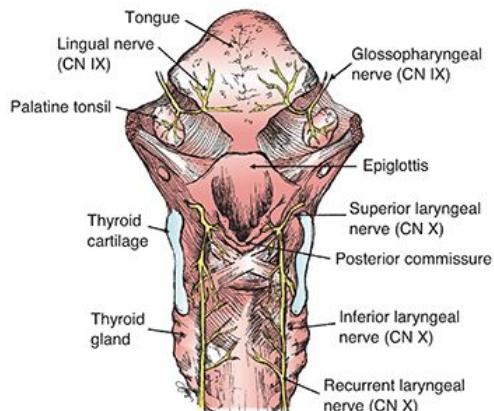

FIGURE 24.2 Diagram of the larynx from the base of the tongue to below the thyroid cartilage as viewed from its posterior aspect. Note the relationship of the superior laryngeal, inferior laryngeal, and recurrent laryngeal nerves and the posterior aspect of the larynx, thyroid, and trachea. Tracheal and thyroid surgery places these nerves at risk. *Reprinted by permission from Springer: Jaeger JM, Blank RS. Essential anatomy and physiology of the respiratory system and the pulmonary circulation. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011:51-69. Figure 4.1. Copyright © 2011 Springer Science+Business Media, LLC.*

The primary support structure of the larynx is the thyroid cartilage that forms the point of articulation of the paired arytenoid cartilages with the vocal ligaments and their controlling musculature. Other essential structures include the hyoid bone and its attachments, the epiglottis, the cricoid cartilage, and the corniculate cartilages. The hyoid bone is a U-shaped bone that is attached directly to the stylohyoid ligament and muscle; to the mandible and tongue by the hyoglossus, mylohyoid, geniohyoid, and digastric muscles; and to the pharynx by the middle pharyngeal constrictor muscle. Beneath the hyoid bone is the remainder of the larynx suspended by its attachment, the thyrohyoid membrane and muscle. Although its function other than as a flexible anchor is unclear, it is possible to bisect its mandibular attachments (“suprathyroid release”) and mobilize the larynx in order to facilitate its caudal displacement in tracheal resection procedures. The epiglottis is the midline elastic cartilage found inferior to the base of the tongue. It is anchored anteriorly to the hyoid bone and inferiorly to the inside of the anterior portion of the thyroid cartilage immediately above the vocal cords. Bilateral folds of the epiglottis curve posteriorly to form a mucosal ridge attached to the arytenoid cartilages sitting on top of the posterior lamina of the cricoid, the aryepiglottic folds. The epiglottis, aryepiglottic folds, and the corniculate tubercles form the inlet into the glottis below. The thyroid cartilage contains the larynx with its paired lamina fused anteriorly at the laryngeal prominence and extending posteriorly to terminate in superior and inferior horns or cornu. The thyroid cartilage serves as a stable point of attachment for numerous small muscles and ligaments, which manipulate the vocal cords. The thyroid cartilage also has a mobile, membranous attachment to the cricoid ring.

The paired vocal cords attach posteriorly to the vocal process of each arytenoid and anteriorly meet at the junction of the thyroepiglottic ligament of the anterior portion of the thyroid cartilage. The triangular opening formed by the vocal ligaments is the glottis with its apex anteriorly (**Figure 24.3**). The mean length of the relaxed open glottis is approximately 23 mm in males and 17 mm in females. The glottis at its widest (posterior) point is 6 to 9 mm but can be “stretched” to 12 mm.⁶ It should be noted that the vocal cords are covered by a thin, adherent mucosa, producing a pearly white appearance. The absence of any submucosa implies that the vocal cords are unlikely to “swell” significantly as there is minimal space to accumulate edema fluid. However, the folds of mucosa and fibrous tissue lying parallel to the true vocal cords just superiorly in the glottis, the vestibular folds or “false vocal cords,” can become edematous. The intrinsic laryngeal musculature functions to open the glottis during inspiration; close the glottis and constrict the superior structures during swallowing; and finely control abduction, adduction, and tension of the true vocal cords during phonation.

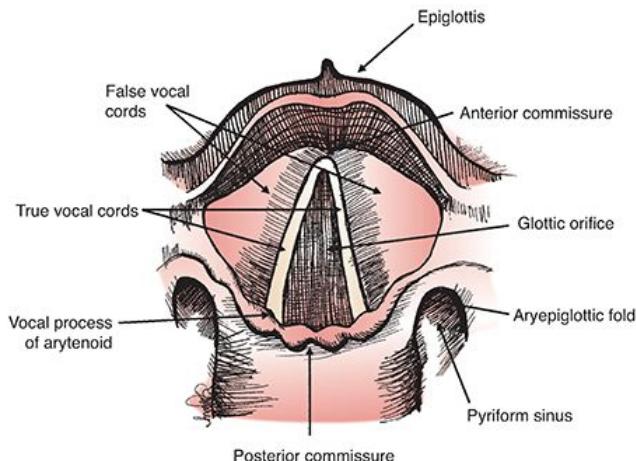

FIGURE 24.3 Diagram of the glottis as seen from above using a laryngoscope or fiberoptic bronchoscope. Note the triangular-shaped glottic introitus with its narrowest aspect at the anterior commissure. Passage of bronchoscopes, endotracheal tubes, and, especially, double-lumen tubes should be directed posteriorly where the vocal cords will spread the widest. Note that the vocal process of the arytenoid cartilage pivots on a small point and can be traumatized and displaced with rough handling. *Reprinted by permission from Springer: Jaeger JM, Blank RS. Pharyngeal Innervation

Innervation of the pharynx is supplied via sensory and motor branches of the glossopharyngeal nerve (CN IX) and vagus nerve (CN X) (external and internal branches of the superior laryngeal nerves, recurrent laryngeal nerves). The sensory innervation of the nasopharynx is derived from the maxillary division of the trigeminal nerve (CN V), whereas the oropharynx is diffusely innervated by sensory branches from the glossopharyngeal nerve (CN IX). The internal branch of the superior laryngeal nerve pierces the lateral aspect of the thyrohyoid membrane along with the superior laryngeal artery and vein to provide sensation for the base of the tongue, vallecula, epiglottis, aryepiglottic folds, pyriform recesses, and the superior aspect of the true vocal cords. The external branch of the superior laryngeal nerve provides motor innervation to the cricothyroid muscle, a tensor of the true vocal cords. The recurrent laryngeal nerves supply sensation to the vocal cords and tracheobronchial tree as well as motor innervation to all the remaining intrinsic musculature of the larynx. The right recurrent laryngeal nerve passes inferior to the right subclavian artery, but the left originates at the level of the aortic arch and loops around the ligamentum arteriosum then both nerves ascend cephalad along the tracheoesophageal groove. This anatomy must be appreciated during esophageal and thyroid surgery and during both cervical and anterior mediastinoscopy, as these structures can be at risk. The larynx receives its blood supply from the superior and inferior laryngeal arterial branches of the superior and inferior thyroid arteries, respectively. These arteries follow the course of the superior and recurrent laryngeal nerves.

The major function of the upper airway is to provide a conduit for the initial inhalation then exhalation of gases to and from the lungs while contributing to multiple other functions (eg, eating, drinking, speaking). With respect to inhalation, the nasopharynx and posterior pharynx warm and humidify the inspired gas. This aids in maintaining core temperature and protects the more delicate epithelial lining of the lower airways from desiccation. The airway epithelium secretes mucus, which coats the airway surface and maintains tissue hydration and also serves to trap particulate matter, bacteria, and viruses. Mucus also contains a number of enzymes with antioxidant, antiprotease, and antibacterial properties.⁷

Another important role of the airways and their mucus coat is the filtering of inhaled particulate matter by an elaborate defense system that takes advantage of the airflow characteristics of the upper and lower

airways and their associated epithelium. There are three mechanisms at work to produce mechanical filtering of inspired gases.¹ The first, inertial impaction, is capable of trapping particles larger than 10 microns by virtue of the turbulent flow across the mucus lining of the passageways. It accomplishes this task in minutes with mucus and saliva eventually swallowed. Gas flow slows within the bifurcating and branching tracheobronchial tree until it becomes more laminar. Particulates impact the airway wall according to particle size (sedimentation). Normally, the particles, including bacteria and similar-sized particles, are trapped in the mucus at this level of more proximal airways and are transported cephalad by the constant motion of the cilia, an apical feature of the respiratory epithelium, at a rate of approximately 2.5 mm/minute in the bronchi but over 5 mm/minute in the trachea. Lower airway mucus is usually cleared in about 24 hours, although this can be drastically retarded in disease states, such as cystic fibrosis or chronic bronchitis, or conditions altering ciliary function or growth, such as tobacco smoking.⁸ The filtering processes appear effective down to particles approximately 0.01 micron in diameter.

Upper Airway Gas Flow

Gas flow is directly proportional to the pressure gradient (change in airway pressure [ΔP]) and inversely proportional to the resistance. When a gas (or liquid) flows through a straight unbranched tube, flow will usually be laminar and resistance is directly proportional to the viscosity of the gas and inversely proportional to the fourth power of the radius.

$$\text{Resistance} = 8 \times \text{length} \times (\text{viscosity} / \pi) \times (\text{radius})^4$$

However, at very high flow rates or when gas flows through an irregular tube or orifice, flow tends to become turbulent and resistance becomes proportional to the density of the gas and inversely proportional to the fifth power of the radius (ie, changes in airway caliber affect resistance to turbulent flow more than laminar flow). Reynolds number is a dimensionless number that allows estimation of whether a flow is turbulent or laminar.⁹

$$\text{Reynolds number} = \text{velocity} \times \text{diameter} \times \text{density} / \text{viscosity}$$

In the airway, Reynolds numbers for air during quiet breathing are <2,000 throughout most of the upper and lower airway (**Figure 24.4**). Reynolds numbers >4,000 are associated with turbulent flow, and 2,000 to 4,000 is a mixture of laminar and turbulent flows. Helium is a gas with a low density compared to air or oxygen; however, the viscosity of the three is almost equal. A mixture of 80% helium/20% oxygen has a density approximately 0.33 that of air and 0.30 that of oxygen. In conditions of increased turbulent flow in large airways due to a mass or edema, breathing a mixture of helium and oxygen will decrease dyspnea for some patients (this is also why breathing helium changes phonation so that a person may imitate Donald Duck). This applies only to turbulent flows in large airways. Helium does not relieve dyspnea due to increased distal laminar airflow resistance such as in asthma or chronic obstructive pulmonary disease (COPD).

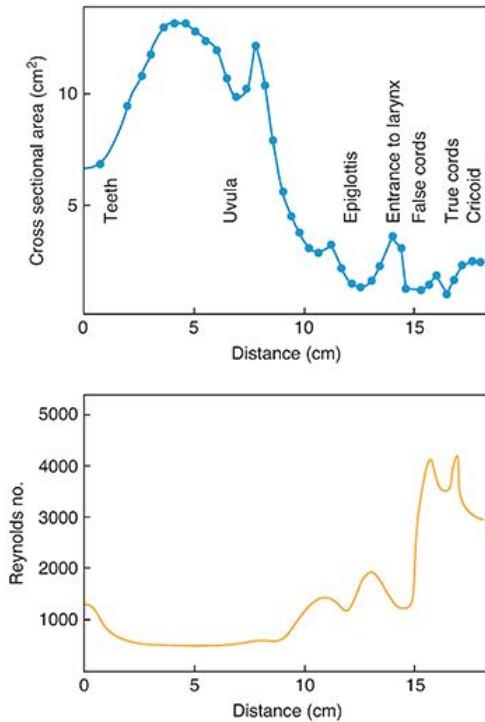

FIGURE 24.4 The cross-sectional area of the upper airway at various levels from the teeth to the cricoid cartilage (top) and the corresponding Reynolds numbers at each level (bottom) for air during a quiet inspiration (flow = 0.5 L/second). Flow will be laminar at Reynolds numbers <2,000 and turbulent at numbers >4,000. *From Burwell DR, Jones JG. The airways and anaesthesia—I. Anatomy, physiology and fluid mechanics. Anaesthesia. 1996;51(9):849-857. Copyright © 1996 The Association of Anaesthetists of Great Britain and Ireland. Reprinted by permission of John Wiley & Sons, Inc.*

Tracheal and Bronchial Structure

The trachea originates at the cricoid cartilage (at the level of C6 vertebra) and extends approximately 10 to 12 cm (females) and 12 to 14 cm (males) to terminate in a bifurcation (carina) at the T4/5 vertebral level (2nd intercostal space, the angle of Louis) (**Figure 24.5**). The trachea is 22 ± 1.5 mm (males) to 19 ± 1.5 mm (females) in diameter and consists of 16 to 20 U-shaped cartilaginous rings that are closed posteriorly by fibrous tissue and a longitudinal smooth muscle band, the trachealis muscle.

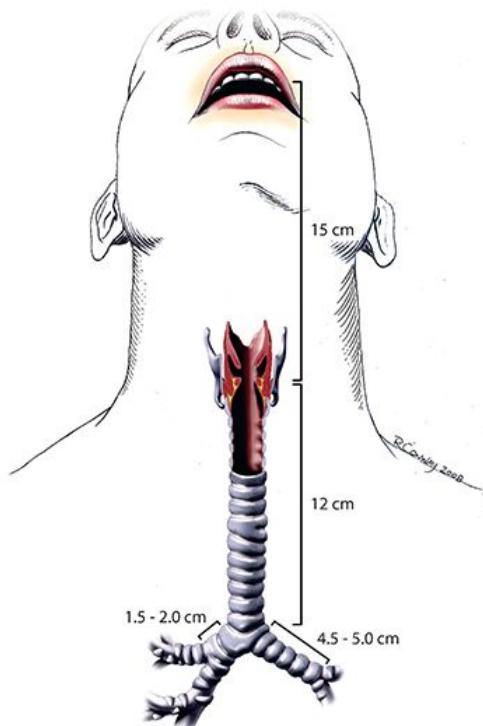

FIGURE 24.5 The average length from the incisors to the vocal cords is approximately 15 cm, and the distance from the vocal cords to the tracheal carina is 12 cm. The average distance from the tracheal carina to the takeoff of the right upper bronchus is 2.0 cm in men and 1.5 cm in women. The distance from the tracheal carina to the takeoff of the left upper and left lower lobe is approximately 5.0 cm in men and 4.5 cm in women. These anatomic distances apply to individuals with a height of 170 cm. Reprinted by permission from Springer: Campos J. Lung isolation in patients with difficult airways. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011:247-258. Figure 17.1. Copyright © 2011 Springer Science+Business Media, LLC.

The right main bronchus is wider (16 vs 13 mm), shorter (1.5-2.5 cm vs 4.5-5.0 cm), and more vertical than the left. The right main bronchus gives off the upper lobar bronchus and then continues as the bronchus intermedius giving off the right middle lobar bronchus and right lower lobar bronchus at the hilum of the lung at T5 ([Figure 24.6](#)). The left main bronchus passes inferiorly and laterally below the aortic arch, anterior to the esophagus and descending thoracic aorta, to reach the hilum of the left lung at T6. These dimensions can be quite variable among individuals, and chest pathology can drastically change the anatomy.

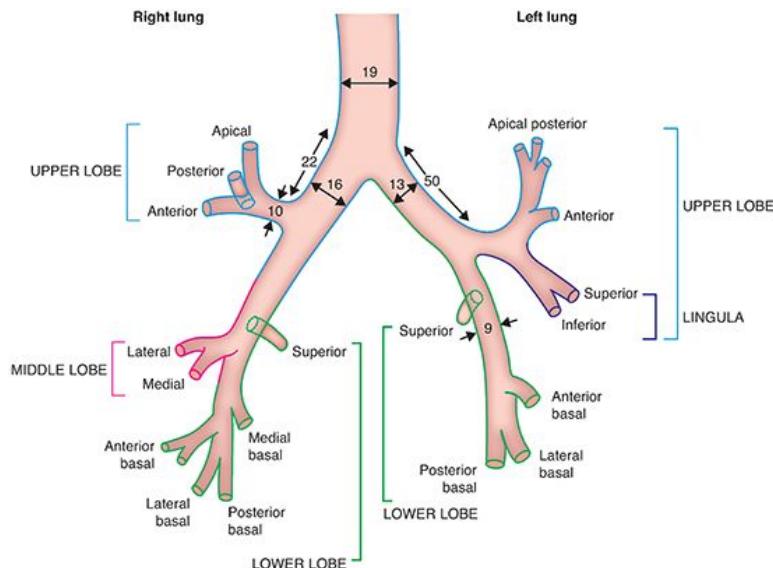

FIGURE 24.6 Diagram of the trachea, lobar, and segmental bronchi showing median lengths and diameters for a 170-cm-tall patient. The lengths and diameters of the bronchi vary considerably between individuals.

The lobar bronchi (right upper, right middle, right lower and the left upper, left lower) extend into their segmental bronchi that can be readily visualized during flexible bronchoscopy. The right upper lobe bronchus gives off 3 segmental bronchi (apical, anterior, posterior) ([Figure 24.7](#)), the right middle lobe bronchus splits into 2 segmental bronchi (lateral, medial), and the right lower lobe bronchus divides into a superior segment (directed posteriorly) and a basilar segmental bronchus, which divides into 4 segments (medial basal, anterior basal, lateral basal, posterior basal) for a total of 10 segmental branches on the right. The left upper lobar bronchus splits into the superior division with “3” segments (a “fused” apical-posterior and an anterior) and the inferior division or lingual with 2 segments (superior and inferior). The left lower lobe bronchus branches into 4 lower segmental branches (superior, a “fused” anteromedial basal, lateral basal, and posterior basal) for a total of “10” segments on the left. An online interactive bronchoscopy simulator is available to demonstrate this anatomy ([Figure 24.8](#)).

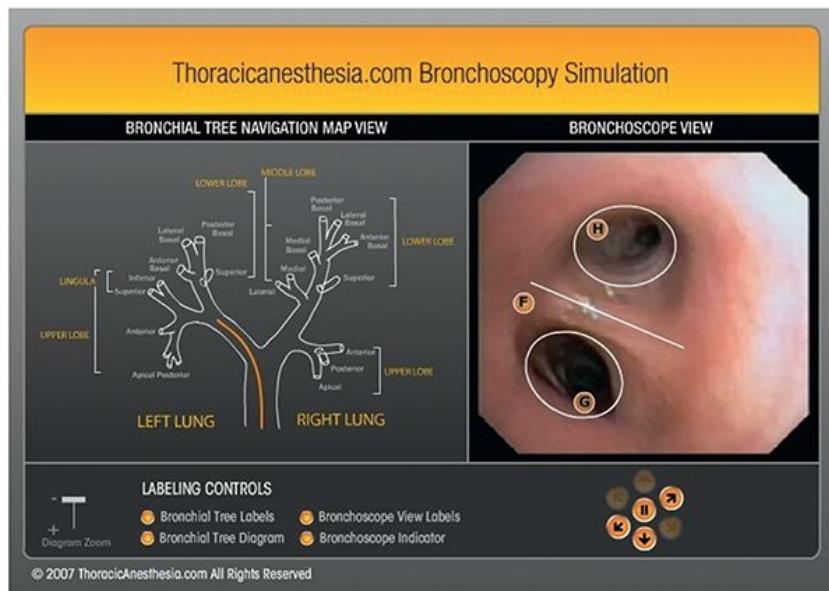

FIGURE 24.8 The free online bronchoscopy simulator at www.thoracicanesthesia.com. The user can navigate the tracheobronchial tree using real-time video by clicking on the lighted directional arrows under the “Bronchoscope View” (right). Clicking on the labels on the “Bronchoscope View” gives details of the anatomy seen. The process is aided by the “Bronchial Tree Navigational Map View” (left), which shows the simultaneous location of the bronchoscope as the orange line in the airway.

Respiratory Airways and Alveoli

The airways continue to divide into smaller diameter conduits until one arrives at the bronchioles with diameters less than 0.8 mm. At this level, the airways lose all remnants of cartilage and begin the transformation from purely conducting airways to those described as respiratory bronchioles. Respiratory bronchioles eventually divide into the final four generations of alveolar ducts, which then consist primarily of openings into the terminal alveolar sacs. In the descriptive model of Weibel ([Figure 24.9A](#)),¹⁰ the trachea branches into 23 generations of airways. The first 15 generations serve as conducting airways and the subsequent 8 generations become sufficiently thin walled to allow some degree of gas exchange and are called **acinar** airways. One clinical aspect of this geometric progression of increasingly narrower airways (and blood vessels) by divergence and multiplication is that the overall cross-sectional area and therefore resistance to gas flow (or blood flow) becomes markedly less compared to the resistance of the proximal airway (or blood vessel) ([Figure 24.9B](#)). This has an important impact on distribution of gas and blood flow, flow velocity, and, hence, transit time through key areas of gas exchange.

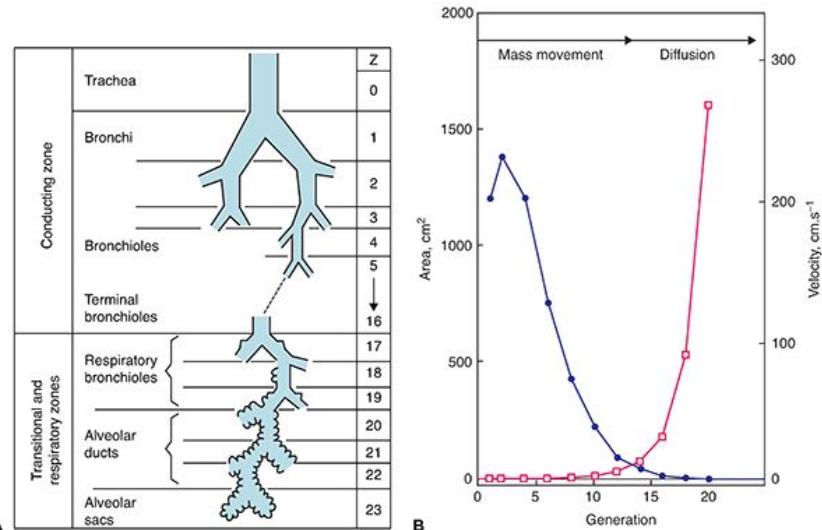

FIGURE 24.9 A, The symmetrical branching model of the tracheobronchial tree. B, The change in cross-sectional area (open squares) and gas velocities (closed circles) seen with normal quiet breathing. Mass movement of gas predominates down to the 14th/15th generation of bronchi below which diffusion becomes the predominant method of gas exchange. The airway dead space is the volume of the airways through which mass movement predominates. *From Burwell DR, Jones JG. The airways and anaesthesia—I. Anatomy, physiology and fluid mechanics. Anaesthesia. 1996;51(9):849-857. Copyright © 1996 The Association of Anaesthetists of Great Britain and Ireland. Reprinted by permission of John Wiley & Sons, Inc.*

The interior of the trachea is lined with ciliated columnar epithelium, goblet cells (responsible for mucus production) (Figure 24.10), and interspersed specialized chemical and tactile neuroreceptors. The lining of the airways transitions from pseudostratified columnar epithelia in the larger bronchi to a thinner cuboidal ciliated variety in the small bronchi. The airway epithelium and submucosa also contain lymphocytes, mast cells, and a variety of neuroendocrine cell types. The next layer consists of circumferential bands of smooth muscle cells and a connective tissue layer containing submucosal glands and plates of cartilage (replacing the solid cartilage rings in the very large airways) (Figure 24.11). The outermost layer is a loose adventitial shell with lymphatic vessels, sympathetic and parasympathetic nerves, and nourishing blood vessels.

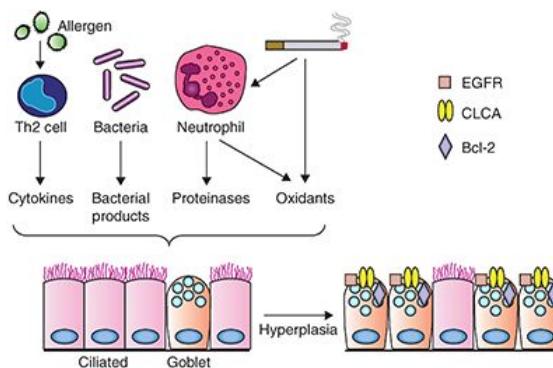

FIGURE 24.10 Normal respiratory epithelium (bottom left) has a predominance of ciliated to goblet cells. Goblet cell hyperplasia (lower right) occurs in response to chronic inflammatory stimuli (upper left), which upregulate mucin production and/or induce goblet cell hyperplasia with associated increases in expression of epidermal growth factor receptors (EGFR), calcium-activated chloride channels (CLCA) and the antiapoptotic factor B-cell lymphoma 2 (Bcl-2). *Modified by permission from Springer: Yeazell L, Littlewood K. Surgery. New York, NY: Springer; 2011:103-119. Figure 7.3. Copyright © 2011 Springer Science+Business Media, LLC.

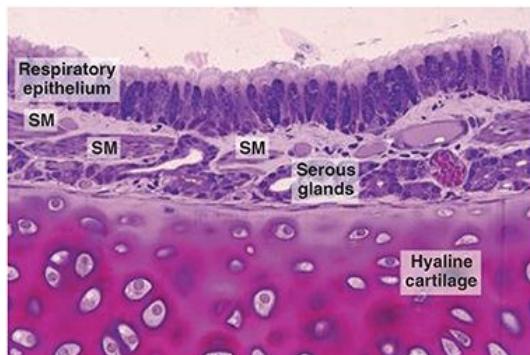

FIGURE 24.11 Microphotograph of a histologic section of the wall of an intrapulmonary bronchus. The mucosa, as in the trachea and extrapulmonary bronchi, consists of an epithelium (ciliated pseudostratified columnar with goblet cells), a basement membrane, and a lamina propria. The latter is rich in elastic fibers of the recoil mechanism. Unlike more proximal air passages, a muscularis is present and lies just external to the lamina propria. It is composed of two sets of smooth muscle (SM) fibers, which extend down the bronchial tree in a right and left spiral. The submucosa is a layer of loose connective tissue, which lies outside the muscularis. Bronchial glands are present in this layer and also extend into the intercartilaginous intervals. The cartilage-fibrous layer lies outside the submucosa. It contains discontinuous plates of hyaline cartilage and fibrous connective tissue. *Repubublished with permission of McGraw Hill LLC from Junqueira LC, Carneiro J. Basic Histology: Text and Atlas. 10th ed. New York, NY: Lange Medical Books/McGraw Hill, 2003; permission conveyed through Copyright Clearance Center, Inc.*

The respiratory bronchioles terminate in a pulmonary acinus, which has the appearance of a cluster of grapes on a network of stems. Each acinus may contain multiple alveolar ducts communicating with 2,000 alveoli arranged in a ringlike, honeycomb network. The alveolus is considered the primary site of gas exchange between the blood and gas in the lung. The alveolar septa are about 5 to 8 microns thick and are opposed by an alveolar surface on either side with the alveolar capillary bed sandwiched inside. The walls of the alveoli are extremely thin, between 0.1 and 0.2 microns, a feature that promotes rapid equilibration of gas by diffusion with the pulmonary capillary blood. In addition, gas can exchange between alveoli through pores of Kohn. There are approximately 300 million alveoli in the human lung, which provides an extraordinary surface area for gas exchange (eg, 70 m²).

There are three major cell types found in the alveolus: alveolar type I cells, alveolar type II cells, and alveolar macrophages. However, there are other cell types found under certain conditions in the lung (eg, inflammation). Alveolar type I cells are squamous epithelial cells that cover most of the alveolar surface. These nucleated cells have few cytoplasmic organelles and a sparse cytoplasm splayed out in sheets over the alveolar surface forming a thin barrier between the air space and the pulmonary capillary endothelium. Alveolar type II cells are fewer in number, somewhat spherical, and coated on their apical surface with microvilli. In contrast to type I cells, alveolar type II cells possess many organelles including multilayered granular structures called **lamellar bodies** ([Figure 24.12](#)). These lamellar bodies are the source of pulmonary surfactant, a lipoprotein coating the interior surface of the alveolus and capable of significantly reducing the surface tension of the alveolus air-surface interface. Surface tension reduction is considered an important physical mechanism to reduce any tendency for alveolar collapse at very low lung volumes.

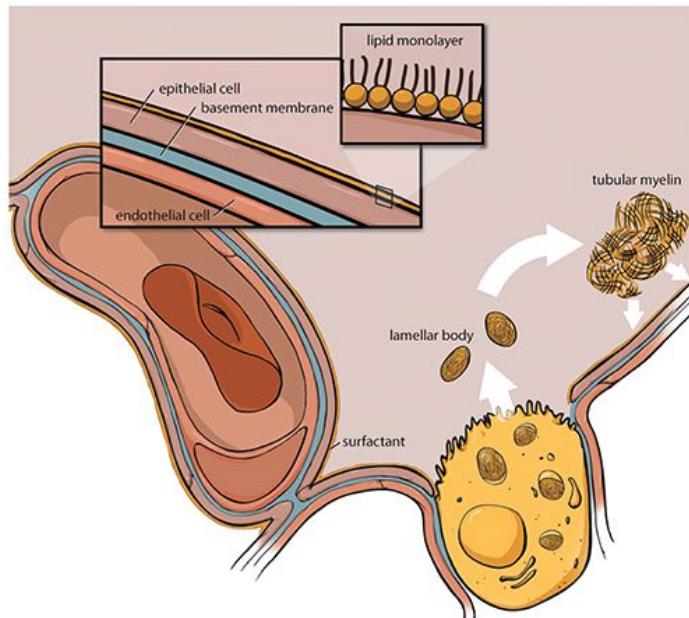

FIGURE 24.12 The diagram presents a scheme of the alveolar air-blood barrier, which consists of endothelial cells, epithelial cells (type I pneumocytes), and their common basement membrane. The large cuboidal cell (bottom right) is a type II pneumocyte producing surfactant, contained within its cytoplasm as lamellar bodies (onion-like structures), which are exocytosed into the alveolar lumen, then transform into tubular myelin and finally form surfactant (lipid monolayer) covering the surface of type I pneumocytes. The upper left-hand side inset shows details of the thin alveolar-capillary membrane; the right-hand side inset shows a scheme of the surfactant monolayer. *Modified by permission from Springer: Wasowicz M. Anesthesia for combined cardiac and thoracic procedures. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011:453-464. Figure 32.1A. Copyright © 2011 Springer Science+Business Media, LLC.*

The immune defenses of the lung are extremely important because of the direct exposure of this organ to the external environment via the airways. There are a number of excellent reviews of the immune function of the lung, but it is important to realize that there are many questions unanswered about how the lung responds to invasion and inflammation. From a clinical standpoint, the pulmonary inflammatory response will greatly influence the perioperative management of the surgical patient. A few major defensive cell types residing in the alveolar spaces and interstitium are worth mentioning. Alveolar macrophages are derived from bone marrow monoblast precursor cells and migrate to the lung parenchyma ([Figure 24.13](#)).¹¹ Alveolar macrophages are free to move over the surface of the alveolus and phagocytize foreign material that enters the alveolus including bacteria and particulates. Macrophages are cleared either through the lymphatics or are carried up and expelled via the airways. Lymphocytes, largely T lymphocytes, are widely distributed in the normal lung within paratracheal and hilar lymph nodes, in the interstitium of the bronchial tree as nodules or individual cells and in the alveolar walls. They play a critical role in the lung's primary immune response to inhaled antigens. Under some pathologic conditions in the lung, it is becoming apparent that an exaggerated inflammatory response and the activity of these cells and others may be harmful to the lung; the acute respiratory distress syndrome (ARDS) and emphysema are examples.

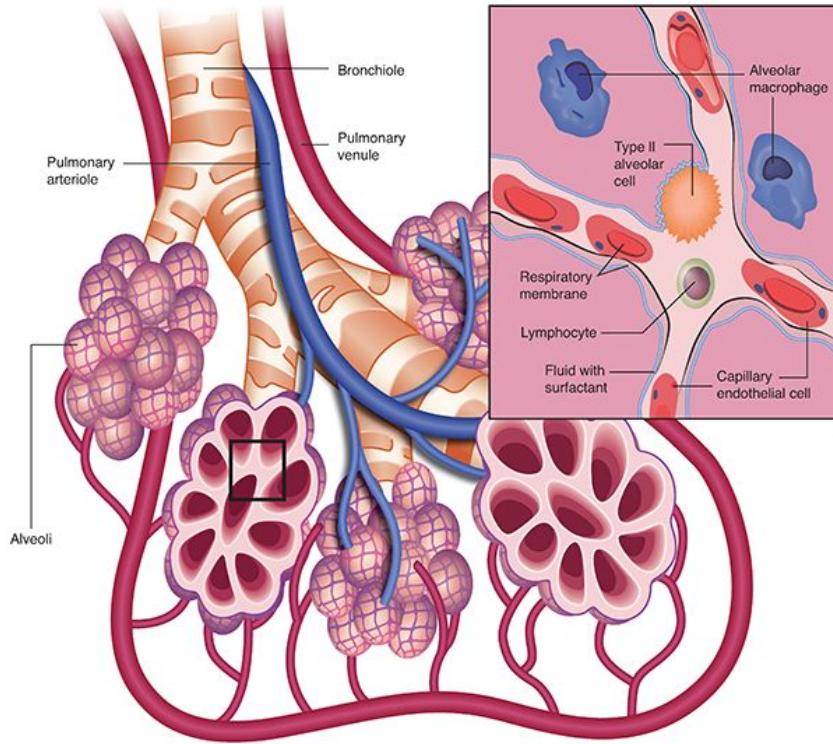

FIGURE 24.13 Diagram of a normal acinus of the lung showing the pulmonary capillaries. In the enlargement (upper right) the macrophages move freely into and out of the alveoli; however, the lymphocytes normally remain within the pulmonary capillaries. Pulmonary Circulation

Although the blood flow through the pulmonary circulation is normally equal to the blood flow through the systemic circulation (a major exception being intracardiac shunting when it exceeds systemic circulation), the pressures in the pulmonary circulation are normally lower than the systemic circulation because the pulmonary vascular resistance (PVR) is lower than the systemic resistance (approximately one-sixth of systemic resistance). This is because the pulmonary vessel walls contain less elastic and muscular tissue than systemic vessels of corresponding caliber. Pulmonary arterioles contract rapidly in response to hypoxemia in the alveoli and to a lesser extent to hypoxemia in mixed venous blood. This hypoxic pulmonary vasoconstriction (HPV) is unique to the pulmonary circulation (systemic arterioles dilate in response to hypoxia) and permits regional matching of perfusion to ventilation.

Like all endothelium, the vascular luminal wall of the pulmonary capillaries is lined by glycocalyx, a microcilia layer that acts as a molecular sieve.¹² This >0.1-micron layer prevents adhesion of platelets and leukocytes and is thought to trap larger molecules close to the endothelial membrane and locally increase the oncotic pressure. The glycocalyx covers the pores between endothelial cells and acts as a molecular sieve to control fluid flux. A healthy glycocalyx is important to prevent edema formation in the lung. However, the glycocalyx is damaged by inflammation and ischemia reperfusion, and this may contribute to the increased flux of fluid into the pulmonary extracellular matrix in these conditions.

The air passages receive their blood supply from systemic bronchial arteries down to the level of the respiratory bronchioles. Only one-third of the bronchial circulation returns to the systemic venous system, the remainder drains into the pulmonary veins, and this constitutes the largest portion of the normal extrapulmonary venoarterial shunt. This bronchial shunt is less than 1% of the cardiac output in healthy individuals but may increase to 10% in bronchiectasis, emphysema, and some congenital cardiac conditions.

Thorax and Muscles of Respiration

The lungs are contained within the thorax. The bony thorax is composed of the 12 ribs, the sternum anteriorly, and the thoracic vertebral column posteriorly. The caudal end of the thorax is formed by the diaphragm, and the cranial end of the thorax is the thoracic inlet, within the ring formed by the first ribs, containing the trachea, esophagus, and the neurovascular supply to the head and arms. Bulk movement of air into and out of the lungs occurs as a result of changes in intrathoracic pressure created by rhythmic changes in the volume of the thorax. Expansion of the chest cavity occurs when three respiratory muscle groups work in concert. The diaphragm, intercostal muscles, and the accessory muscles (sternocleidomastoids, scalenes) are controlled by the respiratory centers of the brain to contract in a rhythmic pattern designed to match ventilation to gas exchange requirements. The abdominal musculature (rectus abdominis, external oblique, internal oblique, and transversus abdominis) can be recruited when more force is required for exhalation, although abdominal muscle tone may stabilize the rib cage during inspiration as well.¹

Inspiration

The diaphragm is unique in that its muscle fibers radiate from a central tendinous structure to insert peripherally on the ventrolateral aspect of the first three lumbar vertebrae, the aponeurotic arcuate ligaments, the xiphoid process, and the upper margins of the lower six ribs. Its motor innervation is solely from the right and left phrenic nerves, which originate from the 3rd, 4th, and 5th cervical spinal nerves. In the relaxed state, it forms a pronounced “dome” that closely apposes the chest wall for some distance before arching across. Contraction of the diaphragm causes a large caudal displacement of the central tendon resulting in a longitudinal expansion of the chest cavity. Simultaneously, its insertions on the costal margins cause the lower ribs to rise and the chest to widen. This diaphragmatic motion is responsible for the majority of quiet respiration. As the dome descends, it displaces the abdominal contents caudally. The fall in pleural pressure and accompanying lung expansion produce an increase in abdominal pressure and outward movement of the abdominal wall. The supine and Trendelenburg positions or surgical retractors can significantly interfere with this abdominal motion especially in the morbidly obese, necessitating controlled ventilation under anesthesia.

The intercostal muscles are thin, sheetlike muscles with origins and insertions between the ribs. The internal intercostal muscles have their fibers oriented obliquely, caudally, and dorsally, from the rib above to the rib below. The external intercostal muscles have their fibers oriented obliquely, caudally, and ventrally, from the rib above to the rib below. All intercostals are innervated by the intercostal nerves running in the neurovascular bundle under the inferior lip of each rib. The contraction of the external intercostal muscles produces an inspiratory action by elevating the upper ribs to increase the anteroposterior dimensions of the chest in a “bucket-handle” motion. The lower ribs are also elevated by virtue of the force applied and their point of rotation to increase the transverse diameter of the thorax. The internal intercostals apply their force in such a direction as to rotate the ribs downward, decreasing the thoracic anteroposterior dimension to aid in active expiration (when required) and cough. In general, the intercostal muscles do not play a major role in quiet respiration but do in exercise or other conditions requiring high levels of ventilation.

The principal accessory respiratory muscles are the sternocleidomastoid and scalene muscles. The scalene muscles originate from the transverse processes of the 4th through the 8th cervical vertebrae and slope caudally to insert on the first two ribs. Their contraction during periods of high ventilatory demand elevates and fixes the cephalad rib cage during inspiration. Similarly, the sternocleidomastoid muscles elevate the sternum and increase the longitudinal dimensions of the thorax.

Expiration

Expiration is a passive process in quiet breathing and is largely the response to relaxation of the inspiratory muscles and the balance of forces generated by the elastic recoil of the lungs and chest wall. When high levels of ventilation are required as in exercise or if airway resistance increases (as in exacerbations of asthma or COPD), the expiratory phase becomes an active process with forceful contraction of the rectus abdominis, the transverse abdominis, and the internal and external oblique muscles. The contraction of the abdominal musculature retracts the abdominal wall and pulls the lower ribs downward, which increases intraabdominal pressure and accelerates the cephalad displacement of the diaphragm during exhalation. The internal

intercostal muscles depress the rib cage and provide a minor contribution to forced expiration. Innervation of the abdominal musculature is from thoracic nerves 7 through 12 and the 1st lumbar nerve.

Like most skeletal muscles, the diaphragm and intercostal muscles contain a heterogeneous mix of fiber types. The diaphragm has between 49% and 55% type I (slow-oxidative) fibers, the remainder a mix of the “faster high activity” types IIA and IIB fibers.¹³ The types of skeletal muscle fibers are distributed fairly evenly throughout the diaphragm. Of note, the respiratory muscles retain the ability to adapt to stress and training. This includes responses to lung pathology, which might seem maladaptive. Emphysema is a good example. The diaphragm undergoes changes at the sarcomere level, physically “losing” contractile units as hyperinflation of the lungs leads to increasing thoracic dimensions and “flattening” of the diaphragm.¹⁴ Loss of sarcomeres in series with the central tendon may help to restore the mechanical advantage of the optimal length-tension relationship for the muscle.

Respiratory Mechanical Function

The basics of mechanical function of the respiratory system are the interaction of two opposing springs: the chest wall, which at rest is trying to expand, and the lungs, which at rest are trying to contract ([Figure 24.14](#)). The lungs and chest wall move together as a unit. This is made possible by the enclosed, airtight thoracic cavity where the outer surface of the lungs and its visceral pleura are in close proximity to the parietal pleura covering the inner surface of the chest wall and the mediastinal structures. Changes in the intrathoracic volume are only possible because the inside of the lung is in continuity with the ambient atmosphere outside the thorax via the trachea and pharynx. The intimate contact between the layers of pleura is maintained by a negative intrapleural pressure generated in part by the intermolecular forces of the pleural fluid excluding gas from this space. This lubricating fluid allows freedom of the pleural layers to slide over one another but highly resists separation of the layers much like two panes of glass with a thin layer of water between them.

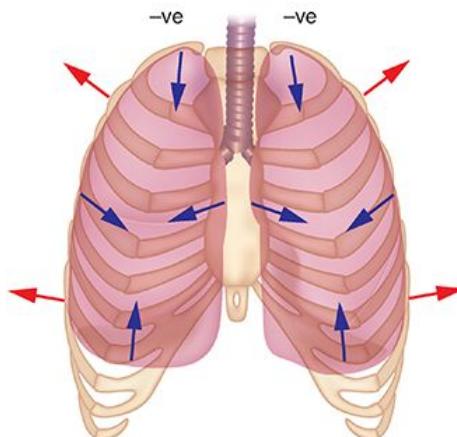

FIGURE 24.14 The respiratory system is at an elastic equilibrium at rest at functional residual capacity. The outward recoil of the chest wall (red arrows) is balanced by the inward recoil of the lungs (blue arrows). The opposing forces generate the negative intrathoracic pressure (mean approximately $-5\text{ cm H}_2\text{O}$) with a superior-inferior gradient due to gravitational effects on the lung parenchyma.

Normally, the intrapleural pressure is about $-5\text{ cm H}_2\text{O}$ when the respiratory system is at equilibrium. Because of the deforming effect of gravity on the lung parenchyma, there is a vertical gradient of intrapleural pressure. This gradient is largest in the seated or upright position ([Figure 24.15](#)). The volume of gas contained in the lungs at this resting point is termed **functional residual capacity**. For a healthy young adult male, total lung capacity (TLC) will be approximately 6 to 6.5 L and FRC will be 2.5 to 3 L. The oxygen contained in the FRC (500-600 mL) is the only reservoir of oxygen in the body.

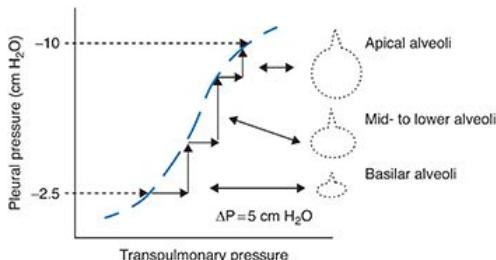

FIGURE 24.15 The static relationship between the transpulmonary pressure (alveolar pressure – pleural pressure) and the pressure in the pleural space results in a sigmoid curve of respiratory compliance. Pleural pressure is normally negative relative to atmospheric pressure. In the seated or upright position, the gradient is small at the base of the lung (intrapleural pressure [P_{PL}] least negative) but larger at the apex (P_{PL} most negative) because of the deforming effect of gravity on the lung parenchyma. This disparity results in larger alveoli at the apex and then the dependent alveoli at the base. As a result of this sigmoid relationship, a given change in transpulmonary pressure produces the largest change in volume (and pleural pressure) where the alveoli are on the steepest portion of this curve (mid to lower alveoli). *Reprinted by permission from Springer: Jaeger JM, Blank RS. Essential anatomy and physiology of the respiratory system and the pulmonary circulation. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011:51-69. Figure 4.3. Copyright © 2011 Springer Science+Business Media, LLC.*

Pathologic conditions such as the introduction of air or blood into the intrapleural space can rapidly disrupt this lung–chest wall interaction, leading to a compromise in respiratory function but also interfere with cardiovascular function. Examples of disruption of the intrapleural space would be a pneumothorax, empyema, pleural effusion, or bronchopleural fistula.

Lung Volumes and Spirometry

By convention, the static and dynamic subdivisions of gas contained within the lung are given a common nomenclature of volumes and capacities (Table 24.1 and Figure 24.16). Volumes are most commonly measured by spirometry (Figures 24.17 and 24.18) and capacities are then calculated as the sum of specific volumes. Simple spirometry can give all of the volumes and capacities listed in Table 24.1 except FRC, TLC, and residual volume (RV), all of which require a separate measurement of RV. The RV can be measured by washin or washout dilution calculations using a relatively insoluble gas such as nitrogen or helium and a closed breathing circuit. In modern pulmonary function labs, these laborious techniques have largely been replaced by whole-body plethysmography, which is both simpler and more accurate (Figure 24.19), which measures FRC, and this can be used to calculate RV by subtraction of expiratory reserve volume measured by spirometry.

TABLE 24.1

Lung volumes and capacities

Lung volumes	Definition
Tidal volume (VT)	Air volume inspired and expired during a relaxed breathing cycle
Residual volume (RV)	Volume remaining in the lung after a maximal expiratory effort
Expiratory reserve volume (ERV)	The volume of air that can be forcibly exhaled between the resting end-expiratory volume and RV
Inspiratory reserve volume (IRV)	The volume of air that can be inspired with maximal effort above the normal resting end-expiratory position of a VT
Forced expiratory volume in 1 second (FEV ₁)	The volume of air that can be exhaled in 1 second with maximal effort from the point of maximal inspiration
Lung capacities	
Vital capacity (VC)	The amount of air that can be exhaled from the point of maximal inspiration to

	the point of maximal expiration (IRV + ERV)
Forced vital capacity (FVC)	The volume of air that can exhaled with maximal effort from TLC
Total lung capacity (TLC)	Total volume of air in the lungs after a maximal inspiration (IRV + ERV + RV)
Functional residual capacity (FRC)	Amount of air in the lung at the end of a quiet exhalation (ERV + RV)

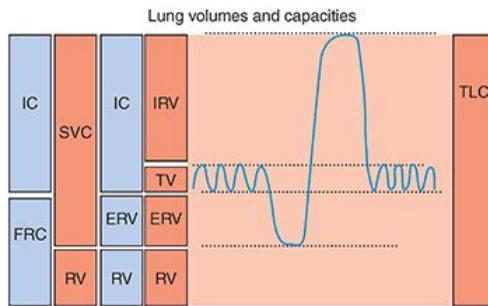

FIGURE 24.16 Complete pulmonary function testing will provide data on lung volumes and capacities to differentiate obstructive from restrictive lung diseases. Functional residual capacity (FRC) = expiratory reserve volume (ERV) + residual volume (RV). Measuring closing volume and closing capacity requires insoluble gas washout techniques and is not included in routine pulmonary function testing. However, an appreciation of the variable relationship between closing capacity and FRC and the effects of anesthesia on FRC is essential for the anesthesiologist to understand the changes in gas exchange that occur during anesthesia. Abbreviations: IC, inspiratory capacity; IRV, inspiratory reserve volume; SVC, slow vital capacity; TLC, total lung capacity; TV, tidal volume. *Reprinted by permission from Springer: Slinger P, Darling G. Spirometry measurements are commonly reported as “observed” (or measured) and “predicted” (Figure 24.20). Predictions are based on population statistical means, which take into account age, sex, and height. For example, an observed forced expiratory volume in 1 second (FEV_1) of 1.0 L for an 85-year-old male, 152

cm in height (5 ft tall) is 85% predicted (within the normal range of $100\% \pm 20\%$) but an FEV₁ of 1.0 L for a 30-year-old male, 182 cm (6 ft) is 20% predicted, which would be consistent with severe end-stage lung disease. The FEV₁, forced vital capacity (FVC), and their ratio (FEV₁/FVC) are the most useful spirometry measurements for the anesthesiologist to assess the severity of a patient's lung disease or to evaluate a patient's operability for lung resection surgery.¹⁵

In addition, complete pulmonary function testing in the laboratory will commonly report measurements of volume ratios, flows, lung resistance, lung diffusion capacity for carbon monoxide, and other measurements. The majority of these other values, although useful for distinguishing among different types and severities of pulmonary diseases in clinical chest medicine, are not commonly used in anesthesia. The exception is the lung diffusion capacity for carbon monoxide, which is a measurement of lung parenchymal function (ie, alveolocapillary gas transfer).

Closing Capacity and Closing Volume

The key to understanding the complex changes that develop in the respiratory system during anesthesia is to appreciate the relationship between FRC and closing capacity (CC). The CC is the sum of closing volume (CV) and RV. The CV is the lung volume below which small airways begin to close (or at least cease to contribute expiratory gas) during expiration. Closure of small airways in the basal portions of the lung during deep expiration is a normal phenomenon due to the gravity-dependent increase in pleural pressure at the bases and due to the lack of parenchymal support in distal airways. The CV and CC are not commonly measured in the pulmonary function lab. Measurement is either by a washin technique with a small bolus of an insoluble tracer gas such as xenon 133 slowly inhaled then exhaled from RV (**Figure 24.21**) or by nitrogen washout after inspiration of a breath of oxygen from RV. Normal values for CC in seated healthy young adults are 15% to 20% of vital capacity.⁵ The CC increases with age due to loss of structural parenchymal

support tissue in the lung and an increase in RV. The FRC increases slightly with age but the increase is greater for CC ([Figure 24.22](#)).¹⁶ The CC changes very slowly over time. However, FRC changes on a minute-to-minute basis as the mechanical advantage of the two springs (lung and chest wall) that determine it changes. The CC exceeds FRC in the supine position at age 45 and in the upright position by age 65. During anesthesia, a decrease in the elastic recoil of the chest wall due to the muscle-relaxing effects of almost all general anesthetics (with the possible exception of ketamine) and neuromuscular blockers causes FRC to decrease, and it will often fall below CC.¹⁷ Similarly, an increase in elastic recoil of the lung due to fluid retention in the pulmonary parenchyma will lower the FRC. When an alveolar unit falls below its CC, even for a brief period during one respiratory cycle, the concentration of oxygen (alveolar PO_2 [PAO_2]) in that unit falls slightly. This results in the increase of venoarterial admixture (“shunt”; see the following text) and decrease in arterial oxygen tension (PaO_2) seen in the elderly and during general anesthesia. When a region of the lung is kept below its CC, the loss in volume will eventually lead to atelectasis ([Figure 24.23](#)) as the gas trapped in the alveoli is absorbed. A large part of the anesthesiologist’s job in the perioperative period is restoring the balance between FRC and CC. Because CC cannot be changed, this involves improving FRC by a variety of techniques to improve the mechanical advantage of the chest wall. These techniques may include ensuring adequate reversal of neuromuscular blockers, upright positioning, regional analgesia, and possibly the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). The physiologic differences between PEEP and CPAP are subtle. However, by common usage, when positive pressure is applied during expiration to the airway of a patient who is having positive pressure ventilation, this applied airway pressure is referred to as **PEEP**. When a patient is breathing spontaneously, an applied airway pressure is referred to as **CPAP**.

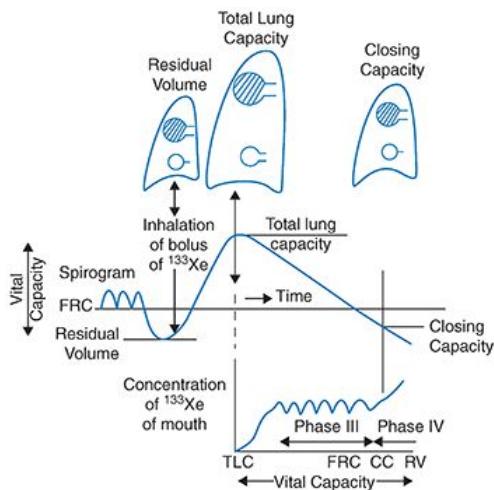

FIGURE 24.21 Measurement of closing capacity (CC) by the use of a tracer gas such as xenon 133 (^{133}Xe). The bolus of tracer gas is inhaled from residual volume and due to closure of some small airways is distributed only to those alveoli whose airways are still open (shown as the shaded areas in the diagram). During expiration, the concentration of the tracer gas becomes constant after the dead space is washed out. This plateau (phase III) gives way to a rising concentration of tracer gas (phase IV) when there is closure of the airways leading to the alveoli, which did not receive the tracer gas. The measured volume from the onset of phase IV until the end of expiration (residual volume [RV]) is the closing volume (CV). The CC is calculated as the sum of CV and RV (which is measured separately, see “[Lung Volumes and Spirometry](#)” section in earlier discussion). *Reprinted from Lumb AB. Compliance

Compliance is the change in lung volume (ΔV) for a given ΔP . It is the reciprocal of “elastance.” Monitoring changes in respiratory compliance is extremely important in ventilated patients as an early warning of changes in the lung or chest–abdominal wall complex that may negatively affect gas exchange. Compliance of the respiratory system (C_{RS}) is measured as the ΔV divided by the ΔP ; this represents the difference between alveolar pressure, at a given lung volume, and ambient (atmospheric) pressure.

$$C_{RS} = \Delta V / \Delta P$$

The C_{RS} is dependent on the interaction of the compliance of the lung itself (C_L) and the compliance of the chest wall (C_{cw}). These two springs act similar to series capacitors in an electrical system, that is, storing energy, and the reciprocal of respiratory compliance is the sum of the reciprocals of C_L and C_{cw} :

$$1/C_{RS} = 1/C_L + 1/C_{cw}$$

C_L is calculated as $\Delta V / \Delta P$, where ΔP = alveolar pressure – intrapleural (“transmural”) pressure.

C_{cw} is calculated as $\Delta V / \Delta P$, where ΔP = intrapleural pressure – ambient pressure.

Intrapleural pressure is not easy to measure directly in the clinical setting. Esophageal pressure, from a balloon manometer, is commonly used as an approximation of intrapleural pressure in respiratory research. As the respiratory system inflates, both the lung and chest will produce their own unique compliance curves ([Figure 24.24](#)).

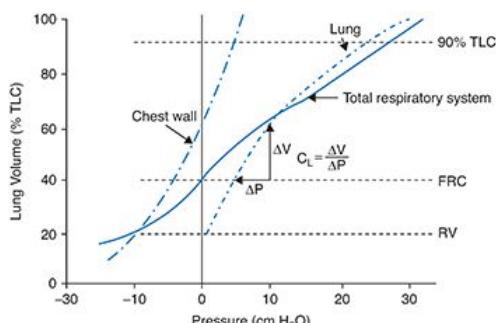

FIGURE 24.24 Static pressure-volume curves of the respiratory system. The isolated chest wall compliance curve (C_{cw}) (large dash-dot line) crosses the zero pressure or equilibrium point at approximately 60% of total lung capacity (TLC). The isolated lung compliance (C_L) (small dash-dot line) approaches its equilibrium point at about 20% TLC or residual volume (RV). The algebraic summation of the reciprocals of C_{cw} and C_L produces the compliance of the total respiratory system (C_{RS}) (solid line). The outward recoil of the chest wall and the inward recoil of the lung will balance at functional residual capacity (FRC). Note that the chest wall will passively contribute to lung inflation up to 60% TLC above which the chest wall will oppose inflation and the compliance (slope of the solid line) will begin to decrease. Abbreviations: ΔP , change in airway pressure; ΔV , change in lung volume. *Reprinted by permission from Springer: Jaeger JM, Blank RS. Essential anatomy and physiology of the respiratory system and the pulmonary circulation. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011:51-69. Figure 4.4. Copyright © 2011 Springer Science+Business Media, LLC.*

Factors affecting C_L include the following:

1. Lung volume. Compliance is greatest at FRC and remains at this level until the lung inflates or deflates to approximately 15% of TLC above or below FRC, that is, the slope of C_{RS} is the steepest in

this range, which includes the range of normal tidal volume breathing. Compliance is related to the normal FRC for a given lung and can be corrected for normal lung volume as the “specific compliance” (compliance/FRC), which is relatively constant at all ages.

2. Surface tension of the alveoli. This is probably the major factor determining lung recoil and C_L . A lung that is filled with water is actually more compliant than a normal lung because the air-fluid surface tension interaction is lost. Similarly, a lung that is depleted of surfactant is less compliant than normal. Without surfactant, the alveoli would be expected to behave like communicating bubbles and conform to the Laplace equation:

$$P = 2T / R$$

Where P is the gas pressure within a bubble, T is the surface tension of the wall, and R is the radius of the bubble. If the radius is decreased without a change in surface tension, the pressure will increase in the bubble and a small bubble will empty into a larger bubble (in the lung, this would lead to atelectasis). However, in the lung, surface tension decreases as the radius of the alveoli decreases and this opposes the collapse of smaller lung units. The exact mechanisms by which surfactant causes this effect are debated.¹⁸ It could be related to a tighter packing of surfactant molecules as the radius decreases or the formation of surfactant multilayers. Other factors that affect the C_L include pulmonary blood volume and interstitial edema.

Factors affecting C_{cw} include posture, obesity, ossification of the costal cartilages, and scarring of the skin. The interaction of the compliances of these two springs produces the characteristic sigmoid pattern of the compliance curve of the respiratory system (see [Figure 24.24](#), solid line). At FRC, which is normally the relaxation volume of the respiratory system, the pull of the two springs in opposite directions balance one another. In a normal healthy individual, as the respiratory system inflates to 60% of TLC, the chest wall is aiding the muscles of respiration to inflate the lungs. However, as the lung inflates above this volume, the muscles of inspiration must work to distend both the lungs and the chest wall.

Dynamic compliance is the $\Delta V/\Delta P$ of the respiratory system measured at the instant gas flow. In a ventilated patient, this ΔP will = peak airway pressure – PEEP. This reflects the normal behavior of the respiratory system but will include the effects of airway resistance and the normal hysteresis of the lung parenchyma (hysteresis in this context refers to the tendency of an elastic material to resist change of shape both during stretch and contraction). Dynamic compliance will be affected by both the frequency of respiration and the velocity of gas flow.

Static compliance is the $\Delta V/\Delta P$ of the respiratory system measured at a point of no gas flow and when the pressure gradient has been allowed to equilibrate in the entire airway. This is difficult, but not impossible, to achieve in an awake subject by relaxing at end inspiration against a closed airway. However, it is simple to measure in an anesthetized and paralyzed patient during ventilation in a volume-controlled mode (with a fixed inspiratory flow) by using an end-inspiratory pause. The ΔP for static compliance will = plateau airway pressure – PEEP.

Both static and dynamic compliances provide useful information for the anesthesiologist. The static compliance reflects more the actual distending pressure in the patient’s alveoli. The difference between the two reflects the effects of airway resistance. During pressure-control ventilation, with a decreasing inspiratory airflow pattern, there will not be a discernible difference in the peak or plateau in the airway pressure, so distinguishing between static and dynamic compliance is clinically difficult ([Figure 24.25](#)). This negative, that is, loss of monitoring, aspect of pressure-control ventilation is largely compensated by the ability of pressure-control ventilation to more uniformly distribute gas flow in patients with COPD who have large differences in regional compliance within the lung (see the following text).

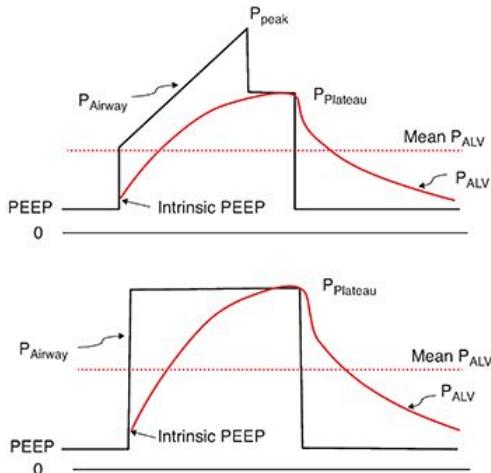

FIGURE 24.25 Comparison of the airway (P_{Airway} , black line) and alveolar (P_{ALV} , red line) pressures (vertical axis) for volume-control ventilation with an end-inspiratory hold (plateau) (top) and pressure-control ventilation (bottom) plotted against time (horizontal axis). For volume-control ventilation, the difference between the peak airway pressure (P_{peak}) and the plateau pressure (P_{Plateau}) represents the resistance to gas flow. This is primarily due to the combined nonelastic resistance of the airway and circuit. This gas-flow resistance cannot easily be monitored during pressure-control ventilation, which has only a P_{Plateau} . Note that the mean P_{ALV} in healthy individuals is approximately the same with the two methods of ventilation for the same tidal volumes. Abbreviation: PEEP, positive end-expiratory pressure. Reprinted by permission from Springer: Ward DS. *Intraoperative ventilation strategies for thoracic surgery*. In: Slinger P, ed. *Principles and Practice of Anesthesia for Thoracic Surgery*. New York, NY: Springer; 2011:297-308. Figure 21.4. Copyright © 2011 Springer Science+Business Media, LLC.

The inflation and deflation limbs of the compliance curve of the respiratory system are different (Figure 24.26). For dynamic compliance, this is due to both airway resistance and lung hysteresis. These curves combine to produce the familiar “pressure-volume loop” (or “PV” or “ $\Delta V/\Delta P$ ” or “compliance” curve) of the lung displayed by many modern anesthetic machines, and its shape is determined mainly by the dynamic C_{RS} . The gap between the expiratory and inspiratory limbs of the combined curve will widen as tidal volume and respiratory rate increase. It is possible to generate a $\Delta V/\Delta P$ curve using static compliance if the lung is slowly inflated in a stepwise fashion. This curve will also show a gap between inspiration and expiration due mainly to lung hysteresis. This gap will be smaller than that for the dynamic $\Delta V/\Delta P$ curve.¹⁹ An automated breath-by-breath calculation of compliance is displayed by the ventilation monitors of many modern anesthetic machines. It is difficult for these clinical monitors to measure at a true static “no flow” point at end inspiration and therefore measured compliance changes may be truly due to increased tissue elastance (eg, atelectasis or pulmonary edema) but may also be affected by changes in dynamic compliance (airway resistance); for example, bronchospasm or secretions.

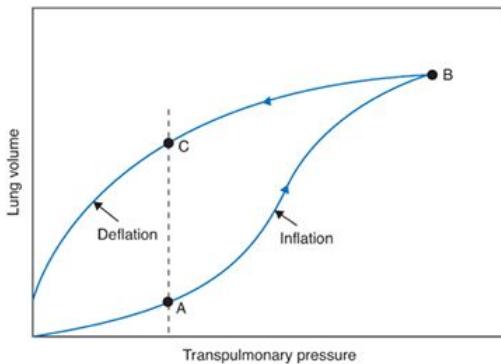

FIGURE 24.26 The pressure versus volume (PV) curve of the lung, often called the “compliance” curve. In this case, lung volume is plotted against transpulmonary pressure. Note that for the same pressure, the lung has a larger volume (ie, is more compliant) during deflation than during inflation, as represented by the distance between points A and C. This is due to hysteresis of the lung tissue and is present whether the curves are measured dynamically (during a continuous flow) or statically (during interrupted flow). For a dynamic PV curve, the distance AC will be greater than for a static curve due to the additive effects of airflow resistance. The point of maximum slope of the inspiratory curve (inflation arrow) normally corresponds to functional residual capacity (FRC). If the lung is inflated starting at FRC, the “lower inflection point” of the curve (point A) is not seen.

Resistance

Respiratory system resistance is a complex and important topic. It is important because, in the perioperative period, complications such as bronchospasm or secretions in an endotracheal tube or partial circuit obstruction will present primarily as increased resistance. It is complex because there are many types of resistance that contribute to the overall resistance of the respiratory system. When anesthesiologists think of respiratory resistance, they are mainly thinking of the nonelastic resistance to gas flow and they are primarily thinking of frictional airflow resistance. Nonelastic resistance is a major component of the work of breathing, and because it cannot be stored, it is lost and dissipated as heat. Nonelastic resistance also includes the resistance of lung and chest wall tissue to deformation and compression of intrathoracic gas. Elastic resistance is the recoil of the lung and chest wall, and because it is recovered during expiration, it does not contribute to the work of breathing.

Respiratory resistance (R_{RS}) is calculated as the pressure gradient divided by the inspiratory flow. During a constant flow situation such as volume-control ventilation, this would be calculated from [Figure 24.25](#) as

$$R_{RS} \text{ (cm H}_2\text{O/L per second)} = P_{\text{Peak}} - P_{\text{Plateau}} \text{ (cm H}_2\text{O)} / \text{inspiratory gas flow (L per second)}$$

However, normal spontaneous ventilation and pressure-control ventilation have variable flow rates and a mean gas-flow rate approximation is necessary to calculate respiratory resistance. Airflow resistance in normal healthy individuals breathing spontaneously is approximately 1 cm H₂O/L/second. This can increase to 5 to 10 cm H₂O/L/second in COPD and asthma.²⁰ Breathing through an 8-mm internal diameter endotracheal tube at a flow of 1 L/second creates a resistance of approximately 5 cm H₂O/L/second, and this increases to 8 cm H₂O/L/second for a 7-mm endotracheal tube.²¹

To quantitatively measure respiratory resistance in the operating room is not simple because it is difficult to separate respiratory system resistance from apparatus resistance. In the pulmonary function laboratory, this is done with plethysmography and a variety of flow-interrupter techniques. Fortunately, it is relatively simple to monitor changes in respiratory resistance in the operating room by following changes in dynamic compliance.

Gas flow during respiration is a mixture of turbulent and laminar flows and the turbulent/laminar interface moves in the air column during the respiratory cycle. Laminar flow occurs beyond the 11th-generation airways. Turbulent flow in the larger conducting airways aids clearing of secretions by coughing. In a healthy person, frictional airflow resistance is mainly due to larger airways: Mouth and pharynx 40%, larynx and large airways 40%, and small airways (<3 mm diameter) contribute 20%.²² However, changes in airflow resistance are most commonly due to changes in the caliber of the small airways. Small airway caliber can be decreased by contraction of smooth muscle in the airway wall or by compression (due to reversal of the normal transluminal pressure gradient in the collapsible distal airways).

Airway resistance is inversely proportional to lung volume and increases exponentially as the lung deflates below FRC. The application of PEEP or CPAP to patients who have a decreased FRC will benefit their respiration not only by raising their FRC above CC but also by decreasing their respiratory resistance, and thus their work of breathing, at a higher lung volume.

An increase in resistance to inspiration is detected by the muscle spindles in the diaphragm and leads to an increased force of contraction. This spinal reflex is preserved during anesthesia. In the awake patient, this reflex is augmented by a conscious cortical response that also increases the force of inspiration.²³ Increased expiratory resistance does not normally initiate a response if the resistance is <10 cm H₂O. The FRC is increased passively by the increased resistance until the increased elastic recoil balances the increased work of expiration. However, the ensuing increased intrathoracic pressure may decrease venous return and cardiac output. Patients tolerate increased airway resistance by increasing the work of breathing and in the short term will usually maintain a normal partial pressure of carbon dioxide (Paco₂). Eventually, a major increase in airway resistance may lead to respiratory muscle fatigue and the Paco₂ will start to rise. An elevated Paco₂ in a patient with increased respiratory resistance who has a normal baseline Paco₂ is an ominous sign of impending respiratory failure.

The Equal Pressure Point

Expiratory respiratory resistance will normally be lower than inspiratory resistance because the lung is at a larger volume at all stages of expiration than inspiration (see [Figure 24.26](#)). However, there are situations when expiratory resistance exceeds inspiratory resistance, these include the following: during a forced expiration (or cough) in a normal patient, during quiet breathing in some patients with severe emphysema (see the following text), and during forced expiration in some patients with an intrathoracic tracheal tumor or tracheobronchial compression from a mediastinal mass. In these instances, where expiratory resistance exceeds inspiratory resistance, the underlying cause is dynamic airway compression, which creates a moving flow limiting narrowing in the airway called the **equal pressure point** (EPP). In [Figure 24.27](#) at FRC before inspiration, ([Figure 24.27A](#)) airway pressure throughout is zero (no-flow situation) because the intrapleural (transpulmonary) pressure is -5 cm H₂O; there is a net +5 cm H₂O pressure distending the airways and alveoli. As inspiration begins, ([Figure 24.27B](#)) intrapleural and alveolar pressure falls by 3 cm H₂O and flow begins. Because of the pressure drop along the airway, the pressure will be negative in the airway but less than the alveolar pressure. This increases the distending pressure of the airways in this case from +5 to +6 cm H₂O. At end inspiration, ([Figure 24.27C](#)) the distending pressure in the no-flow condition is +8 cm H₂O and the pressure through the airway returns to zero. During quiet expiration, the recoil intrapleural pressure returns to -5 cm H₂O, and this creates a net pressure in the alveolus of +3 cm H₂O, which diminishes proximally as air flows out the tracheobronchial tree. The downstream distending pressure falls along the airway (represented by +6 cm H₂O in [Figure 24.27D](#)). Because this is a dynamic process, due to tissue resistance, the airway caliber will normally be larger at a given point for the same distending pressure during expiration than during inspiration. In a no-flow situation, the same distending pressure will result in equivalent airway diameters. During a forced expiration, ([Figure 24.27E](#)) the airway pressures increase (in this case by 24 cm H₂O, resulting in a net intrapleural pressure of +16 cm H₂O for same lung volume as [Figure 24.27C](#)) and a gradient is created along the expiratory air column. At the point where the intrapleural pressure equals the air column distending pressure (+16 cm H₂O), an EPP is created. The airway will narrow

proximal to this point (+15) to the thoracic outlet (+14). This becomes the flow-limiting point of expiration, and no amount of increased effort can increase the expiratory flow at a particular lung volume because the driving pressure is fixed by the difference between the alveolar and intrapleural pressures (8 cm H₂O in [Figure 24.27E](#)). This EPP allows the creation of a point of gas-flow acceleration and turbulence in the expiratory air column during normal coughing that has a Bernoulli effect (decreased lateral pressure in a region of increased flow velocity) to detach secretions from the tracheobronchial walls. During forced expiration, as lung volumes decrease and airway pressures decrease, intrapleural pressures are maintained and the EPP will move distally in the airway.²⁴

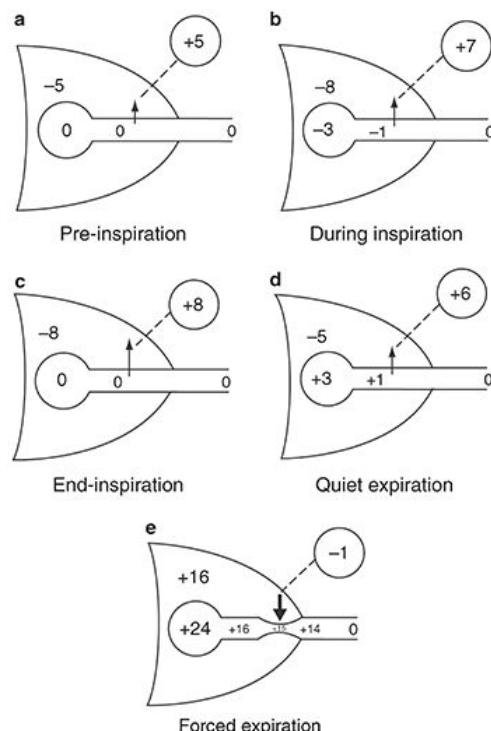

FIGURE 24.27 The effects of the intrapleural and alveolar pressures during quiet breathing (a-d) and the creation of an equal pressure point in the airway of a normal patient during forced expiration (e) (see text for details). New York, NY: Springer; 2011:343-365. Figure 24.7. Copyright © 2011 Springer Science+Business Media, LLC.

During a maximal respiratory effort, the EPP is responsible for the difference in the shapes of the expiratory versus inspiratory limbs of the flow-volume curve ([Figure 24.28](#)). The linear portion of the expiratory flow, after the initial peak flow, is caused by the EPP. The peak flow is effort dependent, but the linear portion of the expiratory flow is effort independent (ie, no amount of increased expiratory effort at a given lung volume can increase the maximal flow rate at that volume). During quiet breathing, the inspiratory and expiratory limbs of the flow-volume curve are mirror images due to the absence of an EPP. In the range of lung volumes used during quiet breathing, both inspiratory and expiratory flow normally can be increased approximately threefold by maximal effort if needed.

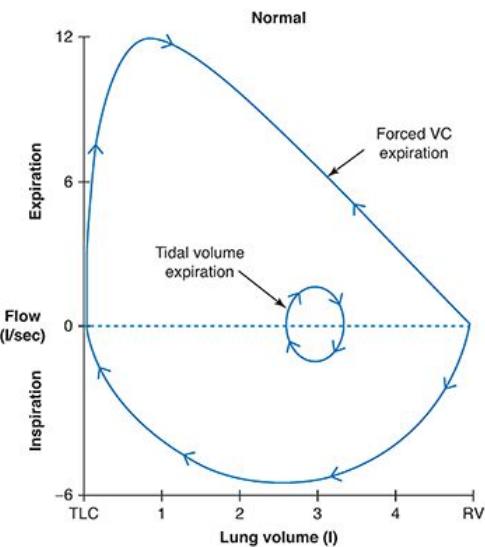

FIGURE 24.28 The airflow versus lung volume plot during maximal force inspiration and expiration of a normal individual (outer curve) from residual volume (RV) to total lung capacity (TLC). The inner elliptical curve “tidal volume” is during normal quiet breathing. During maximal inspiration, the curve is hyperbolic. During maximal expiration (forced vital capacity [VC] expiration), after the initial peak, the curve becomes linear due to the formation of an equal pressure point in the airway.

Work of Breathing

Work is the product of $force \times distance$ or $pressure \times volume$. Technically, **work** is calculated for a single event. However, the term **work of breathing** is commonly used to denote the ongoing energy expenditure required by the respiratory system. During normal quiet breathing, expiration is passive and does not require work. Half of the work of inspiration is stored in the deformation of the muscles of inspiration and the lung tissue. This potential energy provides the work necessary for expiration. The other half of the work of inspiration is dissipated as heat in overcoming the frictional forces of tissue and gas movement. The oxygen requirement for the work of breathing is less than 2% of the normal basal oxygen consumption (3-4 mL/kg/minute). In healthy individuals, the oxygen consumption of the muscles of respiration does not become important until rates of respiration approaching maximal minute ventilation (60-80 L/minute; ie, 15 \times basal ventilation) are reached. However, in patients with COPD, due to the mechanical inefficiency of the respiratory system, increasing the minute ventilation to 20 L/minute may increase the oxygen consumption of the muscles of respiration to levels of 200 mL/minute.²⁵

The work performed against the elastic resistance of the lung and chest wall increases proportionally when breathing is slow and deep. Conversely, the work performed against airflow resistance increases when breathing is rapid and shallow. Each individual will have an optimal rate and tidal volume that minimizes the work of breathing depending on the compliance and resistance of his or her respiratory system. At rest, he or she will normally breathe at a rate that minimizes the oxygen consumption required for gas exchange. For normal adults, this usually corresponds to a resting respiratory rate of 15 to 16 breaths per minute. For patients with obstructive diseases, this rate will usually tend to be lower and higher for patients with restrictive lung diseases.⁹

Although the work of breathing is minimal for healthy individuals, it may represent a significant challenge for a patient with respiratory or cardiac failure who has diminished reserves. This always needs to be considered when weaning such a patient from mechanically assisted ventilation.

Respiratory Fatigue

Fatigue of the respiratory system may occur at any point from the central nervous system (CNS) to the muscles of respiration. The diaphragm is possibly the most fatigue-resistant skeletal muscle and can sustain

resistive loads of up to 40% of maximal indefinitely. However, fatigue will occur with loads exceeding 40%. Because the oxygen supply requirement for the diaphragm is high in proportion to its mass, it is susceptible to hypoxia either due to decreased oxygen content of the arterial blood or due to decreased cardiac output.²⁶ The diaphragm can be rested for a short period by mechanical ventilation, but histologic evidence of muscle fiber atrophy can be seen after as little as 18 hours of mechanical ventilation, and clinical evidence of weakness is seen within days.²⁷ Ventilator-induced diaphragm dysfunction is characterized by atrophy of both type I and II fibers, with altered gene expression leading to an increase in proteolysis.²⁸

Physiology of Ventilation and Perfusion

Initially, it is a difficult concept to grasp, but ventilation is preferentially distributed to the smaller alveoli close to the middle and lower portion of the lungs rather than to the larger alveoli in the more superior lung regions. This is because the lower alveoli are at a steeper portion of their compliance curve (see **Figure 24.15**). The most frequent explanation for this nonuniformity is the effect of gravity on the lung parenchyma. In the upright posture, the greatest vertical height is attained by the lung. The tendency for the lung to retract away from the chest wall at its apex creates a more negative (subatmospheric) pleural pressure than the pleural pressure at the lower dependent portions of the lung where its weight reduces the magnitude of the negative pleural pressure. The gradient of pleural pressure from the lung apex to its base has been estimated at 0.4 cm H₂O per each centimeter of vertical height. Obviously, one might expect less of a transpulmonary pressure gradient from nondependent to dependent portions of the lung when supine or prone as compared to the upright position. In the upright individual, during a spontaneous breath, inspired gas will tend to preferentially enter those open alveoli near the base of the lung, which are the most compliant. As the breath continues, the gas will enter the more apical, less compliant alveoli and any previously atelectatic basilar alveoli as they become recruited by the traction exerted by the remainder of the expanding lung. Also, the rate of inspiration directly impacts the homogeneity of gas distribution. At high inspiratory rates, air is distributed more evenly throughout the lung than at very slow rates.²⁹

Pulmonary Circulation

The lung circulation is composed of two sources of blood flow: the pulmonary circulation from the main pulmonary artery and the smaller bronchial circulation arising from the aorta. The pulmonary circulation dominates, by volume, and serves to deliver the mixed venous blood to the alveolar capillaries to facilitate gas exchange and to act as a large, low-resistance reservoir for the entire cardiac output from the right ventricle. The bronchial circulation serves to provide nutritional support to the airways and their associated pulmonary blood vessels.³⁰ The bronchial circulation also provides a constant source of heat and moisture for warming and humidifying the inspired air.

Pulmonary Hemodynamics

Despite receiving all of the cardiac output from the right ventricle, the pulmonary vasculature maintains a relatively low pulmonary blood pressure. The normal adult mean pulmonary artery pressure (P_{PA}) is 9 to 16 mm Hg with systolic P_{PA} of 18 to 25 mm Hg. Several features enable the pulmonary circulation to maintain this high flow at such low pressures. First, the pulmonary vasculature is extremely thin walled with far less arterial vascular smooth muscle than its systemic counterparts. The result is a highly compliant reservoir capable of accommodating an average 3.2 L/minute/m² blood flow at rest or 6 to 8 times that flow during exercise. Second, the total PVR is quite low, on the order of less than 250 dyne•s/cm⁵. This minimizes the pressure work faced by the less robust right ventricle while still enabling the right ventricle to match the output of the left ventricle. The PVR can change as a result of numerous factors, hypoxia, acidosis, mitral valve stenosis or regurgitation, left ventricular failure, primary pulmonary hypertension, or pulmonary emboli, to name just a few. The PVR can be calculated using data from a pulmonary artery catheter as

$$\text{PVR} = [(P_{PA} - PAOP) / CO] \times 79.9$$

where PAOP is the pulmonary artery catheter occlusion pressure, which is assumed to reflect the left atrial pressure, CO is cardiac output (L/minute), and the factor, 79.9 converts from mm Hg/L/minute to units of absolute resistance ($\text{dyne}\cdot\text{s}/\text{cm}^5$).

Distribution of Perfusion

There is a gradient of distribution of perfusion of the lung that is similar but not identical to the gradient of distribution of ventilation, with increased perfusion of regions in the central and lower regions compared to the upper regions. This perfusion gradient depends in part on the architecture of the lung and the resistance of the pulmonary vessels, which varies with lung volume and is lowest in the regions of the lung closest to FRC (Figure 24.29). Gravity, posture, and alveolar pressure will also have effects on the distribution of pulmonary blood flow.³¹

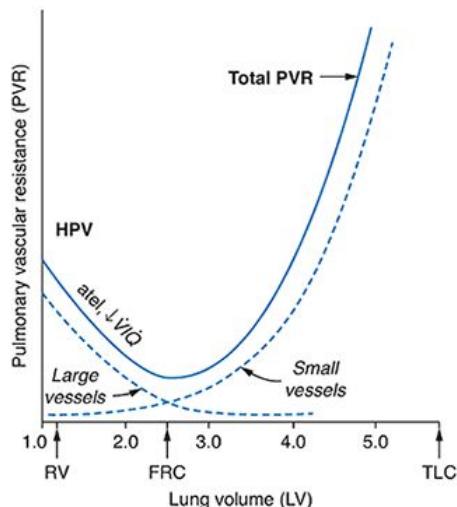

FIGURE 24.29 The relationship between pulmonary vascular resistance (PVR) and lung volume. The PVR is lowest at functional residual capacity (FRC) and increases as the lung volume decreases toward residual volume (RV), owing primarily to the increase in resistance of large pulmonary vessels. The PVR also increases as lung volume increases above FRC toward total lung capacity (TLC) because of an increase in resistance of small interalveolar lung vessels. Abbreviation: atel, atelectasis; HPV, hypoxic pulmonary vasoconstriction; V/Q, ventilation/perfusion.

Matching of Ventilation and Perfusion

Within certain limits, the lung attempts to match ventilation to perfusion. However, the matching is never ideal because the ventilation and perfusion gradients are not identical (Figure 24.30). This matching is closer during spontaneous ventilation than during positive pressure ventilation. With positive pressure ventilation, the effects of alveolar pressure are increased and pulmonary blood flow distribution becomes less homogeneous. This led to the concept of perfusion zones of the lung as described by West et al³² (Figure 24.31A). In this concept, zone 1 (apical) is a region where alveolar pressure (P_A) exceeds both P_{PA} and pulmonary venous pressure (P_{PV}); hence, this ventilated lung region has no perfusion. In zone 2 (transitional), P_{PA} exceeds P_A , which exceeds P_{PV} with partial limitation of pulmonary blood flow. In zone 3 (basilar), $P_{PA} > P_{PV} > P_A$, so there is unrestricted pulmonary blood flow. In zone 4 (atelectatic), a region of lung collapse, $P_{PA} >$ pulmonary interstitial fluid pressure (P_{ISF}) $> P_{PV} > P_A$, so again, there is a limitation of pulmonary blood flow depending on the tissue pressure in the region of collapse. Although West's zones have been a useful concept to emphasize the effects of airway and alveolar pressure on pulmonary blood flow, these zones are an oversimplification. First, because alveolar pressure does not remain constant but varies throughout the respiratory cycle, more so during positive pressure than controlled ventilation. Thus, the boundaries between

these zones are constantly moving. Also, it has been demonstrated by perfusion scanning that the distribution of blood flow in the lung is not actually in layers (like a cake) but in concentric spheres (like an onion) ([Figure 24.31B](#)).

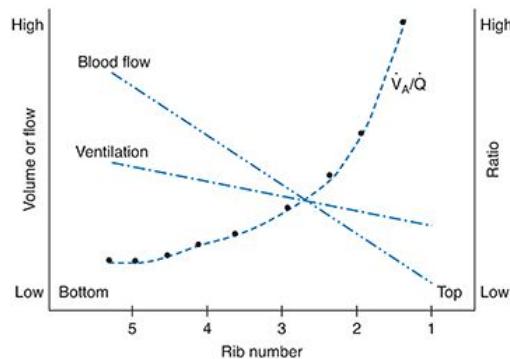

FIGURE 24.30 Distribution of blood flow (perfusion) and alveolar ventilation and the ventilation-to-perfusion ratio (VA/Q) as a function of the distance from the base of the lung (to the left in the figure) to the apex (to the right). In the upright position, both ventilation and blood flow are greater at the base of the lung than at the apex. However, the gradient is steeper for blood flow than ventilation. Thus, the VA/Q ratio is higher at the apex than in the mid or dependent lung regions. *Reprinted by permission from Springer: Jaeger JM, Blank RS. Essential anatomy and physiology of the respiratory system and the pulmonary circulation. In: Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. FIGURE 24.31 The distribution of pulmonary blood flow in the upright position. A, Pulmonary blood flow as affected by gravity and alveolar pressure. This classic description based on the work of West et al³² divides pulmonary blood flow into four zones: P_A , alveolar pressure; P_{pa} , pulmonary artery pressure; P_{pv} , pulmonary

venous pressure, P_{if} , pulmonary interstitial fluid pressure. B, Subsequent investigations with lung scanning have shown that blood flow is actually distributed more in a central to peripheral pattern. *Reproduced with permission from Slinger P, ed. Principles and Practice of Anesthesia for Thoracic Surgery. New York, NY: Springer; 2011.*

Due to the combined effects of the architecture of the lung parenchyma and vasculature and gravity, there is a matching of ventilation and perfusion (VA/Q) in the lung. Typical resting values in an adult are 4 and 5 L/minute for alveolar ventilation and cardiac output for a VA/Q ratio of 0.8. As can be seen from [Figure 24.32](#), this VA/Q matching is optimal in central lung regions but becomes unequal at the apex and base of the lung. Positive pressure ventilation, decreased cardiac output, atelectasis, and many disease states will further interfere with normal VA/Q matching.

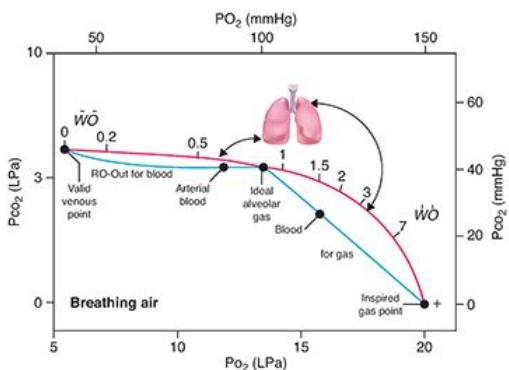

FIGURE 24.32 The heavy line indicated all possible values of alveolar Po_2 and PCO_2 with ventilation/perfusion ratios ranging from zero (to the left, lung base) to infinity (to the right, lung apex) for a person breathing air. Mixed expired gas is a mixture of ideal alveolar gas and dead space. Arterial blood is a mixture of blood with the same gas tensions as ideal alveolar gas and shunt (mixed venous blood).

Dead Space

Like many concepts in respiratory physiology, dead space is crucially important in clinical practice and deceptively simple on the surface but actually extremely complex. Any portion of an inspired breath, which does not enter gas exchanging lung units, is dead space. Minute ventilation (VE) is the sum of alveolar ventilation (VA) and dead space ventilation (VD):

$$V_E = V_A + V_D$$

Dead space can be subdivided into two primary components: physiologic dead space and apparatus dead space. Apparatus dead space will only apply to patients attached to a breathing circuit. Physiologic dead space is further subdivided into airway dead space and alveolar dead space ([Figure 24.33](#)). The airway dead space is the portion of a breath that goes to the mouth, pharynx, and tracheobronchial tree but does not enter the alveoli. Airway dead space is also called **anatomic** dead space by some authors, but this latter is a confusing term. Alveolar dead space is the portion of a breath that enters alveoli, which are ventilated but not perfused (ie, West's zone 1).

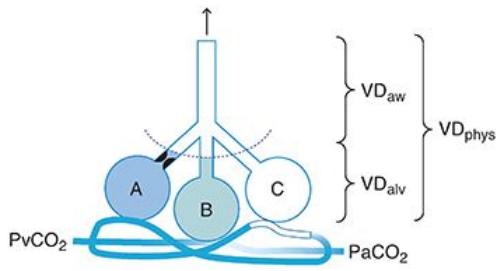

FIGURE 24.33 A simplified three-compartment model of the lung with A representing shunt; B, an ideal gas unit; and C, alveolar dead space (VD_{alv}). Physiologic dead space (VD_{phys}) is filled with air containing no carbon dioxide, shown as the white area. The VD_{phys} is the sum of airway dead space (VD_{aw}) and VD_{alv} . The airway-alveolar interface is demonstrated by the dotted line. Abbreviation: $PvCO_2$, venous PCO_2 . Reprinted with permission from Tusman G, Sipmann FS, Bohm SH. Rationale of dead space measurement by volumetric capnography. Anesth Analg. 2012;114(4):866-874. Copyright © 2012 International Anesthesia Research Society.

Airway dead space is relatively constant. However, it does vary directly with lung volume and bronchodilation increases airway dead space. As tidal volume (VT) decreases, the portion of each breath that is dead space (VD/VT) ratio will increase. Airway dead space will decrease slightly, at lower lung volumes, but not enough to compensate for the fall in VT. Airway dead space is decreased by endotracheal intubation because much of the mouth and pharynx dead space is bypassed. However, the net effect on total dead space will depend on the additional equipment dead space of the circuit attached to the patient. For most correctly functioning modern anesthetic apparatus, equipment dead space is not clinically important.

A healthy person, breathing spontaneously, will have practically no alveolar dead space. Tidal volume breathing will usually result in a VD/VT of approximately 0.3, entirely due to airway dead space. Alveolar dead space, however, becomes clinically important during positive pressure ventilation and in any condition of altered hemodynamics. Decreased cardiac output, pulmonary embolism, and changes in posture will all have clinically important effects on alveolar dead space, usually by increasing zone 1. These three components, apparatus, airway, and alveolar, make up the total dead space.

Measurement of Dead Space

The measurement of dead space was described initially by Bohr.³³ Mixed expired gas is collected, and carbon dioxide (CO_2) analyzed to give a mean expired CO_2 tension ($PECO_2$) and the arterial blood gas ($Paco_2$) sampled. The Bohr equation is

$$V_D/V_T = (Paco_2 - PECO_2) / Paco_2$$

The derived VD/VT can be applied to minute ventilation or to a single breath. In a healthy person breathing spontaneously, because the alveolar dead space is very small, the end-tidal CO_2 tension ($PETCO_2$) can be substituted for $Paco_2$ in the Bohr equation to measure dead space. In the ventilated patient, alveolar dead space is often clinically significant, and the absolute number calculated for dead space with this calculation will be falsely low. Similarly, $PETCO_2$ can be substituted for $PECO_2$ to give an estimate of the alveolar dead space for a ventilated patient. This calculation is crude as an absolute measurement; however, the gradient $Paco_2$ - $PETCO_2$ is clinically an extremely useful trend. It is uncommon for airway dead space to change during the course of an anesthetic, so any increase in the $Paco_2$ - $PETCO_2$ gradient is most likely due to an increase in alveolar dead space. The $Paco_2$ is inversely related to the V_A :

$$Paco_2 = (VCO_2 / V_A) \times K$$

Where VCO_2 is the total body production of CO_2 and VA is the alveolar ventilation and K is a constant. Because the patient's metabolic rate is usually constant during anesthesia (if body temperature is maintained), VCO_2 is relatively constant. Changes of minute ventilation (tidal volume \times respiratory rate) will usually cause a direct and inverse change in the $Paco_2$. However, this equation uses VA , not minute ventilation. If the dead space increases (eg, decreased cardiac output) and minute ventilation is unchanged, VA will decrease and $Paco_2$ will rise.

Ventilation monitoring during anesthesia includes monitoring of expired CO_2 . This is usually presented as time-based capnography. Volume-based capnography is similar but may allow for more accurate measurement of dead space and CO_2 production ([Figure 24.34](#)).³⁴

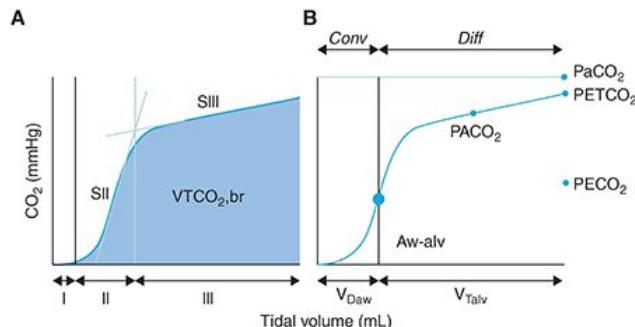

FIGURE 24.34 Capnometry. Expired carbon dioxide (CO_2) tension plotted here against tidal volume. The CO_2 is most commonly displayed plotted against time. Integration of the expired gas flow and CO_2 signals allows calculation of CO_2 production (volume of expired CO_2 per breath [$VTCO_2$, br]). The expired CO_2 curve has three phases (I, II, III) and two slopes (SII and SIII). Airway dead space (V_{Daw}) can be measured from the midpoint of SII, the airway-alveolar (Aw-alv) gas interface. The slope of SIII increases with increased inequality of regional ventilation in the lung. Abbreviations: Conv, convection; Diff, diffusion; $PACO_2$, mean alveolar PCO_2 ; $PECO_2$, mixed expired PCO_2 ; $PETCO_2$, end-tidal PCO_2 ; V_{Talv} , alveolar tidal volume. *Reprinted with permission from Tusman G, Sipmann FS, Bohm SH. Shunt

Shunt or venous admixture is the portion of the venous blood returned to the heart that passes to the arterial circulation without being exposed to normally ventilated lung units. There are two major subdivisions of shunt: extrapulmonary and pulmonary. Extrapulmonary shunt is venous blood that does not pass through the lungs. There are two normal sources of this shunt: the thebesian veins in the left heart and the bronchial circulation. These normally represent <1% of the total cardiac output. Abnormal types of extrapulmonary shunt include congenital cardiac defects with right-left communications.

Pulmonary shunt is venous blood passing through lung regions with decreased or no V_A . [A in Figure 24.33](#) is an illustration of this concept in which shunt and dead space seem to be unrelated. However, like so much in respiratory physiology, [Figure 24.33](#) is an oversimplification. Shunt and dead space are the extremes of the continuum of ventilation and perfusion matching (see [Figure 24.33](#)). Shunt has a large effect on Pao_2 but a limited effect on $Paco_2$. Shunt is the commonest cause of hypoxemia during anesthesia. Other causes are a low alveolar oxygen tension (eg, hypoventilation or a low inspired oxygen concentration [FIO_2]) or a decreased mixed venous oxygen content (eg, low cardiac output) ([Figure 24.35](#)). The fraction of total cardiac output (Q_T) that is shunt (Q_S) can be calculated from the arterial (Cao_2), pulmonary end-capillary ($Cc' O_2$), and mixed venous (pulmonary arterial) (Cvo_2) oxygen contents. Calculation of blood oxygen contents are discussed as follows.

$$Q_S/Q_T = Cc'_{O_2} - Ca_{O_2} / Cc'_{O_2} - Cv_{O_2}$$

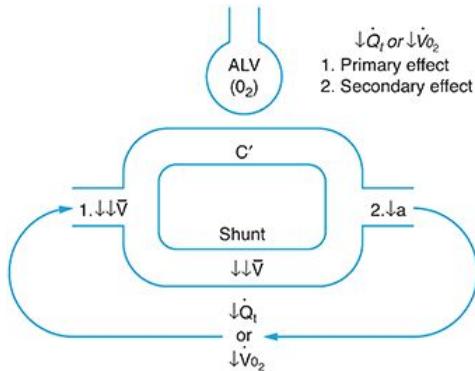

FIGURE 24.35 A simplified diagram of the effects of a decrease in mixed venous oxygen saturation (v) on arterial oxygenation (a). Mixed venous blood passes either through ventilated lung regions (ALV), where it is oxygenated in the pulmonary capillaries (C'), or through nonventilated (Shunt) lung regions. A decrease in mixed venous oxygen due to either a decrease in cardiac output (\dot{Q}_t) or an increase in oxygen consumption (\dot{V}_{O_2}) will pass through the pulmonary shunt and result in a fall in arterial oxygenation. *Reprinted from Lumb AB. Nunn's Applied Respiratory Physiology. 7th ed. Edinburgh: Churchill Livingstone/Elsevier; 2010. Copyright © 2010 Elsevier. With permission.*

This can be remembered as the little step in oxygenation in [Figure 24.35](#) ($Cc'_{O_2} - Ca_{O_2}$) divided by the big step in oxygenation ($Cc'_{O_2} - Cv_{O_2}$), so normally the shunt fraction (Q_S/Q_T) will be very small (<.05).

Alveolar-Arterial Oxygen Difference (A-aDO₂)

Although the concept of shunt is extremely important and useful in anesthesia, it is uncommon to actually calculate the shunt fraction in patients. Similar to the calculation of the PaCO_2 - ETCO_2 gradient as a monitor of changes in dead space, the gradient of PAO_2 to Pao_2 tension ($A-a\text{DO}_2$) can be used as a crude monitor of shunt. The $A-a\text{DO}_2$ gradient is proportional to shunt, but the absolute gradient increases as FIO_2 increases. However, if FIO_2 and mixed venous PO_2 (Pv_{O_2}) (ie, cardiac output and temperature) remain relatively constant, the trend of the $A-a\text{DO}_2$ is a reasonably reliable monitor of changes in shunt. The PAO_2 is calculated from the theoretical “ideal” alveolar gas equation:

$$\text{PAO}_2 = \text{PiO}_2 - \text{Paco}_2 / \text{RQ}$$

Because the volume of CO_2 produced is normally less than the volume of oxygen consumed, the Paco_2 cannot be substituted directly into the equation. In order to estimate the actual tension of oxygen in the ideal alveolus, the Paco_2 is divided by the respiratory quotient (RQ).

The RQ (CO_2 production / oxygen consumption) is a dimensionless number, which varies according to which substance is being consumed for fuel by the body. For carbohydrates, the approximate RQ = 1.0; for proteins, 0.9 to 0.8; and for fats, 0.7. A mixed value for RQ of 0.8 is commonly used in this equation.

The inspired PO_2 (PiO_2) depends on the fractional concentration of inspired oxygen (FIO_2) and the barometric pressure (P_B) minus the saturated pressure of water vapor in the alveolus (P_{H2O}), which is 47 mm Hg:

$$\text{PiO}_2 = \text{FIO}_2 \times (P_B - P_{H2O})$$

So, the combined alveolar gas equation becomes

$$PAO_2 = [FIO_2 \times (P_B - P_{H2O})] - Paco_2 / RQ$$

For a person breathing air ($FIO_2 = 0.21$) at sea level (approximately $P_B = 760$ mm Hg) with a $Paco_2$ of 40 mm Hg, the ideal alveolar PO_2 calculation would be

$$PAO_2 = [0.21 \times (760 - 47)] - (40 / 0.8) = 100 \text{ mm Hg}$$

This is a simplified version of the equation, which does not compensate for differences in the inspired and expired tidal volumes but is clinically useful for rapid calculation of the A-aDO₂.

Hypoxic Pulmonary Vasoconstriction

The lung has a unique reflex to try and minimize these perturbations in VA/Q matching. This reflex is HPV. The pulmonary arterioles are unique in that they will respond to regional hypoxemia by constricting.³⁵ The arterioles in essentially all other tissues in the body vasodilate in response to hypoxemia. This reflex will tend to redirect blood flow from poorly or nonventilated lung regions to better ventilated regions. The primary stimulus for HPV is alveolar hypoxia. The HPV begins within seconds and is biphasic with most of the rapid-phase response complete within 20 minutes. A slower phase begins after approximately 40 minutes and continues to increase over many hours (Figure 24.36).³⁶ Of note, once the slow phase of HPV has started, the resolution of HPV will also be delayed. This has important implications for bilateral thoracic surgery cases involving sequential periods of alternating one-lung ventilation (OLV).

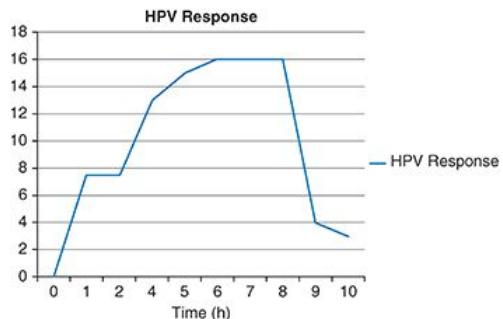

FIGURE 24.36 The relationship between hypoxic pulmonary vasoconstriction (HPV) (vertical axis) and time in hours (horizontal axis) in humans exposed to isocapnic hypoxia (approximate inspired PO_2 60 mm Hg), beginning at 0 hour with a return to normoxia at 8 hour. The HPV response was measured as the increase in echocardiographic right ventricular systolic pressure. Note the two-phase, rapid and slow, onset of HPV. Also note that after prolonged HPV, the pulmonary pressures do not return to baseline for several hours. *Based on data from Talbot NP, Balanos GM, Dorrington KL, et al. Two temporal components within the human pulmonary vascular response to 2 h of isocapnic hypoxia. J Appl Physiol (1985). 2005;98:1125-1139.*

A low PvO_2 , and therefore low pulmonary artery PO_2 , will augment the HPV response to a hypoxic FIO_2 , but low PvO_2 alone has no effect.³⁷ As the size of the hypoxic lung segment increases, PVR increases, mixed venous oxygen tensions begin to fall, and the ability of HPV to shunt blood to the remaining well-ventilated lung becomes compromised. The HPV remains intact despite chemical sympathectomy, bilateral vagotomy, and denervation of the carotid and aortic chemoreceptors.³⁸ Bilateral lung transplant recipients retain their hypoxic pulmonary vasoconstrictive responses.³⁹ The HPV is augmented by conditions and chemicals, which globally enhance PVR such as acidemia, hypercapnia, histamine, serotonin, and angiotensin II.

The actual cellular oxygen sensor for HPV has yet to be determined. Current research implicates the mitochondria of the pulmonary vascular smooth muscle cell as the main site. Numerous biochemical studies have indicated that selective interruption of the mitochondrial electron transport chain complexes can impair HPV. A unifying theme seems to be the hypoxia-induced change in the level of oxygen free radicals and hydrogen peroxide in the smooth muscle cell. These changes affect the release of calcium from the

sarcoplasmic reticulum and the voltage-dependent membrane conductance to potassium resulting in depolarization and contraction of the smooth muscle, hence vasoconstriction.⁴⁰ The response may involve decreased production of nitric oxide by the pulmonary epithelium and endothelium.⁴¹

Movement of Gas

Oxygen Transport

Oxygen diffuses into the plasma of the pulmonary capillary blood, driven by its concentration gradient from the alveoli. This oxygen is then taken up by partially desaturated hemoglobin (Hb) molecules in the red blood cells of mixed venous blood to form oxyhemoglobin. Due to the high affinity of Hb for oxygen, a large proportion (normally >98%) of the total oxygen in arterial blood is carried within the red blood cells as oxyhemoglobin. Less than 2% is circulated as dissolved oxygen. However, it is actually the tension of the oxygen dissolved in plasma (PaO_2) that is measured in an arterial (or venous [Pvo_2]) blood gas sample. There is a dynamic equilibrium between the oxygen dissolved in plasma and that bound to Hb within the red blood cells. The quantity of oxygen dissolved in blood is directly proportional to its partial pressure. For each mm Hg of PO_2 , there is 0.003 mL of dissolved oxygen per 100 mL of blood. Thus, for a PaO_2 of 100 mm Hg, there will be 0.3 mL of dissolved oxygen in 100 mL of blood. This compares to approximately 20 mL of oxygen bound to Hb in the red cells and is usually not of clinical importance. However, this dissolved oxygen can approach 1.5 mL with an FIO_2 of 1.0 and can be clinically even more important in hyperbaric environments.

Normal adult hemoglobin (HbA) is a four-protein molecule with two α chains and two β chains. Each protein chain is attached to one heme unit ([Figure 24.37](#)). Heme is an iron-porphyrin complex capable of reversible binding to one oxygen molecule at its ferrous (Fe^{++}) atom. As each of the four heme units binds an oxygen molecule, it causes a change in the shape of the Hb molecule, which, in turn, causes the other heme units to be more exposed. The result is that each successive oxygen molecule is bound less (or more) tightly and released more (or less) easily. So, the release of oxygen by Hb as the PO_2 in the surrounding plasma falls (and conversely the uptake of oxygen by Hb as the PO_2 rises) is not in a linear correlation with PO_2 but curvilinear producing the oxyhemoglobin saturation curve (or dissociation curve) ([Figure 24.38](#)).

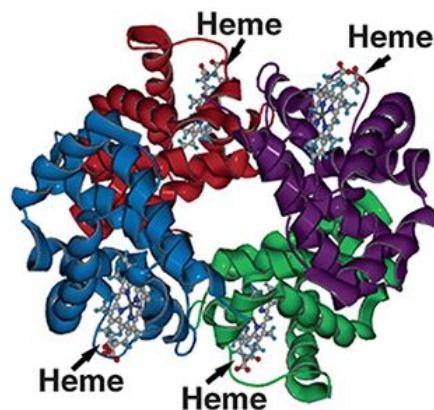

FIGURE 24.37 An oxyhemoglobin molecule is composed of two paired proteins. For hemoglobin A, these are two α chains and two β chains. Each globin chain is bound to a heme group capable of binding a single oxygen molecule.

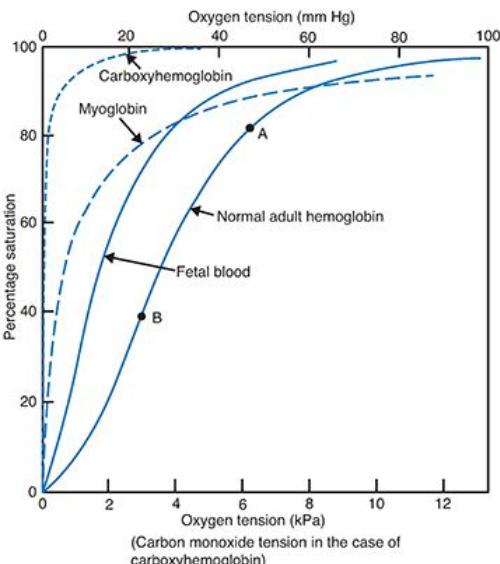

FIGURE 24.38 Dissociation curves of normal adult (HbA) and fetal (HbF) hemoglobin. Curves for myoglobin and carboxyhemoglobin are shown for comparison.

The PO_2 values of 40, 50, and 60 will correspond (approximately) to saturations of 70%, 80%, and 90%, respectively.

The oxygen content of blood can be calculated if the Pao_2 , the concentration of Hb in the blood, and the percentage saturation of Hb is known. Pure oxyhemoglobin will contain 1.39 mL/g. The saturation of the Hb in a blood sample is measured spectrophotometrically by comparing the absorption of two different wavelengths of near infrared light; one wavelength at which oxyhemoglobin and deoxyhemoglobin have approximately the same absorbance (typically 940 nm) and one at which they differ widely (typically 660 nm). Pulse oximetry uses the same principle but corrects for the peak arterial phase of a capillary blood flow by subtracting for the baseline venous flow absorption. Modern rapid blood gas analyzers often estimate oxygen saturation based on measured PO_2 and standard oxyhemoglobin (HbO_2) curves corrected for pH.

$$\text{The content of oxygen in blood} = \text{dissolved O}_2 + \text{O}_2 \text{ bound as HbO}_2$$

$$\text{For } 100 \text{ mL blood} = (\text{PO}_2 \times 0.003) + (\text{Hb concentration} \times \text{saturation}/100 \times 1.39)$$

For a patient with an Hb of 15 g/dL a PO_2 of 100 and saturation of 99% the blood, oxygen content would be $= (100 \times 0.003) + (15 \times 0.99 \times 1.39) = 0.3 + 20.6 = 20.9 \text{ mL oxygen}/100 \text{ mL blood}$. Mixed venous blood commonly has a saturation of approximately 70% and thus an oxygen content of 15 mL/100 mL.

Shifts of the Oxyhemoglobin Dissociation Curve

There are multiple different normal and abnormal variants of the Hb molecule. Each of these different Hb molecules has a different oxyhemoglobin dissociation curve (see [Figure 24.38](#)). By convention, to compare these curves, the PO_2 at the point of 50% saturation (P_{50}) is used as a reference. For HbA, the P_{50} is 26 mm Hg. Fetal hemoglobin (HbF) has two α chains and four γ chains. It is the major form of Hb present at birth and is replaced by HbA over the first 6 months of life. The HbF has a P_{50} of 19, so it is “left shifted” from HbA. Because its affinity for oxygen is stronger than HbA, oxygen is preferentially drawn from the mother’s blood to that of the fetus.

Carboxyhemoglobin is an abnormal Hb formed when carbon monoxide binds with heme. Carbon monoxide displaces oxygen from heme, and it shifts the oxyhemoglobin curve to the extreme left so that oxygen is not released to the tissues and cellular hypoxia results. The Fe^{++} atom in heme can be oxidized to

Fe^{+++} by a variety of drugs and chemicals such as nitrates. This forms a type of Hb called methemoglobin and will not bind oxygen.

The normal HbA oxygen saturation curve shifts to the left or right secondary to a variety of physiologic changes. An increase in hydrogen ion (H^+) concentration (ie, a decrease in serum pH), an increase in body temperature (T) and an increase in 2,3-diphosphoglycerate (DPG) shift the curve to the right. The 2,3-DPG is a compound normally present in red blood cells that tends to decrease the affinity of Hb for oxygen. It is increased by exposure to a low environmental oxygen (eg, at altitude) or in anemia. This can be remembered as DPG, H^+ , and T shift the Hb oxygen saturation curve to the right (riGHT). And their converses (decrease DPG, alkalosis, hypothermia) shift the curve to the left. In most situations of physiologic stress (ie, hypercarbia, acidosis, etc), it is advantageous to have the oxyhemoglobin curve shifted to the right and to increase oxygen unloading to the tissues.

There is normally no significant oxygen storage capacity in the body. This is unlike CO_2 , which has large stores in the body (see the following text). Oxygen is like rocket fuel and can be toxic to tissues in excess over a prolonged period. An average-size adult's oxygen consumption is approximately 250 mL/minute. The total content of oxygen in the blood will be approximately 700 to 800 mL and in the FRC 500 mL (breathing air). Tissue hypoxia will begin very quickly if the oxygen supply is cut off. Washing out the FRC with an FIO_2 of 1.0 can potentially provide a reserve of 2,500 mL of oxygen, a supply adequate for several minutes of apnea.

Carbon Dioxide Transport

The CO_2 is the main product of aerobic metabolism of proteins, fats, and carbohydrates. The CO_2 is moderately soluble in all body fluids (approximately 20 times more soluble than oxygen) and diffuses down its concentration gradient from its site of intracellular production into the capillary and venous blood. Similar to oxygen, the tension of dissolved CO_2 in blood is the portion measured in blood gas analysis. As can be seen in [**Figure 24.39**](#), CO_2 transport is like an upside-down iceberg with the dissolved CO_2 as the only visible portion. But, this is only a small proportion of the total CO_2 in the blood. The majority of CO_2 is transformed to bicarbonate ion (HCO_3^-) in the following reaction:

The first step of this reaction is slow in plasma but progresses rapidly in the presence of the enzyme carbonic anhydrase, which is present in red blood cells. The majority of CO_2 in the blood follow this pathway and is transported in the blood as HCO_3^- after diffusion into red cells and enzymatic conversion ([**Figure 24.40**](#)). A small portion of the CO_2 is transported in the blood combined to Hb as carbamino compounds. Blood with lower oxyhemoglobin saturation (ie, venous blood) is capable of carrying more CO_2 than blood with well-saturated Hb (ie, arterial). This is known as the Haldane effect. The Haldane effect is complicated and involves both increased carbamino- CO_2 carrying by desaturated Hb and also increased buffering of intracellular H^+ by deoxygenated Hb, which is less acidic than oxygenated Hb.

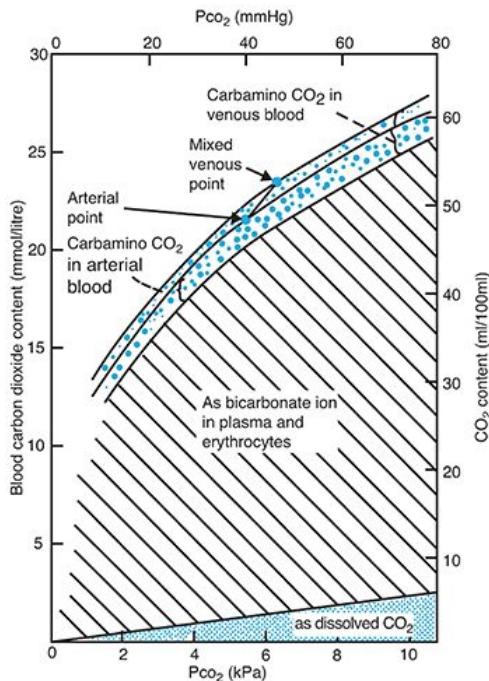

FIGURE 24.39 Transport of carbon dioxide (CO_2) in blood compared to the measured CO_2 tension. The tension dissolved CO_2 at the bottom is measured in blood gas analysis, but it is only the tip of the upside-down iceberg. The majority of CO_2 is transported as dissolved bicarbonate in the plasma and red blood cells. These vary with PCO_2 but are little affected by the oxygenation of hemoglobin. Carbamino transport of CO_2 is strongly influenced by the oxygenation of hemoglobin (the Haldane effect). *Reprinted from Lumb AB. Nunn's Applied Respiratory Physiology. 7th ed. Edinburgh: Churchill Livingstone/Elsevier; 2010. Copyright © 2010 Elsevier. With permission.*

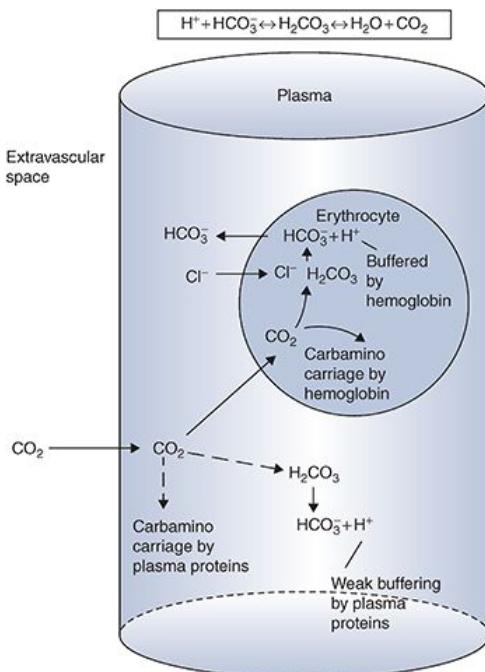

FIGURE 24.40 Carbon dioxide (CO_2) enters the plasma in molecular form from the tissues. The majority of CO_2 is transformed into bicarbonate (HCO_3^-) in the red blood cells; this reaction is catalyzed by carbonic anhydrase. A small proportion of plasma CO_2 is attached to plasma proteins as carbamino compounds or directly converted to HCO_3^- in the plasma. Some CO_2 in the red cell is also attached to hemoglobin as carbamino compounds. The excess hydrogen ions (H^+) generated in the red blood cell are transferred to the plasma in exchange for chloride ion (Cl^-). This is called the “chloride shift.” Abbreviations: H_2CO_3 , carbonic acid; H_2O , water. *Reprinted from Lumb AB. Nunn's Applied Respiratory Physiology. 7th ed. Edinburgh: Churchill Livingstone/Elsevier; 2010. Copyright © 2010 Elsevier. With permission.*

There are two effects that are involved in the physiology of gas transport in the blood. They can be remembered as follows:

1. Shifts of the OHb curve due to changes in H^+ , the Bohr effect ($b\text{OHr}$)
2. Changes in CO_2 transport due to changes in oxygen saturation, the Haldane effect (the other one)

Because the volume of CO_2 in blood is large compared to the volume of oxygen, for changes of approximately equal volumes of gas in the blood, the PCO_2 will change much less than the PO_2 . For example, the volume production of CO_2 is approximately 80% of the oxygen consumption. However, the difference in PCO_2 between venous and arterial blood is normally only 5 mm Hg, whereas the difference between arterial and venous PO_2 is typically 60 mm Hg.

Control of Respiration

Central Nervous System

The stimulus for normal breathing is generated spontaneously by a combination of at least six groups of neurons in the medulla of the brainstem. Each neuronal group seems to be primarily responsible for one phase of the respiratory cycle: early inspiration, late inspiration, early expiration, etc. The function of these neuronal groups is primarily under the control of the central chemoreceptor area, also in the medulla. The central chemoreceptor increases or decreases minute ventilation according to the cerebral spinal fluid pH to maintain normocapnia ([Figure 24.41](#)).⁴²

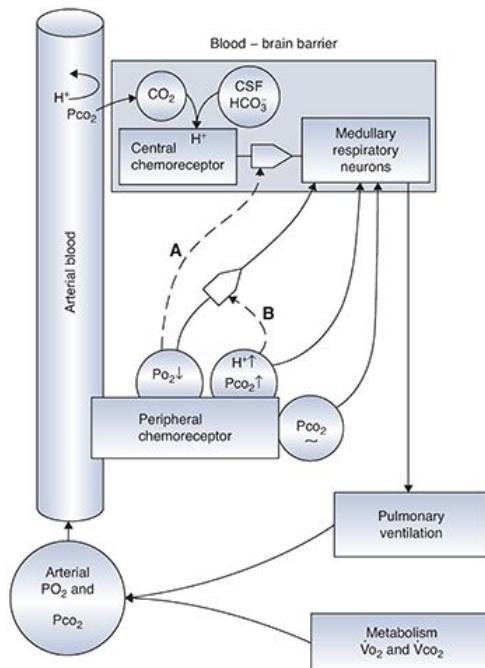

FIGURE 24.41 A diagram of the connections between individual components of the chemical and neural portions of the physiologic control of respiration (see text for details). Abbreviations: CO₂, carbon dioxide; CSF, cerebrospinal fluid; H⁺, hydrogen ion; HCO₃⁻, bicarbonate. *Reprinted from Lumb AB. Nunn's Applied Respiratory Physiology. 7th ed. Edinburgh: Churchill Livingstone/Elsevier; 2010. Copyright © 2010 Elsevier. With permission.*

Dissolved CO₂ in plasma diffuses easily across the blood–brain barrier into the cerebrospinal fluid (CSF) where it interacts with H₂O to form H⁺ and HCO₃⁻. The H⁺ concentration in the CSF is the primary controller for normal minute ventilation. The H⁺ and HCO₃⁻ in plasma cross the blood–brain barrier very slowly. The brainstem central chemoreceptor is acutely sensitive to changes in pH. Normally, an awake individual's Paco₂ will vary less than 3 mm Hg. If the PaO₂ is normal, minute ventilation will increase 2 to 3 L/minute for each 1 mm Hg increase in Paco₂ to restore arterial and CSF pH to normal levels. Ventilation will increase in a linear fashion as Paco₂ rises until a maximal stimulation somewhere over a Paco₂ of 100 mm Hg is reached or until the respiratory mechanics will no longer permit an increase in minute ventilation. At levels over 100 mm Hg, dissolved CO₂ in the CSF begins to exert a narcotic effect on the CNS.

The central chemoreceptor is acutely sensitive to CNS depressants. Opioids, sedatives, and most general anesthetics decrease the respiratory response to hypercapnia.

Peripheral Chemoreceptors

The peripheral chemoreceptors are located primarily in the carotid bodies at the bifurcation of the carotid arteries and also in aortic bodies above and below the aortic arch. These receptors respond primarily to changes in PaO₂.⁴³ They function as a backup system and in the normal individual do not have a primary role in control of ventilation. The innervation of the carotid bodies is via the glossopharyngeal nerve (CN IX) and the aortic bodies via the vagus nerve (CN X). Although there is some tonic activity from these peripheral chemoreceptors, they do not normally stimulate ventilation until the PaO₂ falls to below a threshold of approximately 70 to 80 mm Hg. This threshold will be lowered in individuals who are adapted to altitude and in some chronic respiratory or congenital hypoxic cardiac diseases. The nerve stimulus from the peripheral chemoreceptors has two complementary actions to increase ventilation. Primarily, there is a direct effect on the medullary respiratory neurons. Secondarily, there is an effect to increase the sensitivity to the stimulus of

the central chemoreceptor to CSF pH (dashed line A in [Figure 24.41](#)). The peripheral chemoreceptors also are sensitive to changes in arterial pH and PaCO_2 , and acidosis will increase the hypoxic drive (dashed line B in [Figure 24.41](#)). The hypoxic drive due to the peripheral chemoreceptors is decreased by volatile anesthetics, even in very low concentrations such as 0.1 minimum alveolar concentration, which are often present immediately after recovery from general anesthesia.⁴⁴ Although the hypercapnic response is also blunted in a dose-dependent fashion by volatile anesthetics, the response to hypoxemia is even more profoundly blocked.

Because of the combined effects of residual opioids on the central chemoreceptors and the blunting of hypoxic drive by trace amounts of volatile anesthetics, it is a common practice to initially administer supplemental oxygen to patients in the recovery room after general anesthesia then to follow the oxygen saturation using pulse oximetry as the supplemental oxygen is decreased prior to discharge. In the absence of shunt, with supplemental oxygen to raise the FiO_2 to 0.4, a patient's minute ventilation can fall temporarily to one-third of its normal value without significant hypoxemia (however, the PaCO_2 will rise and the pH will fall).

Other Neural Connections to the Medullary Respiratory Centers

The entire airway from the mucosal lining of the nose and mouth to the distal bronchi has both afferent and efferent neural connections to the central respiratory neurons. These connections are responsible for many of the normal respiratory reflexes such as the phasic inspiratory dilation of the upper airway during inspiration to maintain patency of the supraglottic airway. This reflex activity is easily reduced or eliminated by CNS sedatives and anesthetics and is responsible for much of the upper airway obstruction seen during anesthesia and compounds the airway obstruction in patients with obstructive sleep apnea (OSA). Irritants in the airway trigger cough and sneeze reflexes via these neuronal connections.

The lung has stretch receptors that, in the nonsedated state, respond to regional changes in compliance associated with atelectasis by triggering a recruitment maneuver such as a sigh or a yawn (if you are yawning as you read this, hopefully it is to recruit your lungs and not because the content is boring). Passive stretching of the lungs can result in either inhibition of inspiration (Herring-Breuer reflex) or gasping (Heads reflex) depending on the clinical context.

The pulmonary capillaries are densely innervated by unmyelinated nerves (C fibers). This innervation is not important during normal ventilation but may be responsible for causing a sensation of dyspnea when the capillaries become engorged during congestive heart failure.

Abnormal Breathing Patterns

Abnormal patterns of breathing are rare. There are several recognized abnormal patterns, which involve dysfunction of the central chemoreceptors. Primary alveolar hypoventilation syndrome (Ondine's curse) is a congenital insensitivity of the central chemoreceptor to changes in CSF pH. It results in apnea and hypoventilation, particularly during sleep. It can be treated with noninvasive ventilation and diaphragmatic pacing. Cheyne-Stokes respiration is a pattern of 10- to 20-second periods of apnea followed by periods of hyperventilation.⁴⁵ It is seen in some patients with CNS damage or severe illness and also during adaptation to altitude. It is caused by a delayed response interval in the central chemoreceptor. Cheyne-Stokes respiration is the most severe form of periodic breathing, which is seen to some degree in neonates and the elderly and during sleep at all ages.

Altered Physiologic Conditions

Anesthesia

Nunn⁴⁶ showed that during anesthesia and spontaneous ventilation, gas exchange was altered by shunt and inhomogeneous V/Q ratios. He concluded from his observations that a normal range of PaO_2 could be maintained if the PAO_2 was at least 200 mm Hg, which would require an FiO_2 of at least 35%. Brismar and colleagues⁴⁷ in 1985 demonstrated using computed tomography that within 5 minutes of the induction of

anesthesia, dependent regions of the lung developed an increase in density consistent with atelectasis. It is now accepted that this occurs in dependent lung regions in approximately 90% of patients who undergo general anesthesia using a wide variety of agents. Epidural anesthesia may be the one modality that appears to cause very little atelectasis and no change in VA/Q matching or oxygenation.

The near-universal finding of rapid lung collapse upon induction of anesthesia and the rapid reappearance after discontinuation of PEEP has led to the conclusion that atelectasis is due to compression of lung tissue rather than alveolar gas absorption behind occluded airways.⁴⁸ The fluoroscopic study by Froese and Bryan⁴⁹ of diaphragmatic motion of spontaneously breathing volunteers demonstrated that in the supine position, the dependent portion of the diaphragm has the greatest displacement with each breath. Initiation of paralysis with neuromuscular-blocking agents and positive pressure ventilation creates a reversal of this motion with the nondependent or superior aspect of the diaphragm undergoing the greatest displacement with each ventilated breath.⁴⁹ Others have confirmed and extended these observations using computed tomography.⁵⁰ It is now apparent that the geometry of the chest and diaphragm is altered under general anesthesia with relaxation of the chest wall and a marked cephalad displacement of the most dorsal portion of the diaphragm at end expiration.

Absorption atelectasis can occur when the rate of gas uptake into the blood exceeds the rate of ventilation of the alveolus. The extreme condition is total occlusion of an airway, which isolates the alveolar gas in the distal alveolar and respiratory airways. The gas pressure within this compartment initially is nearly at atmospheric pressure. However, given that mixed venous blood continues to perfuse this area, and the fact that the sum of the gas partial pressures within mixed venous blood is subatmospheric, gas uptake from the occluded compartment by blood continues and the alveoli collapses. Computer modeling has demonstrated that the rate of gas absorption from unventilated areas is dependent on the initial FIO_2 .⁵¹ Higher initial FIO_2 (100% vs 30%) has been shown to produce clear atelectasis immediately following induction of anesthesia, which increases by 40 minutes following induction. This is also associated with a measurable increase in shunting.⁵² However, in many clinical situations, the airway is not completely occluded but rather ventilation to an area becomes severely reduced. If the inspired VA/Q ratio of a respiratory unit is reduced, a point is reached where the rate at which inspired gas enters the alveolus is exactly balanced by the gas uptake into the blood. If VA/Q ratio drops below this critical equilibrium point, the volume of the alveolus declines and collapse ensues. Again, this process is augmented by the presence of a high PAO_2 and a rapid rate of gas uptake.

Loss of alveolar surfactant may play a role in alveolar instability at low alveolar volumes and collapse. The rapidity of alveolar collapse following alveolar recruitment maneuvers and discontinuation of PEEP has suggested that atelectasis per se may interfere with surfactant production. Therefore, atelectatic regions of the lung may be predisposed to recurrence of collapse because of reduced levels of surfactant, increased alveolar surface tension, and, the aforementioned mechanisms, all contributing to reduced alveolar volumes. The effects of anesthetic drugs on HPV and V/Q matching are considered in [Chapter 25](#).

Position

In the spontaneously breathing patient, awake or during anesthesia, the majority of gas exchange are due to caudal displacement of the diaphragm, which occurs primarily in the dorsal portions of the thoraces. During deep anesthesia and paralysis, the diaphragm becomes relatively flaccid. The weight of the abdominal contents pushes cranially on the dorsal diaphragm, and during inspiration, with positive pressure ventilation, gas preferentially distributes to the now more compliant ventral portions of the lungs.⁵³ The distribution of perfusion remains largely unchanged with predominance to the central and dependent portions of the lung. Thus, matching of V/Q is decreased with induction of anesthesia and further decreased with paralysis and positive pressure ventilation. The addition of low levels of PEEP (<10 cm H₂O, after recruitment) will usually ameliorate this mismatch by slightly overdistending ventral lung regions but moving dependent lung regions to a more compliant portion of their pressure-volume curve.

During anesthesia and positive pressure ventilation in the prone position, the majority of diaphragm displacement during inspiration will remain in the dorsal (now the nondependent) portions of the thoraces and

ventilation will be more homogeneously distributed in the lungs compared to the supine position. Matching of ventilation to perfusion will usually be superior in the prone position when compared with the supine position. However, unlike the supine position, the addition of PEEP in the prone position may lead to deterioration in V/Q matching.⁵⁴ This applies to patients with normal lungs. This is unlike the situation in the patient with ARDS. In these patients in the supine position, pulmonary edema collects in the parenchyma of the dorsal portions of the lung. The combination of prone position and PEEP may lead to a more favorable matching of ventilation to perfusion. Prone positioning in ARDS has been shown to improve lung elastance, transpulmonary driving pressure, $\text{PaO}_2/\text{FiO}_2$, and Paco_2 clearance in the early period after placing a patient prone.⁵⁵ However, this effect may not be persistent.

The effects of the lateral position are discussed in the “One-Lung Ventilation” section.

Obesity

The increased weight of the abdominal contents and chest wall impose a restrictive ventilatory pattern on the respiratory system with a decrease of all lung volumes but a preservation of the FEV_1/FVC ratio.⁵⁶ This is primarily important to the anesthesiologist because of the fall in FRC, which leads to increased venoarterial shunt and a tendency to desaturate during induction and maintenance of anesthesia and in the postoperative period. The FRC of an awake mildly obese patient of body mass index (BMI) 30 kg/m^2 will be 75% of predicted for a similar person, but with a BMI of 20 kg/m^2 and for a patient with a BMI $>40 \text{ kg/m}^2$, the FRC will be <66% predicted. Elevated BMI has been shown to be associated with reduced resting PaO_2 and larger A-a gradient, which are thought to be the consequence of reduced expiratory reserve volume.⁵⁷

Early studies of PEEP during anesthesia in obese patients showed mixed results in terms of improving oxygenation. This is due to the rapid development of atelectasis in these patients and the inability of PEEP, by itself, to correct atelectasis. As can be seen in **Figure 24.42**, the combination of a recruitment maneuver and $10 \text{ cm H}_2\text{O}$ PEEP can eliminate atelectasis in a morbidly obese patient. The challenge in respiratory management of the obese patient perioperatively is to minimize the fall in FRC. This can be done with a variety of methods including the use of regional anesthesia/analgesia, avoiding long-acting muscle relaxants, positioning, and the use of postoperative CPAP.

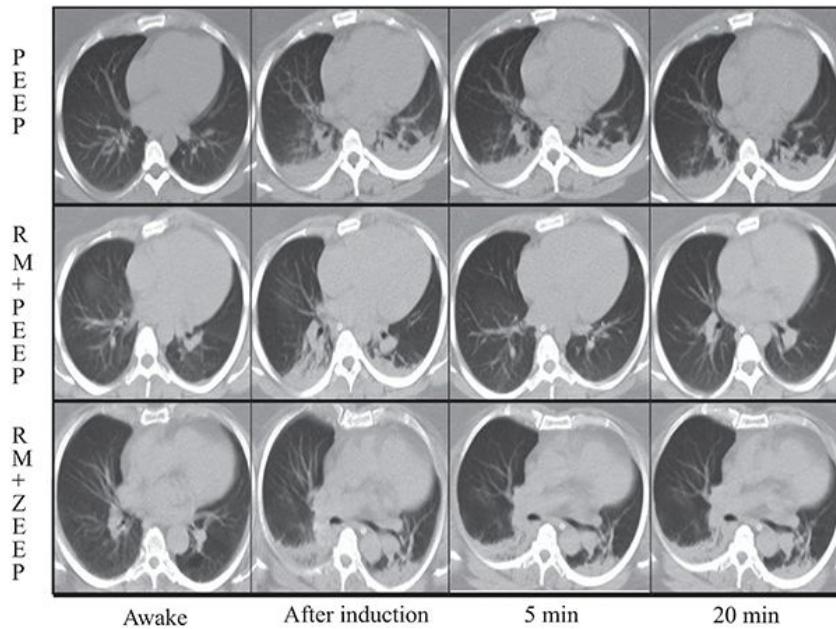

FIGURE 24.42 Each row is a representative computerized tomography scan 1 cm above the diaphragm in three different morbidly obese patients during anesthesia. The patient on the top row received $10 \text{ cm H}_2\text{O}$ positive end-expiratory pressure (PEEP). The patient in the middle row received a recruitment maneuver

(RM) ($55 \text{ cm H}_2\text{O} \times 10 \text{ seconds}$) after induction plus PEEP $10 \text{ cm H}_2\text{O}$. The patient in the bottom row received an RM and then a zero end-expiratory pressure (ZEEP).

Sleep-Disordered Breathing

Approximately 20% of the population has disorders of respiration during sleep ranging from simple snoring to OSA. These disorders all involve variable degrees of upper airway obstruction and apnea during normal sleep. The OSA is defined as more than five episodes per hour of apnea, each >10 seconds. It is often combined with periods of hypopnea in the sleep apnea hypopnea syndrome (SAHS). The OSA may be exacerbated by fluid shifts to the upper body from the legs during sleep in patients with sedentary lifestyles.⁵⁸ The disturbance of normal sleep leads to daytime somnolence, and the periods of hypoxia may contribute to cardiovascular morbidity. Treatments may include weight loss, CPAP devices, and upper airway surgery.⁵⁹ The obesity hypoventilation syndrome is a combination of obesity, hypoventilation, and severe OSA, which has been called the **Pickwickian** syndrome.⁶⁰

Exercise

Normal oxygen consumption at rest is approximately 200 to 250 mL/minute (3-4 mL/kg/minute) for an adult; this is termed **1 metabolic equivalent** (MET). Quick walking or climbing one flight of stairs requires 4 METs, bowling 8 METs, and competitive cross-country skiing 14 METs. Olympic rowers, skiers, and cyclists may exceed 80 mL/kg/minute oxygen consumption (20 METs).⁶¹ To achieve this increase in oxygen consumption requires matching increases in minute ventilation and cardiac output. At a certain point, the increases in ventilation and cardiac output will not be able to supply adequate oxygen to the tissues for aerobic metabolism and further increase in muscle activity will require anaerobic metabolism producing lactic acid. This is called the **anaerobic threshold**. It is most often the accumulation of lactate in tissues causing muscle dysfunction, which limits prolonged exercise and not a limitation on minute ventilation or cardiac output. Exercise training raises the maximal oxygen consumption ($\text{VO}_{2\text{max}}$), the anaerobic threshold, and the tolerance for lactic acidosis. Cardiopulmonary exercise testing (CPET) is an established medical procedure to measure a patient's $\text{VO}_{2\text{max}}$ or to distinguish between respiratory and cardiac limitations in exercise capacity. The $\text{VO}_{2\text{max}}$ has been shown to be a useful preoperative test to identify patients at increased risk for complications from pulmonary resection surgery (preoperative $\text{VO}_{2\text{max}} < 15-20 \text{ mL/kg/minute}$).¹⁵

Although the predictive utility of CPET in other surgeries has previously been unclear, emerging evidence has shown promise. A recent meta-analysis has shown CPET to be useful in predicting 90-day survival as well as overall morbidity and mortality in hepatic resection, hepatic transplant, pancreatic, and general intra-abdominal surgery.⁶² Similarly, CPET poor performance is associated with higher cardiopulmonary complications following open abdominal aorta repair.⁶³

A useful estimate of a COPD patient's $\text{VO}_{2\text{max}}$ can be made from the maximal distance they can walk in 6 minutes the "6-minute walk test" (6MWT). If the distance in meters is divided by 30, the result is an approximation of the $\text{VO}_{2\text{max}}$ (eg, 6MWT distance = 450 m, $\text{VO}_{2\text{max}} = 450 / 30 = 15 \text{ mL/kg/minute}$).⁶⁴

Altered Barometric Pressures

The ambient PO_2 decreases proportionally as the barometric pressure falls with increases in altitude. The PO_2 is 149 mm Hg at sea level, 122 at 5,000 ft of elevation (eg, Denver), and may be as low as 108 mm Hg in a commercial airliner pressurized to 8,000 ft (maximum permitted altitude equivalent). For comparison, on the summit of Mount Everest, the PO_2 is 47 mm Hg (63,000 ft). There are both acute and chronic adaptations to the hypoxia associated with altitude. Primarily, the rapid adaptation involves hyperventilation, driven by the peripheral chemoreceptors to decrease the alveolar PCO_2 and thus increase the alveolar PAO_2 . The secondary alkalinization of blood and CSF returns to normal after several days at altitude as HCO_3^- is excreted. The increased pulmonary pressures due to HPV triggered by hypoxia can lead to high-altitude pulmonary edema. This can be treated with oxygen, diuretics, and pulmonary vasodilators. Increased cerebral blood flow due to

hypoxia is opposed in part by the cerebral vasoconstriction due to hypocapnia but may lead to cerebral edema. Chronic acclimatization to altitude involves a variety of cellular and metabolic changes such as a resetting of the peripheral chemoreceptors and polycythemia.

Anesthesia at mild elevations is generally uncomplicated as long as oxygen saturation is monitored and adequate supplemental oxygen is provided. This can be a problem with nitrous oxide. Most modern commercial vaporizers deliver reasonably accurate dosages of volatile anesthetics at modest elevations (<6,000 ft). Pressure in the air-filled cuff of an endotracheal tube or laryngeal mask airway will increase and decrease significantly with changes in ambient pressure, which may be associated with medical air transport.⁶⁵

Hyperbaric oxygen in medical practice is delivered in a chamber pressurized to 2 to 3 times atmospheric pressure (atm) (ie, 1,400-2,100 mm Hg). Treatments are given with a high FIO_2 , usually from a tight-fitting mask for several hours and repeated as required.⁶⁶ Indications include gas embolism, decompression sickness, necrotizing soft tissue infections, and carbon monoxide poisoning. At high FIO_2 levels, above 2 atm, hyperoxia may cause convulsions. Prolonged exposure to a high PAO_2 causes pulmonary oxygen toxicity and a restrictive lung disease. A high PAO_2 in the neonate can cause retrolental fibroplasia, ultimately damaging the retina of the eye.

Age

Infants and Children

The overall C_{RS} is low in newborns and increases until late adolescence. Alveoli at birth have a lower amount of elastin than adults and a decreased amount of surfactant leading to decreased lung compliance. However, the C_{cw} in newborns and infants is very high due to the absence of ossification of cartilages. This predisposes infants to a significant fall in FRC during anesthesia. In the awake state, FRC is maintained above CC in infants by a rapid respiratory rate. The respiratory muscles of infants have a lower percentage of fatigue-resistant type I fibers, and they are more prone to respiratory fatigue. All airways are proportionately smaller in infants than adults, and airway resistance is higher, resulting in increased work of breathing at rest and particularly during upper or lower airway infections (eg, croup). The narrowest portion of the upper airway is at the cricoid cartilage until age 5 years.⁶⁷

Control of breathing in the newborn is unique. Hypoxia initially causes increased ventilation, as in the adult, but then leads to a decrease in ventilation.⁶⁸ This is more exaggerated in preterm infants. Oxygen consumption is higher in newborns than in adults (6-8 mL/kg/minute). The HbF predominates at birth until 3 to 6 months of age. The HbF has a low P_{50} (18-19 mm Hg), which increases oxygen loading in the placenta but decreases oxygen unloading in the tissues.

The Elderly

Changes in the respiratory system with age include decrease of muscle tone in the dilators of the pharynx, predisposing to upper airway obstruction during anesthesia.⁶⁹ There is a loss of the pulmonary vascular bed, which results in an increase of PVR and a 30% increase in mean P_{PAs} and an increase in the alveolar dead space. The lung parenchyma loses elastic support tissue, resulting in an increase of lung compliance, but the chest wall increases in stiffness, so the net effect is an overall decrease in respiratory system compliance. With the loss of structural support of peripheral airways, the CC increases significantly; this is the change, which has major anesthetic implications. The fall of FRC below CC leads to increased venoarterial shunt and is responsible for the decrease in PaO_2 with age. The mean PaO_2 of healthy patients will decline to approximately 80 mm Hg at age 70, after which it remains stable. The responsiveness of both central and peripheral chemoreceptors to hypercarbia and hypoxemia decreases with age.

Chronic Respiratory Disease

Chronic respiratory disease is commonly divided into two major categories: obstructive and restrictive. In obstructive disease, the FEV_1/FVC ratio is typically less than normal (<80%) with a decreased FEV_1 .

Restrictive disease typically has a normal FEV₁/FVC ratio and a decreased FEV₁. There is some overlap, with some patients (eg, cystic fibrosis) showing a mixed obstructive/restrictive pattern. Severity of these diseases can be graded according to the FEV₁ as a percentage of predicted values: mild, FEV₁ >70%; moderate, 50% to 70%; severe, 30% to 50%; and very severe, <30%.

The COPD incorporates three disorders: emphysema, peripheral airways disease, and chronic bronchitis. Any individual patient may have one or all of these conditions, but the dominant clinical feature is impairment of expiratory airflow. Life expectancy may be less than 3 years in severe COPD patients >60 years of age. Mild COPD patients should not have significant dyspnea, hypoxemia, or hypercarbia, and other causes should be considered if these are present.⁷⁰

Some moderate and severe COPD patients have an elevated PacO₂ at rest. It is not possible to differentiate these “CO₂ retainers” from nonretainers on the basis of history, physical examination, or spirometric pulmonary function testing. This CO₂ retention seems to be related to an inability to maintain the increased work of respiration required to keep the PacO₂ normal in patients with mechanically inefficient pulmonary function and not primarily due to an alteration of respiratory control mechanisms. The PacO₂ rises in these patients when supplemental FIO₂ is administered due to a relative decrease in VA and an increase in alveolar dead space and shunt by the redistribution of perfusion away from lung areas of relatively normal V/Q matching to areas of very low V/Q ratio because regional HPV is decreased and also due to the Haldane effect.⁷¹ However, supplemental oxygen must be administered to these patients postoperatively to prevent the hypoxemia associated with the unavoidable fall in FRC. The attendant rise in PacO₂ should be anticipated and monitored. To identify these patients preoperatively, all moderate or severe COPD patients need an arterial blood gas analysis. Also, it is important to know the patient’s baseline preoperative PacO₂ to guide weaning if mechanical ventilation becomes necessary in the postoperative period.

The COPD patients desaturate more frequently and severely than normal patients during sleep.⁷² This is due to the rapid/shallow breathing pattern that occurs in all patients during REM sleep. In COPD patients breathing air, this causes a significant increase in the VD/VT and a fall in alveolar oxygen tension (PAO₂) and PaO₂. This is not the SAHS. There is no increased incidence of SAHS in COPD.

Right ventricular dysfunction occurs in up to 50% of moderate to severe COPD patients.⁷³ The dysfunctional right ventricle is poorly tolerant to sudden increases in afterload such as the change from spontaneous to controlled ventilation. Right ventricular function becomes critical in maintaining cardiac output as the P_{PA} rises. The right ventricular ejection fraction does not increase with exercise in COPD patients as it does in normal patients. Chronic recurrent hypoxemia is the cause of the right ventricular dysfunction and the subsequent progression to cor pulmonale. Patients who have episodic hypoxemia in spite of normal lungs (eg, central alveolar hypoventilation, SAHS) develop the same secondary cardiac problems as COPD patients. The only therapy that has been shown to improve long-term survival and decrease right heart strain in COPD is supplemental oxygen. The COPD patients who have resting PaO₂ less than 55 mm Hg should receive supplemental home oxygen and also those who desaturate to less than 44 mm Hg with exercise. The goal of supplemental oxygen is to maintain a PaO₂ 60 to 65 mm Hg. Compared to patients with chronic bronchitis, emphysematous COPD patients tend to have a decreased cardiac output and mixed venous oxygen tension while maintaining lower P_{PA}s.

Many patients with moderate or severe COPD will develop cystic air spaces in the lung parenchyma known as **bullae** ([Figure 24.43](#)). These bullae will often be asymptomatic unless they occupy more than 50% of the hemithorax, in which case the patient will present with findings of restrictive respiratory disease in addition to their obstructive disease. A bulla is a localized area of loss of structural support tissue in the lung with elastic recoil of surrounding parenchyma ([Figure 24.44](#)).⁷⁴ The pressure in a bulla is actually the mean pressure in the surrounding alveoli averaged over the respiratory cycle. This means that during normal spontaneous ventilation, the intrabulla pressure is actually slightly negative in comparison to the surrounding parenchyma. However, whenever positive pressure ventilation is used, the pressure in a bulla will become positive in relation to the adjacent lung tissue and the bulla will expand with the attendant risk of rupture,

tension pneumothorax, and bronchopleural fistula. Positive pressure ventilation can be used safely in patients with bullae provided the airway pressures are kept low and there is adequate expertise and equipment immediately available to insert a chest drain and obtain lung isolation if necessary. Due to the lower solubility of nitrogen in plasma compared to nitrous oxide, when a patient is converted from breathing air to breathing a mixture containing nitrous oxide during anesthesia, the nitrous oxide will diffuse into a bulla faster than the nitrogen can be absorbed and the bulla will increase in size with the attendant risk of rupture.

FIGURE 24.43 Coronal computed tomography scan of a patient with bilateral giant lower lobe bullae. During positive pressure ventilation, the risk of bulla rupture and tension pneumothorax must always be kept in mind.

FIGURE 24.44 A, A spider's web seen on a woodbox on a sunny day as a lung model to demonstrate the pathophysiology of bullae. B, Breaking one septum of the spider's web causes a bulla to appear as elastic recoil pulls the web away from the area where structural support has been lost. Although the cells surrounding the bulla appear compressed, this is only due to redistribution of elastic forces. It is not positive pressure inside the bulla that causes this appearance of surrounding compression.

Severe COPD patients are often “flow limited” even during tidal volume expiration at rest. Flow limitation is present in normal patients only during a forced expiratory maneuver. Flow limitation occurs when an EPP develops in the intrathoracic airways during expiration. During quiet expiration in the normal patient, the pressure in the lumen of the airways always exceeds the intrapleural pressure because of the upstream elastic recoil pressure, which is transmitted from the alveoli. The effect of this elastic recoil pressure diminishes as air flows downstream in the airway. With a forced expiration, the intrapleural pressure may equal the intraluminal pressure at a certain point, the EPP, which then limits the expiratory flow (see [Figure 24.27](#)). Then, any increase in expiratory effort will not produce an increase in flow at that given lung volume. Flow limitation occurs particularly in emphysematous patients, who primarily have a problem with loss of lung elastic recoil and have marked dyspnea on exertion. Flow limitation causes dyspnea because of stimulation of mechanoreceptors in the muscles of respiration, thoracic cage, and in the airway distal to the EPP. Any increase in the work of respiration will lead to increased dyspnea. This variable mechanical

compression of airways by overinflated alveoli is the primary cause of the airflow obstruction in emphysema. Severely flow-limited patients are at risk for hemodynamic collapse with the application of positive pressure ventilation due to dynamic hyperinflation of the lungs. Even the modest positive airway pressures associated with manual ventilation with a bag/mask at induction can lead to hypotension because these patients have no increased resistance to inspiration but a marked obstruction of expiration. In some of these patients, this has contributed to the “Lazarus” syndrome in which patients have recovered from a cardiac arrest only after resuscitation and positive pressure ventilation were discontinued.⁷⁵

Patients with severe COPD often breathe in a pattern that interrupts expiration before the alveolar pressure has fallen to atmospheric pressure. This incomplete expiration is due to a combination of factors, which include flow limitation, increased work of respiration, and increased airway resistance. This interruption leads to an elevation of the end-expiratory lung volume above the FRC. This PEEP in the alveoli at rest has been termed **auto-PEEP** or **intrinsic PEEP**. During spontaneous respiration, the intrapleural pressure will have to be decreased to a level, which counteracts auto-PEEP before inspiratory flow can begin. Thus, COPD patients can have an increased inspiratory load added to their already increased expiratory load.

Auto-PEEP becomes even more important during mechanical ventilation. It is directly proportional to tidal volume and inversely proportional to expiratory time. The presence of auto-PEEP is not detected by the manometer of standard anesthesia ventilators. It can be measured by end-expiratory flow interruption, a feature available on most intensive care ventilators. Auto-PEEP has been found to develop in most COPD patients during one-lung anesthesia.⁷⁶

Restrictive lung diseases are often part of a multisystemic disease process such as connective tissue disorders. In a minority of patients, there is no other systemic disease (ie, idiopathic pulmonary fibrosis). Patients are often more debilitated by their underlying disease (eg, rheumatoid arthritis) than their lung disease. Patients with mild to moderate restrictive lung disease are, in general, less of a problem for the anesthesiologist to manage intraoperatively (compared to COPD) and more of a problem postoperatively. Due to the decrease in FRC in restrictive disease, these patients tend to develop an increased shunt during anesthesia and postoperatively. Restoration of the FRC postoperatively is commonly a problem, and the use of regional anesthesia/analgesia, short-acting opioids and muscle relaxants, and noninvasive ventilation are often of benefit in the patient with restrictive disease.

One-Lung Ventilation

An OLV is performed during thoracic surgery to facilitate the surgical exposure in the chest. The OLV is commonly obtained by placement of a double-lumen endobronchial tube or a bronchial blocker with a standard endotracheal tube. During OLV, the anesthesiologist has the unique and often conflicting goals of trying to maximize atelectasis in the nonventilated lung to improve surgical access while trying to avoid atelectasis in the ventilated lung (usually the dependent lung) to optimize gas exchange. The gas mixture in the nonventilated lung immediately before OLV has a significant effect on the speed of collapse of this lung.⁷⁷ Because of its low blood gas solubility, nitrogen (or an air-oxygen mixture) will delay collapse of this lung. This is particularly a problem at the start of minimally invasive thoracic surgery when surgical visualization in the operative hemithorax is limited and in patients with emphysema who have delayed collapse of the nonventilated lung due to decreased lung elastic recoil. It is important to thoroughly denitrogenate the operative lung, by ventilating with oxygen, immediately before it is allowed to collapse. Although nitrous oxide is even more effective than oxygen in speeding lung collapse (because of its solubility), it is not commonly used in thoracic anesthesia because many patients may have blebs or bullae. During the period of two-lung anesthesia before the start of OLV, atelectasis will develop in the dependent lung. It is useful to perform a recruitment maneuver to the dependent lung (similar to a Valsalva maneuver, holding the lung at an end-inspiratory pressure of 20 cm H₂O for 15-20 seconds) immediately after the start of OLV to decrease this atelectasis. Recruitment is important to maintain Pao₂ levels during subsequent OLV.⁷⁸

A major concern that influences anesthetic management for thoracic surgery is the occurrence of hypoxemia during OLV. There is no universally acceptable figure for the safest lower limit of oxygen

saturation during OLV. A saturation greater than or equal to 90% ($\text{PaO}_2 > 60 \text{ mm Hg}$) is commonly accepted, and for brief periods, a saturation in the high 80s may be acceptable in patients without significant comorbidity. However, the lowest acceptable saturation will be higher in patients with organs at risk for hypoxia due to limited regional blood flow (eg, coronary or cerebrovascular disease) and in patients with limited oxygen transport (eg, anemia or decreased cardiopulmonary reserve). Previously, hypoxemia occurred frequently during OLV. Reports for the period 1950-1980 describe an incidence of hypoxemia (arterial saturation $< 90\%$) of 20% to 25%. Current reports describe an incidence of less than 5%. This improvement is most likely due to several factors: improved lung isolation techniques, such as routine fiberoptic bronchoscopy to prevent lobar obstruction from double-lumen tubes; improved anesthetic agents, which cause less inhibition of HPV; and better understanding of the pathophysiology of OLV.

The pathophysiology of OLV is complex and involves the body's ability to redistribute pulmonary blood flow to the ventilated lung. Several factors aid and impede this redistribution, and these are under the control of the anesthesiologist to a variable degree. These factors are illustrated in [Figure 24.45](#). The anesthesiologist's goal during OLV is to maximize PVR in the nonventilated lung while minimizing PVR in the ventilated lung. The PVR is lowest at FRC and increases as lung volume rises or falls above or below FRC. The anesthesiologist's aim, to optimize pulmonary blood flow redistribution during OLV, is to maintain the ventilated lung as close as possible to its FRC while facilitating collapse of the nonventilated lung to increase its PVR.⁷⁹ Most thoracic surgery is performed in the lateral position. Patients having OLV in the lateral position have significantly better PaO_2 levels than patients during OLV in the supine position due to a preferential distribution of blood flow to the dependent lung caused by gravitational forces.

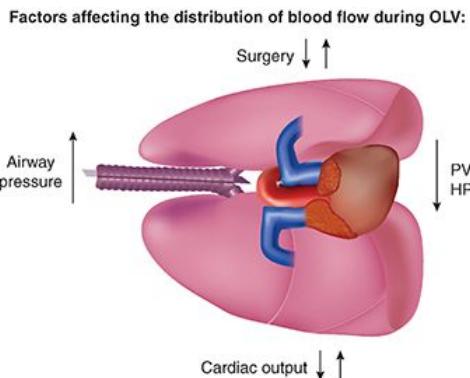

FIGURE 24.45 Factors affecting the distribution of pulmonary blood flow during one-lung ventilation (OLV). Hypoxic pulmonary vasoconstriction (HPV) and the collapse the nonventilated lung, which increase pulmonary vascular resistance (PVR), tend to distribute blood flow toward the ventilated lung. The airway pressure gradient between the ventilated and nonventilated thoraces tends to encourage blood flow to the nonventilated lung. Surgery and cardiac output can have variable effects either increasing or decreasing the proportional flow to the ventilated lung. Gravity will also increase the blood flow to the dependent lung.

Ventilatory strategies during OLV have shifted from historical practice focusing on higher tidal (10 mL/kg) volumes and FiO_2 with or without PEEP to more lung protective strategies based on intensive care literature. In this setting, the use of lower tidal volumes (6 mL/kg), routine use of PEEP recruitment maneuvers, and FiO_2 titrated to SpO_2 or PaO_2 have become more commonplace and recommended.⁸⁰ That being said, the role of lung protective strategies in reducing pulmonary complications during OLV remains inconsistent. More recently, lung protective ventilation strategies have moved beyond low tidal volume and routine use of PEEP to incorporate strategies to individualize ventilation based on compliance. Minimization of “driving pressure” (DP), which is calculated as $\text{DP} = \text{plateau pressure} - \text{PEEP}$, has been shown to reduce postoperative pulmonary complications. Minimization of DP is achieved through titration of both tidal volume and PEEP intraoperatively after performance of recruitment maneuvers. Recent observational and

randomized controlled trials in thoracic surgery patients have shown a reduction in postoperative pulmonary complications.[81,82](#)

Extracorporeal Ventilatory Support

Various devices to supplement or replace the gas exchange function of the lung have been available clinically for the past several decades. These devices have been associated with a high incidence of complications, particularly cerebral hemorrhage and infarction, and have met with questionable outcome results in several studies. However, gradual progress in the technology has seen a resurgence of use of these devices.[83](#) Indications currently may include infant respiratory distress syndrome, adult respiratory distress syndrome, respiratory failure unresponsive to mechanical ventilation, and as a bridge to transplantation in end-stage lung diseases. During extracorporeal ventilation, less injurious mechanical ventilation strategies can be used on the native lungs with relatively normal FIO_2 and tidal volumes to allow some regression of the disease process in the lungs.

The options for extracorporeal ventilatory support include venovenous membrane oxygenation, with an oxygenator and a pump, indicated in primary respiratory failure; venoarterial membrane oxygenation, for combined respiratory and cardiac failure; and pumpless interventional lung assist, with a passive arterial-venous membrane gas-exchange device, which is primarily used in failure of CO_2 excretion with relatively maintained oxygenation.[84](#)

Respiratory Pharmacology

Peter Slinger

This chapter reviews the pharmacology of agents commonly encountered in anesthetic practice that are either administered to treat pulmonary diseases or administered into the airway or systemically for action at end organs other than the lung but have effects on the airway and the pulmonary circulation. The pharmacology of the airways is considered first, then the pharmacology of the pulmonary circulation, and finally, the intrinsic action of the lungs on a variety of exogenous and endogenous substances.

Pharmacology of the Airways

Pharmacologic agents administered via the lungs take advantage of the interface between air and blood allowing for rapid uptake of drugs into the bloodstream or immediate use by cells that populate the airway.¹ The delivery of medications to the lungs can have systemic effects, direct effects on the airway, or both. For example, inhaled anesthetics are delivered via the lungs to act in the brain and have bronchodilatory effects. Conversely, β -adrenergic agonists delivered via aerosol exert direct effects on bronchial smooth muscle with few systemic effects. Drugs administered to the airway take advantage of the rapid exposure to blood and pulmonary parenchymal cells, making them advantageous for treating pulmonary parenchymal diseases such as asthma and chronic obstructive pulmonary disease (COPD).

Influence of the Autonomic Nervous System on the Airways

Traditionally, the autonomic nervous system has been divided into two major parts, the parasympathetic and sympathetic nervous systems. The parasympathetic nervous system regulates airway caliber, airway glandular activity, and airway microvasculature.²⁻⁴ The vagus nerve provides the preganglionic fibers, which synapse with postganglionic fibers in airway parasympathetic ganglia. Acetylcholine activates the muscarinic 3 (M3) receptor of postganglionic fibers of the parasympathetic nervous system to produce bronchoconstriction.⁵ Anticholinergics can provide bronchodilation even in the resting state because the parasympathetic nervous system produces a basal level of resting bronchomotor tone.⁶

Although the sympathetic nervous system plays no direct role in control of airway muscle tone, β_2 -adrenergic receptors are present on airway smooth muscle cells and cause bronchodilation via stimulatory G mechanisms. The abundance of these receptors in the airway allows for pharmacologic manipulation of airway tone.⁷

The autonomic nervous system also influences bronchomotor tone through the nonadrenergic noncholinergic (NANC) system.^{8,9} The exact role of NANC in humans is not well defined; it has excitatory and inhibitory neuropeptides that influence inflammation and smooth muscle tone, respectively. Vasoactive intestinal peptide and nitric oxide (NO) are the main inhibitory transmitters thought to be responsible for airway smooth muscle relaxation. Substance P and neurokinin A are the main excitatory transmitters and have been shown to cause neurogenic inflammation, including bronchoconstriction. The precise role of NANC in healthy and diseased human lung is unclear.

Inhaled Adrenergic Agonists

The mainstay of therapy for bronchospasm, wheezing, and airflow obstruction is β -adrenergic agonists. β -Adrenergic agonists used in clinical practice are typically delivered via inhalers or nebulizers, are β_2 selective, and are divided into short- and long-acting therapies.¹⁰ Short-acting β_2 agonist therapy is effective for the rapid relief of wheezing, bronchospasm, and airflow obstruction. Longer acting β_2 agonists are used as

maintenance therapy providing improvement in lung function and reduction in symptoms and exacerbations ([Table 25.1](#)).

TABLE 25.1

Pharmacologic influence on the autonomic nervous system^a

Systemic adrenergic agonists	Inhaled adrenergic agonists	Inhaled cholinergic antagonists	Systemic cholinergic antagonists
	Short acting	Short acting	
Terbutaline	Albuterol	Ipratropium	Atropine
Epinephrine	Levalbuterol		Scopolamine
Albuterol	Metaproterenol		Glycopyrrolate
	Pirbuterol		
	Long acting	Long acting	
	Salmeterol	Tiotropium	
	Formoterol		
	Arformoterol

Short-acting β_2 agonists bind to the β_2 -adrenergic receptor located on the plasma membrane of smooth muscle cells, epithelial, endothelial, and many other types of airway cells.¹¹ This causes a stimulatory G protein to activate adenylate cyclase converting adenosine triphosphate into cyclic adenosine monophosphate (cAMP). It is unknown precisely how cAMP causes smooth muscle relaxation; however, decreases in calcium release and alterations in membrane potential are the most likely mechanisms. Longer acting β_2 agonists have the same mechanism of action as short-acting β_2 agonists; however, they have unique properties that allow for a longer duration of action. For example, salmeterol has a longer duration of action because a side chain binds to the β_2 -receptor and prolongs the activation of the receptor.¹² The lipophilic side chain of formoterol allows for interaction with the lipid bilayer of the plasma membrane and a slow, steady release prolonging its duration of action.

β_2 Agonists have a central role in the management of obstructive airway diseases allowing for control of symptoms and improvement in lung function. Short-acting β_2 agonists such as albuterol, levalbuterol, metaproterenol, and pirbuterol are prescribed for the rapid relief of wheezing, bronchospasm, and airflow obstruction. Clinical effect is seen in a matter of minutes and lasts up to 4 to 6 hours. Scheduled, daily use of short-acting β_2 agonists has largely fallen out of favor, and they are now used primarily as rescue therapy.¹³⁻¹⁵ Long-acting β_2 agonists are prescribed for control of symptoms when rescue therapies (ie, short-acting β_2 agonists) are used greater than two times per week.¹⁶ Combination therapy including a long-acting β_2 agonist and an inhaled corticosteroid is effective in reducing symptoms, reducing the risk of exacerbation, and improving lung function while minimizing the dose of inhaled corticosteroid.¹⁷

Systemic absorption of inhaled β_2 agonists is responsible for a myriad of side effects, most of which are not serious. Most commonly, β_2 agonist therapy leads to tremors and tachycardia secondary to direct stimulation of the β_2 -adrenergic receptor in skeletal muscle or vasculature, respectively.^{18,19} In severe asthma, β_2 agonists may cause a temporary reduction in arterial oxygen tension of 5 mm Hg or more, secondary to β_2 -mediated vasodilation in poorly ventilated lung regions.²⁰ Hyperglycemia, hypokalemia, and hypomagnesemia also can occur with β_2 agonist therapy, but the severity of these side effects tends to diminish with regular use. Tolerance to β_2 agonists can occur with regular use over a period of weeks and, while not affecting peak bronchodilation, can be evidenced by a decrease in the duration of bronchodilation.

and the magnitude of side effects (tremor, tachycardia, etc).^{21,22} Tolerance likely reflects β_2 -adrenergic receptor downregulation. β_2 Agonist therapy withdrawal after regular use can produce transient bronchial hyperresponsiveness.

Evidence has associated the use of long-acting β_2 agonist therapy without concomitant use of a steroid inhaler with fatal and near-fatal asthma attacks.²³ In light of this evidence, it seems prudent to reserve long-acting β_2 agonists for patients who are poorly controlled on inhaled steroids alone or for those patients with symptoms sufficiently challenging to warrant the potential extra risk associated with use of the agents.

Systemic Adrenergic Agonists

Systemic administration of adrenergic agonists for asthma was used more frequently in the past. Oral, intravenous (IV), or subcutaneous administration of β -specific or nonspecific adrenergic agonists is now reserved for rescue therapy. The mechanism of action of systemically administered adrenergic agonists is the same as it is for inhaled agents. Binding of the drug to the β_2 -adrenergic receptor on smooth muscle cells in the airway is responsible for the bronchodilatory effects. Specifically, β_2 -receptor stimulation induces a stimulatory G protein to convert adenosine triphosphate to cAMP and in turn reduces intracellular calcium release and alters membrane potential.

Terbutaline can be given orally, subcutaneously, or intravenously; albuterol (salbutamol) can be given intravenously; and epinephrine is usually given subcutaneously or intravenously. Regardless of the route of administration, all three will produce bronchodilation. Comparison of IV and inhaled formulations of terbutaline failed to demonstrate any difference in bronchodilation and, with the propensity for IV formulations to cause side effects, inhaled therapy should be considered the first-line treatment.^{24,25} This principle not only applies to terbutaline but all β -adrenergic agonists that are available in IV and inhaled forms. If inhaled therapy is not readily available or if inhaled therapy is maximized and symptoms persist, then subcutaneous epinephrine or terbutaline can be administered with improvement in symptoms and spirometry values.²⁶ In summary, subcutaneous or IV β agonists should be reserved only for rescue therapy.

The side effect profile of systemic adrenergic agonists is similar to the side effect profile for inhalational adrenergic agonists. The most common side effects are tremor and tachycardia. Arterial oxygen tension can be transiently decreased and hyperglycemia, hypokalemia, and hypomagnesemia can also be present. Escalating oral, subcutaneous, or IV doses can be associated with a greater incidence of side effects for the same degree of bronchodilation compared to inhaled β -adrenergic agonists.

Inhaled Cholinergic Antagonists

The use of anticholinergics for maintenance therapy and treatment of acute exacerbations in obstructive airway diseases is common. The parasympathetic nervous system is primarily responsible for bronchomotor tone and inhaled anticholinergics act on muscarinic receptors in the airway to reduce tone. The use of inhaled anticholinergics (see **Table 25.1**) in COPD as maintenance and rescue therapy is considered standard treatment.²⁷ Anticholinergics are not used for maintenance therapy in asthma and are only recommended for use in acute exacerbations.²⁸ The targets of therapy for anticholinergics are the muscarinic receptors located in the airway. There are three subtypes of muscarinic receptors found in the human airway.²⁹ Muscarinic 2 (M2) receptors are present on postganglionic cells and are responsible for limiting production of acetylcholine and protect against bronchoconstriction. The M2 is not the target of inhaled anticholinergics but is antagonized by them. Muscarinic 1 (M1) and M3 receptors are responsible for bronchoconstriction and mucus production and are the targets of inhaled anticholinergic therapy. Acetylcholine binds to the M3 and M1 receptors and causes smooth muscle contraction via increases in cyclic guanosine monophosphate (cGMP) or by activation of a G protein.²⁹ The G protein activates phospholipase C to produce inositol triphosphate, which causes release of calcium from intracellular stores and activation of myosin light chain kinase causing smooth muscle contraction. Anticholinergics inhibit this cascade and reduce smooth muscle tone by decreasing release of calcium from intracellular stores.

There are two inhaled anticholinergics specifically approved for the treatment of obstructive airway diseases. Ipratropium is classified as a short-acting anticholinergic and is commonly used as maintenance therapy for COPD and as rescue therapy for both COPD and asthmatic exacerbations. It is not indicated for the routine management of asthma. Patients treated with ipratropium experience an increase in exercise tolerance, decrease in dyspnea, and improved gas exchange. Tiotropium is the only long-acting anticholinergic available for COPD maintenance therapy. Tiotropium has been shown to reduce COPD exacerbations, respiratory failure, and all-cause mortality.³⁰

Inhaled anticholinergics are poorly absorbed and therefore serious side effects are uncommon. Most commonly, patients experience dry mouth, urinary retention, and can experience pupillary dilation and blurred vision if the eyes are inadvertently exposed to the drug. Some initial data suggested an increase in cardiovascular and stroke complications with tiotropium; however, additional studies did not consistently demonstrate these complications. In general, anticholinergics are safe and effective treatment for patients with obstructive airway diseases.

Systemic Cholinergic Antagonists

The systemically administered anticholinergics atropine and glycopyrrolate act via the same mechanisms as inhaled anticholinergics. Although these anticholinergics can be administered by IV or inhalation, significant systemic absorption occurs, and their use is generally limited by side effects. Atropine, in particular, is limited in use because of its tertiary ammonium structure. It has a tendency to cause tachycardia, gastrointestinal upset, blurred vision, dry mouth, and central nervous system effects secondary to its ability to cross the blood–brain barrier. Glycopyrrolate has a quaternary ammonium structure and is insoluble in lipids, similar to ipratropium and tiotropium, and has fewer systemic side effects than atropine. An IV glycopyrrolate is also clinically limited in use secondary to side effects.³¹ Glycopyrrolate has been studied as inhaled therapy, however, and is an effective bronchodilator with an intermediate duration of action.^{32–35} Clinically, it has never been popular as a mainstay of therapy for obstructive airway diseases.

Influence of Inflammation on the Airway

Asthma and COPD, the most common obstructive airway diseases, have a component of inflammation as part of their pathogenesis. Although inflammation is a common pathogenesis, the characteristics and prominent cellular elements involved in the inflammatory process for each disease are distinct.³⁶ In COPD, neutrophils, macrophages, CD8⁺ T lymphocytes, and eosinophils are more prominent in the inflammatory composition. In asthma, eosinophils play a more prominent role followed by mast cells, CD4⁺ T lymphocytes, and macrophages in the inflammatory composition. Inflammatory cell types present in sputum, biopsy specimens, and bronchoalveolar lavage fluid can help predict the response to antiinflammatory therapy. For example, eosinophilia in induced sputum of a patient presenting with a COPD exacerbation predicts an increase in steroid responsiveness.^{37,38} Patients presenting to the operating room with obstructive airway diseases have a high likelihood of taking one of the antiinflammatory therapies in **Table 25.2** for control of their disease.

TABLE 25.2

Pharmacologic influence on inflammation^a

Inhaled corticosteroids	Leukotriene modifiers	Mast cell stabilizers	Methylxanthines
Monotherapy	Antagonists

Inhaled Corticosteroids

In the treatment of asthma, the use of inhaled corticosteroids (ICS) reduces the inflammatory changes associated with the disease, thereby improving lung function and reducing exacerbations that result in hospitalization and death.³⁹⁻⁴¹ On the contrary, the use of ICS as monotherapy in COPD is discouraged. In COPD, ICS are used as a part of combination therapy along with long-acting β-adrenergic agonists (LABA). The combination of drugs acts synergistically and is useful for reducing inflammation. Currently, combination therapy of ICS and LABA is recommended for use in severe to very severe COPD.⁴² The glucocorticoid receptor α located in the cytoplasm of airway epithelial cells is the primary target of ICS.^{43,44} Passive diffusion of steroids into the cell allows for binding of the steroid ligand to glucocorticoid receptor α, dissociation of heat shock proteins, and subsequent translocation to the nucleus. The complex can bind to promoter regions of DNA sequences and either induce or suppress gene expression. Additionally, the steroid-receptor complex can interact with transcription factors already in place, such as the ones responsible for proinflammatory mediators, without binding to DNA and repress expression of those genes. The steroid-receptor complex also can affect chromatin structure by association with transcription factors that influence the winding of DNA around histones, reducing access of RNA polymerase and other transcription factors, and thus reducing expression of inflammatory gene products.

The ICS are used in asthma as part of a multimodal treatment regimen and are added to a therapeutic regimen when there is an increase in severity or frequency of asthma exacerbations. There is good evidence to show that ICS can reduce both hospitalizations and death in asthma. The use of ICS in COPD is limited to use in severe to very severe COPD and in combination with LABA. Although no improvement in mortality has been consistently demonstrated with combination therapy (ICS/LABA), there are reported improvements in health status and lung function along with a reduction in exacerbations.

Side effects have been reported with the use of ICS in asthma and COPD. A meta-analysis reported an increase in pneumonia and serious pneumonia but not deaths when ICS was used in the treatment of COPD.⁴⁵ Other reported side effects in COPD and asthma include oropharyngeal candidiasis, pharyngitis, easy bruising, osteoporosis, cataracts, elevated intraocular pressure, dysphonia, cough, and growth retardation in children. As with any pharmacotherapy, the risks and benefits of therapy must be weighed, and the patient must be carefully monitored for adverse effects. This is especially true with the use of ICS in obstructive lung diseases.

Systemic Corticosteroids

Systemic corticosteroids given in IV or oral form are used for treatment of asthma and COPD exacerbations. The mechanism of action is the same as it is for ICS, activation or suppression of gene products at a transcriptional level and alteration of chromatin structure. Patients who are hospitalized with a COPD exacerbation will typically receive IV corticosteroids to suppress any inflammatory component that may be contributing to the flare up. A study done at the Veterans Affairs medical centers in the United States published in 1999 reported that corticosteroid therapy shortened hospital length of stay and improved forced expiratory volume in 1 second versus placebo.⁴⁶ The study also compared a 2-week regimen versus an 8-week regimen of corticosteroids and found no difference, concluding that the duration of therapy should last only 2 weeks. In asthma, corticosteroids are recommended for exacerbations that are either severe, with a peak expiratory flow of less than 40% of baseline, or a mild to moderate exacerbation with no immediate response to short-acting β-adrenergic agonists. The recommended duration of therapy is 3 to 10 days without

tapering. Alternatively, some patients with asthma and COPD will be receiving long-term oral corticosteroid therapy because their disease is difficult to manage. Side effects of systemic corticosteroids are well described and numerous. Hypertension, hyperglycemia, adrenal suppression, increased infections, cataracts, dermal thinning, psychosis, and peptic ulcers are reported complications of corticosteroid therapy.⁴⁷

Leukotriene Modifiers

Leukotriene modifiers are used for the treatment of asthma. They are prescribed primarily for long-term control in addition to short-acting β -adrenergic agonists or in conjunction with ICS and short-acting β agonists. Leukotriene modifiers are taken by mouth, produce bronchodilation in hours, and have maximal effect within days of administration. Their role in the management of COPD is not defined.⁴⁸ Arachidonic acid is converted to leukotrienes via the 5-lipoxygenase pathway.⁴⁹ Leukotrienes C₄, D₄, and E₄ are the end products of the pathway and cause bronchoconstriction, tissue edema, migration of eosinophils, and increased airway secretions. Leukotriene modifiers come in two different varieties: leukotriene receptor antagonists and leukotriene inhibitors.⁴⁹ The leukotriene inhibitor zileuton antagonizes 5-lipoxygenase inhibiting the production of leukotrienes.

Leukotriene modifiers improve lung function, reduce exacerbations, and are used as long-term asthma therapy.^{50,51} Clinical trials have reported that ICS are superior to leukotriene modifiers for long-term control and should be the first-line choice.^{52,53} Leukotriene modifiers provide an additional pharmacologic option for the control of asthma. Addition of leukotriene modifiers to ICS will improve control of symptoms of asthma as opposed to ICS alone.⁵⁴

Leukotriene antagonists are usually well tolerated without significant side effects. Links between Churg-Strauss syndrome and the use of leukotriene antagonists have been reported, but it is not clear whether these reports reflect unmasking of a preexisting condition or whether there is a direct link between the two. Zileuton is known to cause a reversible hepatitis in 2% to 4% of patients.

Mast Cell Stabilizers

Cromolyn sodium and nedocromil are the two agents in this category that are used in the treatment of asthma. These agents are delivered by powder inhaler and are not first-line therapy for asthma. They do provide an alternative treatment when the control of asthma is not optimal on other conventional therapies. Cromolyn sodium and nedocromil stabilize submucosal and intraluminal mast cells.⁵⁵ These drugs interfere with the antigen-dependent release of mediators, such as histamine and slow-reacting substance of anaphylaxis, that cause bronchoconstriction, mucosal edema, and increased mucus secretion.

Systematic reviews of the available literature and consensus statements favor the use of ICS over cromolyn sodium or nedocromil as first-line agents to control symptoms of asthma.⁵⁶ Alternatively, cromolyn sodium and nedocromil may be used as preventative treatment before exercise or known allergen exposure causing symptoms of asthma. There are no major side effects reported with the use of cromolyn sodium and nedocromil. The most commonly reported side effects are gastrointestinal upset and coughing or irritation of the throat.

Methylxanthines

The role of theophylline, a methylxanthine, has changed since the introduction of ICS and LABA. Theophylline was a common choice for the control of asthma and COPD because of its bronchodilatory and antiinflammatory effects.⁵⁷ Currently, theophylline is recommended only as an alternative therapy and is not a first-line choice for asthma or COPD.^{58,59} Theophylline acts via multiple pathways causing improvement in symptoms in obstructive lung diseases. Theophylline is a nonselective inhibitor of phosphodiesterase and increases levels of cAMP and cGMP causing smooth muscle relaxation. Antagonism of the A₁ and A₂ adenosine receptors also causes smooth muscle relaxation via inhibition of the release of histamine and leukotrienes from mast cells, another reported action of theophylline. In asthma, theophylline reduces the number of eosinophils in bronchial specimens and, in COPD, reduces the number neutrophils in sputum, having an antiinflammatory effect in both conditions. In addition, theophylline activates histone deacetylase

and reduces the expression of inflammatory genes. Theophylline and aminophylline are reported to improve diaphragmatic function; however, data have not demonstrated this effect consistently.⁶⁰

Theophylline has been relegated to an alternative therapy in both asthma and COPD. This has occurred largely because of its significant side effect profile and the subsequent need for monitoring of blood level. Patients who are already on an ICS and an LABA and still have symptoms may benefit from the addition of theophylline, especially if leukotriene modifiers and other alternatives are not tolerated. Theophylline can cause significant and life-threatening side effects if not dosed carefully and monitored appropriately. Side effects tend to be more prominent when blood levels exceed 20 mg/L. The most common side effects include headache, nausea, vomiting, restlessness, abdominal discomfort, gastroesophageal reflux, and diuresis. The most significant side effects include seizures, cardiac arrhythmias, and death. Adverse effects from theophylline may be avoided if the clinician follows the patient carefully, monitors blood levels regularly, and educates the patient on the signs and symptoms of overdose.

Combined Pharmacologic Therapy of Asthma

Patients with chronic asthma are commonly treated with combination therapy designed to interrupt the bronchoconstrictive pathology by different pharmacologic methods. There is some synergism between antiinflammatory agents and direct acting bronchodilators. A six-step program for managing asthma in adults is outlined in **Table 25.3**, and patients move up or down the steps depending on the severity of their symptoms.

TABLE 25.3					
A stepwise approach to managing asthma in adults ^a					
Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
Inhaled short-acting β_2 -agonist as needed	Low-dose inhaled steroid	Low-dose inhaled steroid	Medium-dose inhaled steroid	High-dose inhaled steroid	High-dose inhaled steroid
	Inhaled short-acting β_2 -agonist as needed	Inhaled long-acting β_2 -agonist	Inhaled long-acting β_2 -agonist	Inhaled long-acting β_2 -agonist	Inhaled long-acting β_2 -agonist
	Alternatives: Leukotriene antagonist or mast cell stabilizers		(Combined inhalers)	Monoclonal antibody (?) (allergic asthma)	Monoclonal antibody (?)
					Oral steroids

Abbreviations: ?, under investigation.

Influence of Anesthetics on the Airways

Volatile Anesthetics

Volatile anesthetics have a host of effects on the respiratory system. Volatile anesthetics reduce bronchomotor tone, and all commonly used volatile anesthetics (**Table 25.4**), except desflurane and nitrous oxide, produce a degree of bronchodilatation that may be helpful in patients with obstructive lung disease or in patients who experience any degree of bronchoconstriction.⁶¹ Rooke and colleagues⁶² in 1997 reported that sevoflurane produced a greater reduction in respiratory system resistance than isoflurane or halothane. Volatile anesthetics likely induce bronchodilation by decreasing intracellular calcium, partly mediated by an increase in intracellular cAMP and by decreasing the sensitivity of calcium mediated by protein kinase C.⁶³ The effect is seen to a greater degree in distal airway smooth muscle secondary to the T-type voltage-dependent calcium channel, which is sensitive to volatile anesthetics.⁶⁴

TABLE 25.4**Anesthetics with a favorable influence on bronchomotor tone^a**

Volatile anesthetics	Intravenous anesthetics
Isoflurane	Propofol
Sevoflurane	Ketamine
Halothane	Midazolam

Volatile anesthetics are administered to provide amnesia and blunt the response to surgical stimulation but can be of use in patients who have obstructive airway diseases or experience bronchoconstriction in the operating room. Multiple case reports provide examples of how volatile agents were used solely for the treatment of status asthmaticus.⁶⁵⁻⁶⁸ The main concern with the use of volatile anesthetics is the rare occurrence of malignant hyperthermia. Hypotension can also be a concern with volatile anesthetics; however, the blood pressure is usually easily restored with small amounts of vasopressors. Deep levels of anesthesia associated with high concentrations of volatile anesthetics may be undesirable, and prolonged administration outside the operating room is problematic.

Intravenous Anesthetics

The IV anesthetics can decrease bronchomotor tone when used for induction or IV anesthesia in the operating room. Ketamine, propofol, and midazolam (see **Table 25.4**) have relaxant effects on airway smooth muscle.⁶⁹ Etomidate and thiobarbiturates do not affect bronchomotor tone to the same extent.⁷⁰ The choice of IV anesthetics for induction and maintenance of anesthesia may be important for a patient with reactive airway disease. The mechanism of reduction of bronchomotor tone for the IV anesthetics is largely unknown. Ketamine is thought to have a direct relaxant effect on smooth muscle.⁷¹ Propofol is thought to reduce vagal tone and have a direct effect on muscarinic receptors by interfering with cellular signaling and inhibiting calcium mobilization.^{72,73} Propofol may be the most effective anesthetic for preventing reflex bronchoconstriction during anesthesia. In a randomized trial, children at risk had fewer adverse respiratory events during induction of anesthesia with IV propofol than inhaled sevoflurane.⁷⁴

Choosing an agent such as propofol or ketamine can be beneficial in patients with bronchospasm or obstructive airway disease. The use of these IV agents for induction or maintenance of anesthesia over other agents can be useful in minimizing the intraoperative effects of bronchospasm. Although each of the IV anesthetics carries a unique side effect profile, the major effects are not related to the airway. The use of ketamine is associated with increased salivation and coadministration of a small dose of anticholinergic can attenuate secretion production. Propofol is associated with hypotension that usually is easily corrected with vasopressors. A schematic representation of the anatomy of the bronchus and the sites of actions of various pharmacologic agents used to treat asthma is shown in **Figure 25.1**.

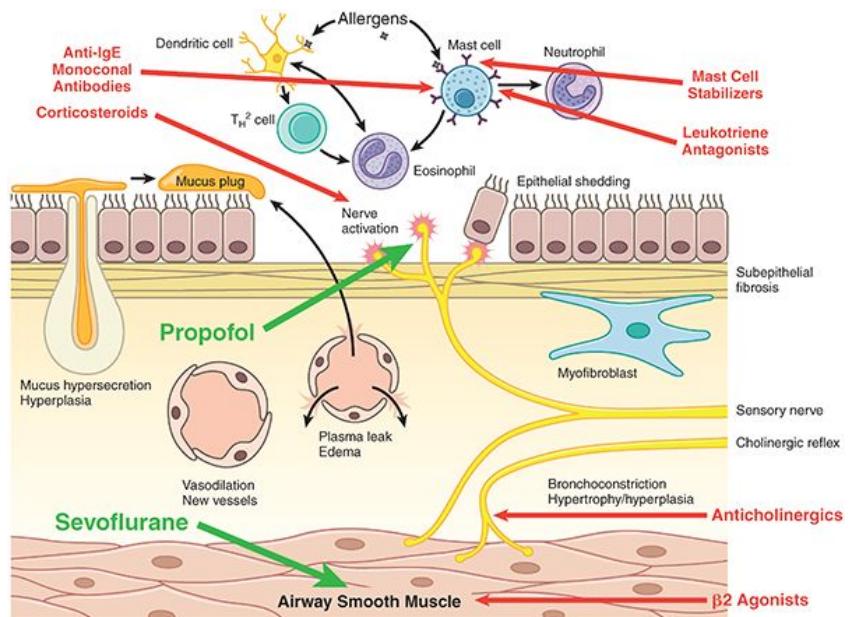

FIGURE 25.1 A diagram of the histology and pharmacology of a section of the asthmatic bronchus. The airway and epithelium are at the top, and the bronchial smooth muscle is at the bottom. Antiinflammatory agents act primarily at the level of the respiratory epithelium, whereas bronchodilators act at the level of the airway smooth muscle. Abbreviation: IgE, immunoglobulin E.

Local Anesthetics

Local anesthetics are primarily used to suppress coughing and blunt the hemodynamic response to tracheal intubation.^{75,76} Although animal models have demonstrated some ability of local anesthetics to relax bronchial smooth muscle, in clinical practice, the use of local anesthetics as pure bronchodilators is limited by toxicity and the ready availability of more potent bronchodilators such as short-acting β -adrenergic agonists.

Influence of Adjunctive Agents on the Airway

Helium (administered as a mixture of helium and oxygen [Heliox]) has the advantage of having a low Reynolds number and less resistance during turbulent airflow especially in large airways (see [Chapter 24](#)). A trial in patients with COPD exacerbations failed to demonstrate a statistically significant reduction in the necessity for endotracheal intubation in patients treated with noninvasive ventilation and helium-oxygen mixtures.⁷⁷ Helium-oxygen mixtures may be useful as short-term temporizing therapy to decrease the work of breathing in patients with upper airway obstruction. The use of helium-oxygen mixtures is limited by a progressive reduction in efficacy at higher inspired oxygen concentrations.

Antihistamines: Histamine release from mast cells and basophils is responsible for airway inflammation and bronchoconstriction in asthma.⁷⁸ Antihistamines are not standard therapy for asthma, but the use of antihistamines and leukotriene modifiers for allergen-induced bronchoconstriction has shown promise for diminishing the early and late responses to allergens.^{78,79} Patients who have allergen-induced asthma or patients who experience an allergic reaction in the operating room may benefit from antihistamines to attenuate the role that histamine plays in bronchoconstriction.

Magnesium sulfate is not standard therapy for asthma exacerbations. Magnesium sulfate is thought to produce additional bronchodilation when given in conjunction with standard therapy for asthma exacerbations. Currently, IV magnesium therapy is reserved as an alternative therapy when the patient has not responded to standard therapy.⁸⁰ The combination of nebulized magnesium sulfate and β -adrenergic agonists have also been studied and show potential benefit in asthma exacerbations.⁸¹ Overall, magnesium sulfate, IV

or nebulized, is not a first-line therapy for asthma exacerbations and should be reserved for situations when the patient is not responding to conventional therapy.

Pharmacology of the Pulmonary Circulation

Patients with pulmonary hypertension (PHTN) are high-risk candidates for both cardiac and noncardiac surgery. They have poor cardiorespiratory reserve and are at risk for having perioperative complications including pulmonary hypertensive crises with resultant heart failure, respiratory failure, and dysrhythmias.^{82,83} Anesthetic management of these patients can be complex and challenging. Drugs affecting the pulmonary vascular bed are routinely administered during anesthesia, and their effects are of particular interest in patients with PHTN. Reducing the consequences of an elevated pulmonary vascular resistance (PVR) and the resulting right ventricular dysfunction should be considered as the primary goal of therapy with pulmonary vasodilators. Owing to the contractile properties of the naive right ventricle, attempts at improving its contractility are generally not effective. Therefore, principles of management of PHTN center on reducing right ventricular afterload while preserving coronary perfusion by avoiding reductions in systemic blood pressure.⁸⁴

Anesthetic Drugs

Evaluating the effects of anesthetic drugs on the pulmonary vasculature is challenging. In clinical practice and research, these drugs are rarely administered in isolation. Their administration can lead to concurrent changes in nonpulmonary hemodynamic parameters such as cardiac output (CO) that ultimately affect pulmonary artery pressure (PAP). An increase in PAP may be the result of increased PVR, increased CO, or an increase in left atrial pressure (LAP) ($PAP = [PVR \times CO] + LAP$). In addition, general anesthesia involves manipulation of variables that affect PVR, including fraction of inspired oxygen (FoI_2), carbon dioxide, and positive pressure ventilation.

Ketamine

Historically, ketamine has occupied a controversial position in anesthesia for patients with PHTN. Despite its current widespread use in these challenging patients, it has been classically taught that ketamine causes pulmonary vasoconstriction and should be used with extreme caution in this group. The mechanism of action of ketamine is not fully elucidated. It is an *N*-methyl-D-aspartic acid receptor antagonist and also binds to opioid receptors and muscarinic receptors.⁸⁵ It appears to stimulate release as well as inhibit neuronal uptake of catecholamines, which may account for its cardiotonics and bronchodilatory effects. Some animal studies have shown an endothelium-independent vasodilatory response to ketamine in the pulmonary bed.

The effects of ketamine on the human pulmonary vasculature appear to be complex and the clinical literature reveals a vast heterogeneity in regard to results. Factors known to affect pulmonary vasoreactivity such as FoI_2 , carbon dioxide, presence of PHTN, and presence of premedicants are not reported or acknowledged in many studies. The hemodynamic effects of a bolus of ketamine can be attenuated or abolished with premedicants such as droperidol, dexmedetomidine, or benzodiazepines.⁸⁶ Early study of the drug's hemodynamic profile in adult patients showed increases of PAP and PVR in the range of 40% to 50%. This, combined with increases in variables contributing to myocardial oxygen consumption, raised concern about the use of ketamine in patients with coronary artery disease and PHTN.

A systematic review of the use of ketamine in children with congenital heart disease and/or PHTN found that PAP, PVR, and heart rate did not change significantly with the administration of ketamine.⁸⁷ In another pediatric study, ketamine maintained pulmonary to systemic blood flow and did not affect pulmonary pressure or resistance in children with intracardiac shunt undergoing cardiac catheterization. Propofol, on the other hand, decreased systemic vascular resistance (SVR) leading to increased right to left shunting.⁸⁸ In adult patients undergoing one-lung ventilation (OLV) for lung resection, ketamine did not significantly increase PAP or PVR compared to enflurane. Other case reports highlight the value of the relative cardiostability of the drug in patients with minimal cardiorespiratory reserve.^{89,90} Many clinicians incorporate this drug into their routine inductions for patients with severe PHTN (eg, pulmonary endarterectomy or lung

transplantation). The advantages, in particular maintenance of stable hemodynamics and coronary perfusion pressure, seem to outweigh the potential disadvantages.

Propofol

Propofol is commonly used in anesthesia, including for patients with PHTN. It is frequently used to maintain anesthesia during and after lung transplantation. The effects of propofol are thought to be primarily mediated by γ -aminobutyric acid receptors. The concerning hemodynamic effect of propofol in the context of PHTN is a decrease in SVR, which can not only have effects on intracardiac shunting, if present, but also can lead to decreased coronary artery perfusion of the right ventricle and resultant right ventricular dysfunction. In regard to direct effects on the pulmonary vasculature, animal studies have shown that during increased tone conditions in the pulmonary vasculature, propofol may act as a pulmonary vasoconstrictor.⁹¹ Propofol has also been shown to interfere with acetylcholine-induced pulmonary vasodilation in dogs.⁹² On the other hand, in isolated pulmonary arteries from human and chronically hypoxic rats, etomidate and to a lesser extent propofol showed vessel relaxation.⁹³ The clinical significance of these contradictory results is unknown.

Etomidate

Etomidate is an imidazole that mediates its clinical actions primarily at γ -aminobutyric acid A receptors. As mentioned earlier, it appears to have vasorelaxant properties in isolated pulmonary arteries. Its major attribute as an induction agent is its stable hemodynamic profile. In patients with cardiac disease, an induction dose of etomidate increased mean arterial pressure (MAP), decreased SVR, and decreased PAP.⁹⁴ In pediatric patients without PHTN presenting for cardiac catheterization, there was no significant change in any hemodynamic parameters after induction with etomidate.⁹⁵

Opioids

Opioids seem to have little to no deleterious effects on the pulmonary vascular system. In anesthetized cats, administration of morphine, fentanyl, remifentanil, and sufentanil caused a vasodilatory response under elevated tone conditions in isolated lobar artery.⁹⁶ The mechanism seems to involve histamine- and opioid-mediated receptor pathways. Clinical experience would echo the cardiostability of judicious narcotic administration in hemodynamically fragile patients.

Volatile Anesthetics

At clinically relevant concentrations, modern volatile anesthetics likely have little to no direct vasodilating effect on the pulmonary vasculature. In pigs, sevoflurane administration depressed right ventricular function with no change in PVR.⁹⁷ This suggests that the decreases in PAP observed with volatile anesthetics may partially occur secondary to the decreases in CO seen with these agents. Nitrous oxide is typically avoided in patients with PHTN as it is believed to cause pulmonary vasoconstriction, perhaps via release of catecholamines from sympathetic nerves supplying the pulmonary vasculature. In patients with mitral stenosis and PHTN presenting for cardiac surgery, administration of nitrous oxide after fentanyl anesthesia (7.5-10 μ g/kg) increased PVR, PAP, and cardiac index.⁹⁸ However, a subsequent study showed that in the presence of high-dose fentanyl (50-75 μ g/kg), 70% nitrous oxide is actually associated with a decrease in PAP and CO in patients with secondary PHTN, with no echocardiographic changes in right ventricular function.⁹⁹

Neuromuscular Blockers

Pancuronium increases PAP in dogs with lung injury.¹⁰⁰ It is theorized to do so indirectly by increases in CO and directly by increasing PVR, possibly by its antagonist actions at muscarinic receptors in the pulmonary vasculature. Rocuronium, cisatracurium, and vecuronium have little to no effect on most cardiac indices in patients undergoing coronary artery bypass graft.¹⁰¹

Magnesium

Magnesium is a vasodilator in both the systemic and pulmonary circulations. The mechanism of action of magnesium's effects on vasodilation is likely through its effects on membrane channels involved in calcium flux and through its action in the synthesis of cAMP. It would appear to be an important cofactor for endothelial-dependent pulmonary vasodilation. It has been used successfully to wean NO in PHTN.¹⁰² Increasing doses of magnesium in piglets with acute embolic PHTN decreased mPAP, increased CO, and decreased PVR.¹⁰³ Magnesium has been used to treat persistent PHTN of the newborn, but controversy surrounds its use.

Regional Analgesia

Pain can increase PVR.¹⁰⁴ Perioperative thoracic epidural analgesia (TEA) is commonly used in abdominal and thoracic surgery. The TEA may decrease PAP through decreases in CO or via attenuation of the pulmonary sympathetic outflow. In pigs, TEA depresses right ventricular function in acute PHTN.¹⁰⁵ Unilateral thoracic paravertebral block with lidocaine has been shown to decrease myocardial contractility up to 30% and significantly decrease systemic pressure; an effect that may be attenuated by epinephrine. In general, the potential benefits of regional anesthesia in thoracoabdominal surgery typically outweigh the risks of hypotension and right ventricular dysfunction. As with most anesthetic interventions in patients with PHTN, careful titration and monitoring is paramount. A few reports illustrate successful use of epidural analgesia in this patient population.¹⁰⁶

Vasopressors and Inotropes

Vasopressors and inotropes are commonly required during anesthesia to counteract the effects of cardiodepressant and vasodilating drugs. Treatment of hypotension in these patients can be difficult to manage given the typical cautious fluid administration most patient populations.

The innervation and receptor content of the pulmonary vasculature is complex. Neurotransmitter receptors in this system include those from the adrenergic, cholinergic, and dopaminergic families as well as histamine, serotonin, adenosine, purines, and peptides. The pulmonary vasculature's response to sympathetic activation will generally result in an increase in PVR. In human pulmonary artery, administration of acetylcholine induces pulmonary relaxation.¹⁰⁷

The response of the pulmonary system to exogenous vasopressor administration is dependent on the clinical situation. Consequently, results of studies are heterogeneous. In anesthetized dogs without PHTN, dopamine, epinephrine, norepinephrine, and phenylephrine all increase PAP to varying degrees by varying mechanisms but with no drug is there a significant increase in PVR.¹⁰⁸ Dopamine does not increase PVR after lung transplantation in pigs.¹⁰⁹ In anesthetized patients with chronic secondary PHTN undergoing cardiac surgery, both norepinephrine and phenylephrine increase PAP and pulmonary vascular resistance index (PVRI) with minimal change in cardiac index.¹¹⁰ Within the clinically relevant MAP target in this study, norepinephrine decreased the mPAP-to-MAP ratio, but phenylephrine did not, suggesting it may be a better choice in this patient cohort. In a dog model of acute PHTN, however, phenylephrine restored perfusion to the ischemic right ventricle and therefore increased CO.¹¹¹ This is a relevant observation, as it illustrates the importance of coronary artery perfusion in the setting of right ventricular strain and that maintenance of systemic pressure by whatever method may be the most important principle in this subset of patients.

Vasopressin has also been studied. In a chronic hypoxic rat model, vasopressin administration resulted in a V1 receptor-mediated pulmonary vasodilation.¹¹² In an acute PHTN model in dogs, vasopressin increased PVR and resulted in a substantial decrease in right ventricular contractility.¹¹³ Human studies of effects of vasopressin on the pulmonary vasculature are limited. Vasopressin has been used successfully after cardiac surgery in patients with PHTN and resistant hypotension.¹¹⁴ The use of vasopressin to treat acute right ventricular failure in patients with IPPH has been described in obstetric anesthesia.¹¹⁵

Pulmonary Vasodilators

Pulmonary vasodilators are typically employed to improve right ventricular function in the setting of PHTN or in an effort to enhance regional pulmonary blood flow and improve intrapulmonary shunt. In the acute care setting, however, it is these agents' pulmonary vasodilatory effects that are being exploited. In general, parenteral and oral vasodilators are hampered by their relatively nonselective actions in the pulmonary vascular bed. In addition to their hypotensive systemic hemodynamic effects, their use may also lead to perfusion of underventilated alveoli, worsen intrapulmonary shunt, and, in turn, worsen oxygenation. The ideal pulmonary vasodilator should have a rapid onset of action and a short half-life and produce regional pulmonary vasodilation. This would avoid systemic hypotension and the potential adverse effects on ventilation-perfusion matching that limit the use of systemic agents in critically ill patients. In this regard, inhaled vasodilators are attractive as they preferentially dilate ventilated alveoli and have less systemic effects.

Nitric Oxide

Inhaled nitric oxide (iNO) is preferentially delivered to ventilated lung units leading to improved perfusion to alveoli that are able to participate in gas exchange. This "selective effect" leads to a decrease in intrapulmonary shunt. Medical grade NO may be administered either noninvasively (via a facemask) or through a ventilator circuit. If administered through a circuit, a device is used that can regulate the concentration of NO and monitor levels of nitrogen dioxide—a by-product of NO when it combines with oxygen ([Figure 25.2](#)). The iNO is approved for infants with respiratory distress syndrome. This approval stems from large prospective placebo-controlled studies demonstrating that NO reduced the need for extracorporeal membrane oxygenation and reduced the requirement for oxygen therapy following intensive care unit discharge.^{[116](#)} Although there is controversy about a dose-response relationship for NO and pulmonary vasodilation, the typical dose ranges from 10 to 40 ppm. Methemoglobin levels need to be monitored when NO is administered for more than 24 hours. Heart and lung transplantation represent two distinct areas where acute pulmonary vasodilation has strong theoretic benefit as it relates to improving acute right ventricular failure and attenuating reperfusion injury, respectively. The acute right ventricular failure complicating heart transplantation may be attenuated with the use of an inhaled pulmonary vasodilator. Although several studies suggest that NO may be useful preoperatively in risk-stratifying patients scheduled for cardiac transplant, only case series support the use of iNO to reverse the right ventricular dysfunction following cardiac transplant. However, based on clinical experience, iNO has become a standard of care in many transplant centers. The beneficial immune-modulating effects of iNO in addition to its vasodilating properties were felt to be responsible for preliminary studies of using iNO to prevent primary graft dysfunction (PGD) after lung transplantation.^{[117](#)} Although a randomized clinical trial failed to show benefit in preventing PGD, it is commonly used to treat the hypoxemia and PHTN seen in established, severe PGD.^{[118](#)} Owing to the inherent cost of using iNO, other pulmonary vasodilators have been evaluated.

FIGURE 25.2 A commercial device for administration of nitric oxide (NO) via a ventilator circuit. The NO is administered into the inspiratory limb of the anesthesia circuit close to the connection to the endotracheal tube. The concentration of the toxic metabolite nitrogen dioxide is monitored in the circuit via an attachment to the expiratory limb (circled in the photograph).

In nontransplant thoracic surgery, NO has been studied as a potential treatment for the gas exchange abnormalities associated with OLV. Its effects are controversial, but it would appear that it exerts its maximal benefits in patients with elevated PVRI and the poorest gas exchange before administration.¹¹⁹ NO can be quickly delivered via the circuit of anesthetic or intensive care ventilator; however, it is expensive and not widely available.

Prostaglandins

Prostanoids induce relaxation of vascular smooth muscle, inhibit growth of smooth muscle cells, and are powerful inhibitors of platelet aggregation.¹²⁰ Inhaled prostanoids involve an aerosol delivery mechanism that is attached by a nebulizer to the ventilator circuit ([Figure 25.3](#)). Treatment may be limited by inefficiencies in aerosolization. Owing to the short half-life of epoprostenol, the drug must also be continuously nebulized.¹²¹ As a result, changes of dose delivery with alterations in ventilator volumes, $\text{F}\text{I}\text{O}_2$, airway pressures, and solvent evaporation may be challenging. The synthetic prostanoids, treprostinil and iloprost, hold promise as inhaled vasodilators in that they may only require intermittent administration. When nebulized, prostanoids can lead to similar improvements in oxygenation and pulmonary pressures as compared to iNO. A crossover study compared iNO to inhaled prostaglandins in patients after lung ($n = 19$) or heart ($n = 6$) transplant. In this acute hemodynamic study, there was no significant difference in hemodynamics or oxygenation between agents.¹²² Prostacyclin can be delivered by nebulizer into a ventilator circuit at a starting dose of 50 ng/kg per minute and clinical effects should be evident within 10 minutes (see [Figure 25.3](#)).¹²³

FIGURE 25.3 Prostacyclin can be delivered via continuous nebulization into an intensive care (pictured here) or an anesthesia ventilator circuit for specific pulmonary vasodilation.

Use of IV prostaglandins during OLV results in a decrease in both systemic and pulmonary pressures and either no change or a decrease in PaO_2 . Selective infusion of prostaglandin into the pulmonary artery of the ventilated lung in a human model during OLV resulted in stable systemic pressure and a reduction in PVR and increase in PaO_2 .¹²⁴ However, this route of administration is not practical in routine thoracic anesthesia practice. Inhaled prostacyclin decreases PVRI and PAP with maintenance of favorable systemic pressures but does not change PaO_2 during OLV.¹²⁵

Both iNO and prostaglandins have been shown to affect platelet function. This could theoretically contribute to perioperative bleeding during large surgeries such as lung transplantation and is a concern in regard to neuraxial analgesia. The clinical relevance of platelet inhibition with these inhaled agents is unknown. In cardiac surgery patients, laboratory confirmation of platelet dysfunction with inhaled prostacyclin did not correlate with chest tube losses.¹²⁶ Also, in an obstetrical patient with PHTN on IV prostacyclin, conversion to inhaled prostacyclin allowed for a successful labor epidural placement with no complications.¹²⁷

Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors prevent the degradation of cGMP and cAMP. The cAMP and cGMP are activated by NO and are intermediaries in a pathway that leads to vasodilation via the activation of protein kinases and reduction in cytosolic calcium. Milrinone is an adenosine-3',5'-cAMP-selective phosphodiesterase enzyme inhibitor. When nebulized, it has been shown to lead to a relative reduction in PVR compared to SVR.¹²⁸ The inhalation of milrinone selectively dilated the pulmonary vasculature without systemic effects. When milrinone is combined with inhaled prostacyclin, there appears to be a potentiation and prolongation of the pulmonary vasodilatory effect.¹²⁹

Owing to the relatively higher expression of phosphodiesterase 5 in the pulmonary circulation relative to the systemic circulation, phosphodiesterase 5 inhibitors have a relative selective effect on PVR as opposed to SVR. In addition to their relatively selective pulmonary vasodilatory effects, their effects on smooth muscle proliferation and cellular apoptosis may be responsible for benefit of these agents when administered chronically in patients with idiopathic pulmonary arterial hypertension. A direct effect on the right ventricle has been postulated; however, the clinical relevance of this finding is uncertain.

Although the benefits of oral sildenafil and tadalafil in chronic pulmonary arterial hypertension have been evaluated in prospective controlled trials, most of the acute applications for these agents have been described in case reports or small cohort studies and as such have not been approved for these indications. In the acute setting, sildenafil has been demonstrated to enhance the effects of iNO and may also be useful in blunting the rebound in pulmonary pressures that occurs during weaning of iNO.¹³⁰ The benefits of sildenafil in acute pulmonary embolism, cardiac transplantation, and in patients with PHTN being considered for pulmonary thromboendarterectomy have also been described.¹³¹

Hypoxic Pulmonary Vasoconstriction

The IV anesthetic agents have no effect on hypoxic pulmonary vasoconstriction (HPV). All of the volatile anesthetics inhibit HPV in a dose-dependent fashion. Animal studies suggest that this inhibition is dependent on the agent: halothane > enflurane > isoflurane/desflurane/sevoflurane.¹³² The older agents were potent inhibitors of HPV, and this may have contributed to the high incidence of hypoxemia reported during OLV in the 1960s and 1970s (see earlier); many of these studies used 2 to 3 minimum alveolar concentration (MAC) doses of halothane during anesthesia.

In doses of less than or equal to 1 MAC, the modern volatile anesthetics (isoflurane, sevoflurane,¹³³ and desflurane¹³⁴) are weak, and equipotent, inhibitors of HPV. The inhibition of the HPV response by 1 MAC of a volatile agent such as isoflurane is approximately 20% of the total HPV response, and this could account for only a net 4% increase in total arteriovenous shunt during OLV, which is a difference too small to be detected in most clinical studies.¹³⁵ In addition, volatile anesthetics cause less inhibition of HPV when delivered to the active site of vasoconstriction via the pulmonary arterial blood than via the alveolus. This pattern is similar to the HPV stimulus characteristics of oxygen. During established OLV, the volatile agent only reaches the hypoxic lung pulmonary capillaries via the mixed venous blood. No clinical benefit in oxygenation during OLV has been shown for total IV anesthesia above that seen with 1 MAC of the modern volatile anesthetics.¹³⁶ Nitrous oxide inhibits HPV. Nitrous oxide is usually avoided during thoracic anesthesia.

The HPV is decreased by systemic vasodilators such as nitroglycerin and nitroprusside. In general, vasodilators can be expected to cause some deterioration in PaO_2 during anesthesia. Thoracic epidural sympathetic blockade probably has little or no direct effect on HPV, which is a localized chemical response in the lung.¹³⁷ However, thoracic epidural anesthesia can have an indirect effect on oxygenation if it is allowed to cause hypotension and a fall in CO, thus decreasing mixed venous oxygen saturation.

Intrinsic Pharmacologic Effects of the Lungs

The lungs receive essentially the entire CO and the surface area of their vascular bed is enormous (70-100 m^2). The lungs contain nearly half of the body's endothelium and have an extraordinarily high perfusion of 14 mL/min/g tissue (as opposed to the next highest renal perfusion of 4 mL/min/g tissue). Thus, there is ample blood-endothelial interface for surface enzyme activity as well as uptake and secretion.¹³⁸ The largest population of cells involved in pulmonary metabolism of blood-borne substances is, as might be expected, the pulmonary endothelium. Consistent with high metabolic activity, endothelial cells typically have both extensive cytoplasmic vesicles and prominent caveolae. The caveolae are tiny membrane invaginations and near-membrane vesicles similar to those found elsewhere in the body, measuring 50 to 100 nm, associated with caveolin proteins, and derived from lipid rafts within the membrane. The predominant activities of these caveolae, thought to include endocytosis and signal transduction, have not been fully delineated and may be pleiotropic.¹³⁹ The endothelial cells structurally have large luminal projections and invaginations, providing an even greater interface area at the microscopic level.

Metabolism by the endothelial cell occurs either on the surface of the cell via enzymes associated with the membrane ("ectoenzymes") or by cytosolic processing after substances are taken up by the cell. Some surface enzymes are distributed along the luminal membrane, whereas others are associated exclusively with the caveolae. **Figure 25.4** schematically depicts these processes with example substances and pathways. Metabolism may be further divided into exogenous versus endogenous substances as well as deactivated versus activated products. The terminology of pulmonary metabolism can be confusing and sometimes

inconsistent. In general, “pulmonary uptake” (or “extraction”) is simply used to describe transfer from blood to lung. It does not indicate whether the substance of interest is subsequently metabolized or returned back into the blood (with or without alteration). “First-pass” uptake is used to describe the amount of substance removed from the blood on the first cycle through the lungs. “Extraction” is also sometimes misused synonymously with first-pass uptake. “Clearance” may be used to describe a substance undergoing actual elimination, either in terms similar to renal clearance as volume of blood from which the substance would be completely removed (milliliters per minute or milliliters per kilogram per minute), or as a comparison of pulmonary arterial concentration versus systemic arterial concentration.

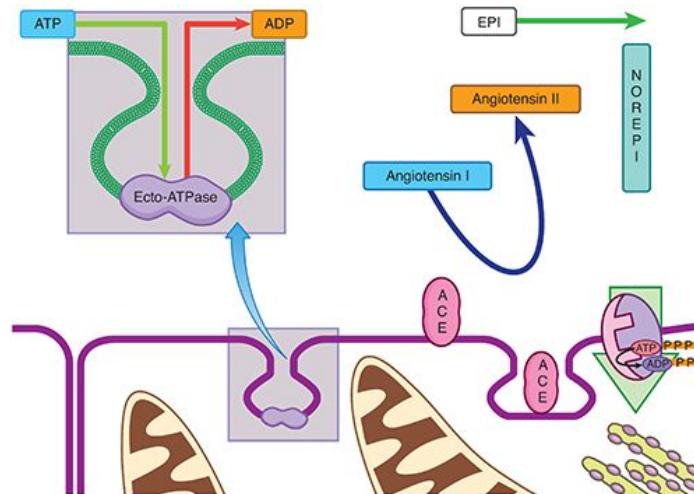

FIGURE 25.4 Schematic examples of pulmonary endothelial metabolism. Surface enzymes may be restricted to the caveolae (ecto-adenosine triphosphatase [ecto-ATPase] in the inset earlier is an example) or present on both the luminal surface and caveola (eg, angiotensin-converting enzyme [ACE]). Another characteristic of pulmonary endothelium is selective uptake, here exemplified by the adenosine triphosphate (ATP)-dependent uptake of norepinephrine (NOREPI), while epinephrine (EPI) is not taken up. Abbreviation: ADP, adenosine diphosphate. Reprinted by permission from Springer: Kleiman AM, Littlewood KE. *Nonrespiratory functions of the lungs*. The lung has a pronounced impact on the blood concentration of substances even when it does not ultimately break them down or secrete them. This is because of simple uptake and retention of substances, often followed by release back into the blood. This “capacitor effect”¹⁴⁰ of the lungs in which any rapid rise or fall in concentration is attenuated is revisited in the following discussion regarding local anesthetic toxicity.

Exogenous Substances

Drugs

The cytochrome P450 monooxygenase enzyme systems are the most studied metabolic pathways for medications. The lungs have been found to have substantial concentrations of P450 isoenzymes, particularly within type II pneumocytes, Clara cells, and endothelial cells. Although P450 and other enzyme systems have long been known to exist in the human lung, the actual activity of lung enzymes ranges from negligible to 33% of that of the liver.¹⁴¹

Opioids

Fentanyl has been shown to have a markedly variable first-pass uptake up to 90% in humans. The same investigators found that significant amounts of fentanyl then returned from the lungs into the blood with a biphasic pattern, equilibrating after about a minute in the fast phase and nearly 25 minutes for the slow phase.

The uptake of fentanyl is higher than expected even for this basic and lipophilic drug. Active uptake of fentanyl has been demonstrated in human lung endothelial cells. Sufentanil demonstrates uptake that is a little more than half that of fentanyl. Morphine has a much lower uptake of about 10%.^{[142](#)}

Local Anesthetics

For lidocaine, there is a first-pass uptake of approximately 50% with significant retention at 10 minutes.^{[143](#)} The uptake of lidocaine has also been examined in a variety of physiologic circumstances. Under extremes of metabolic acidosis and alkalosis, lidocaine demonstrates increased uptake with higher blood pH. It is postulated that this finding is the consequence of increased drug lipophilicity because, in a less acidic environment, more of the drug is in its nonionized form. Bupivacaine has been investigated less extensively than lidocaine and with less consistent results. In most animal species, peak extraction has been reported as high with variable first-pass retention. In humans, however, the effective first-pass extraction appears to be lower when studied by epidural dosing.^{[144](#)}

Two areas of interest in the practice of clinical anesthesia are intimately linked with the pulmonary uptake of local anesthetics. The first is the relative safety of levobupivacaine and ropivacaine in comparison to bupivacaine. These drugs have, in fact, been the subject of several investigations. Early animal studies suggested decreased toxicity of these newer preparations. However, a review of the pharmacodynamics and pharmacokinetics of local anesthetics^{[145](#)} describes the challenges of comparing toxicities in clinical practice. A second area of interest is the treatment of local anesthetic toxicity with lipid emulsion. The issue of pulmonary uptake and delayed release of local anesthetics must be considered in the treatment of suspected local anesthetic toxicity with emulsified lipid.^{[146](#)}

Hypnotics

Thiopental has been found to have nearly 15% first-pass uptake in humans^{[147](#)} with little or no metabolism. The pulmonary uptake of ketamine was found to be slightly less than 10% without subsequent metabolism.^{[148](#)} For propofol, most work shows about 30% first-pass uptake and negligible metabolism of propofol by the lungs.^{[149](#)}

Endogenous Substances

Angiotensin-Converting Enzyme

The lung plays a critical role in the renin-angiotensin system because of the pulmonary endothelium's high concentration of angiotensin-converting enzyme (ACE). When the kidney responds to changes in physiologic parameters such as vascular volume, blood pressure, and adrenergic stimulation by the cleaving of prerenin, the resultant renin catalyzes the formation of angiotensin I from angiotensinogen. It is ACE that then converts angiotensin I to the critically important vasoconstrictor, angiotensin II. Although ACE can be found on vascular endothelium throughout the body as well as in the plasma, the pulmonary endothelium has an abundance of ACE as a surface or an ectoenzyme on the vascular membrane (**Figure 25.5**).^{[150](#)} The newly formed angiotensin II is not taken up or further metabolized by the endothelial cell but rather immediately returns to the blood. Clinically, ACE inhibitors have been useful drugs in the management of systemic hypertension.^{[151](#)}

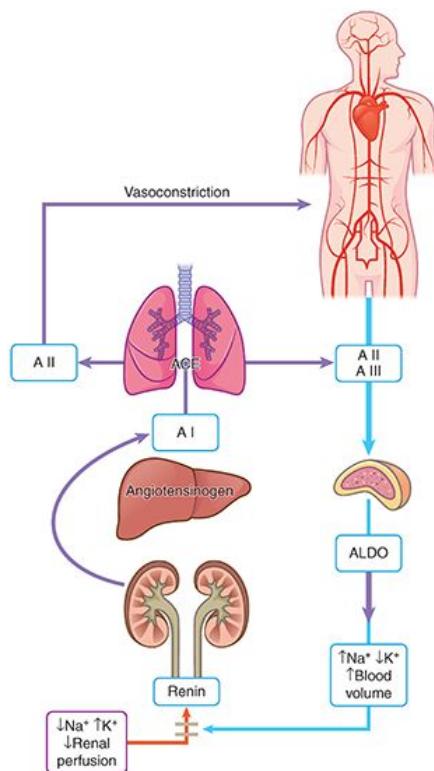

FIGURE 25.5 An example of the lung's central role in the body's endocrine processes, in this case the renin-angiotensin-aldosterone axis. In response to sodium (Na), potassium (K), and renal perfusion changes, renin is secreted by the kidneys. Renin cleaves angiotensinogen (renin substrate) from the liver to form angiotensin I (A I). The lung then converts A I to A II through the action predominately of endothelium-associated angiotensin-converting enzyme (ACE). The A II causes vasoconstriction and is involved in stimulation of aldosterone (ALDO) secretion by the adrenal gland, resulting in retention of Na and volume by the kidney. *Reprinted by permission from Springer: Kleiman AM, Littlewood KE. Bradykinin is a nine-amino acid peptide produced in multiple sites throughout the body from kininogen through the action of plasma kallikrein. It is in turn metabolized by several peptidases. Bradykinin is degraded by ACE and more than 90% of bradykinin is eliminated on first pass through the lungs.¹⁵² Bradykinin's effects are wide ranging, including antithrombotic and profibrinolytic activity in the coagulation system, as well as modulation of NO and prostacyclin release. Specific to the lung, bradykinin has vasodilating effects on normal pulmonary vessels but is vasoconstrictive when the pulmonary endothelium is destroyed in animal models.¹⁵³ Bradykinin is a bronchoconstrictor.¹⁵⁴ Some side effects of ACE inhibitors, such as angioedema and cough, and some of the beneficial impact, such as decreased myocardial infarctions and improved renal function, involve modification of bradykinin metabolism.

Biogenic Amines

Histamine; serotonin (5-hydroxytryptamine or 5-HT); and the three naturally occurring catecholamines, dopamine, norepinephrine, and epinephrine, comprise the group commonly termed *biogenic amines*. 5-HT is produced predominately by the gastrointestinal tract's chromaffin cells. Ingested tryptophan undergoes a two-step conversion first by tryptophan-5-hydroxylase and then by L-amino acid decarboxylase to serotonin. Mast cells and neuroendocrine cells in the lung are also capable of producing serotonin by uptake of tryptophan along the same enzymatic pathway. Once released from the gastrointestinal tract, there is avid uptake of 5-HT, particularly by nerve endings and platelets. These cells do not metabolize 5-HT to any great extent. The

remainder of 5-HT is extracted by the lung and, to a lesser degree, the liver. In the case of these organs, the 5-HT is metabolized to 5-hydroxyindoleacetic acid by cytosolic monoamine oxidase (MAO) and aldehyde dehydrogenase. 5-Hydroxyindoleacetic acid is a useful marker of carcinoid syndrome with increased histamine turnover. The MAO inhibitors block the cytosolic metabolism of 5-HT but not its uptake, whereas several drugs, including volatile anesthetic agents, block uptake but not intracellular metabolism.¹⁵⁵

Because it is not lipophilic, the pulmonary uptake of 5-HT is an active process, predominately via endothelial cells and with some variability between species. The pulmonary uptake of 5-HT by the lung is typically reported to be 90% or greater, meaning that little 5-HT reaches the systemic vasculature under normal circumstances. This model of production and uptake of 5-HT plays a pivotal role in several pathologic processes relevant to clinical anesthesiology. In carcinoid syndrome, the right heart receives a high concentration of 5-HT before being extracted and metabolized by the pulmonary circulation. This is thought to be the reason that the right heart shows the greatest myocardial and valvular injury in this syndrome.¹⁵⁶ The valvular injury of substances related to 5-HT such as methysergide and ergotamine, and those that increase 5-HT such as fenfluramine, and the recreational drug “ecstasy” (3,4-methylenedioxymethamphetamine), known to activate 5-HT receptors, are all similar to carcinoid cardiac disease. When an intracardiac right-to-left shunt is present in the carcinoid patient with a partial bypass of the pulmonary circulation, the left heart demonstrates valvular injury similar to that of the right heart.¹⁵⁷

Pulmonary embolism presents another clinical situation pertinent to 5-HT activity. The mass effect of embolism does not, in itself, account for the typical cardiopulmonary consequences. The platelet aggregation and activation associated with acute pulmonary embolism results in degranulation with the release of 5-HT, well known to be a potent vasoconstrictor and to increase bronchial smooth muscle tone. This release of 5-HT and, perhaps, decreased local uptake of 5-HT are postulated to cause local and regional vascular changes. Other actions of elevated 5-HT, such as promotion of further platelet aggregation and inhibition of the vasodilating prostacyclin likely also play a role in the full response to pulmonary embolism.¹⁵⁸ Histamine, in contrast to 5-HT, has almost no uptake in the pulmonary circulation.

Just as the lung has the enzymes to metabolize both histamine and serotonin but the ability to take up only serotonin, its uptake of catecholamines also demonstrates marked selectivity. Norepinephrine demonstrates a 35% to 50% first-pass uptake with subsequent metabolism by catechol-O-methyltransferase, MAO, aldehyde reductase, and aldehyde dehydrogenase.¹⁵⁹ However, dopamine, isoproterenol, and epinephrine have essentially no uptake.

Arachidonic Acid Metabolites

Extensive production and metabolism of arachidonic acid derivatives occurs in the lung. The term *eicosanoids* refers to the 20-carbon carboxylic acids derived from the metabolism of the lipid membrane component icosatetraenoic acid, more commonly known as arachidonic acid. The action of phospholipase A₂ converts the esterified form, as found in the membrane, and releases arachidonic acid from structural glycerol. Once free, arachidonic acid may follow three main metabolic pathways in the lung: the lipoxygenase pathway produces leukotrienes, lipoxins, and some of the hydroxyeicosatetraenoic acids (HETEs); the cyclooxygenase (COX) pathway produces prostaglandins, thromboxane, and prostacyclin; and the cytochrome P450 monooxygenase system produces cis-epoxyeicosatrienoic acids and HETEs that are different than the products of the lipoxygenase pathway.

The leukotrienes promote inflammatory responses in the lung. They are responsible for bronchoconstriction and increased pulmonary vascular permeability, are chemotactic and chemokinetic for neutrophils, and facilitate eosinophil degranulation.¹⁶⁰ They are produced by activated inflammatory cells within the lung as well as those arriving in response to inflammation. The lipoxins have become identified as critical factors in the resolution of inflammation throughout the body.¹⁶¹ They inhibit eosinophil and neutrophil chemotaxis and adhesion as well as natural killer cell activation. They are endothelium-dependent vasodilators of both pulmonary and systemic vasculature.

The COX catalyzes the cyclization and oxygenation of arachidonic acid, producing prostaglandin G2, which is converted to prostaglandin H2. There are subtypes of the COX enzyme, most notably COX-1 and

COX-2. There has been great interest in COX-2 since its discovery in the 1990s because its inhibition was hoped to be more specific in controlling pain and inflammation without injury to the gastroduodenal mucosa. Although effective, the emergence of a small but real increase in cardiovascular risk of COX-2 inhibitors has tempered their use.¹⁶² Complicating this issue further, many of the nonspecific COX inhibitors such as acetaminophen, salicylates, and the nonsteroidal antiinflammatory agents ibuprofen and naproxen show only slightly less COX-2 avidity than some of the newer COX-2-specific inhibitors. Following the production of prostaglandin H₂, the metabolic pathway divides into branches producing the various bioactive prostanoids; the enzymes of particular interest here are prostaglandin D synthase, prostaglandin E synthase, prostacyclin synthase, and thromboxane synthase. The final products of these pathways typically have opposed or balancing effects locally and regionally. Prostaglandin E₂ and prostacyclin are bronchodilators, for example, whereas prostaglandin F_{2α} (PGF_{2α}), prostaglandin D₂, and thromboxane A₂ cause bronchoconstriction. Similarly, prostaglandin D₂, prostaglandin E₂, PGF_{2α}, and thromboxane A₂ are potent vasoconstrictors, whereas prostaglandin E₁ and PGF₂ are vasodilators.

The cytochrome P450 monooxygenase system provides three pathways of arachidonic acid metabolism, which result in epoxyeicosatetraenoic acids (EETs), HETEs, or dihydroxyeicosatetraenoic acids. The HETEs and EETs have been shown experimentally to affect pulmonary vascular and bronchomotor tone. The 20-HETE and 5-, 6-, 11-, and 12-EETs all have relaxing effects on both the lung vasculature and airways. They are further known to have general antiinflammatory effects, to modulate reperfusion injury, and to inhibit platelet aggregation. Within the lung, 15-HETE and 20-HETE may both modify hypoxic vasoconstriction.¹⁶³

Acid–Base Disorders

Peter Slinger

The management of acid–base disorders requires establishing the cause(s) of the disorder and then treating the underlying physiologic derangement. The treatment of acid–base disturbances is complex for a variety of reasons including the fact that the laboratory information on which we make decisions is rarely complete. This is because we often do not have access to all the data, which influence a patient’s acid–base status (eg, serum phosphate, sulfate). The acid–base disturbance is often evolving rapidly (eg, ischemia, shock), and there may be a delay getting laboratory results. The algorithms that have been designed to help us understand acid–base therapy are based on steady-state conditions and the terminology that we use to describe acid–base chemistry is not intuitive ([Table 26.1](#)). However, using only blood gas and common serum biochemistry data, we can manage the majority of clinical acid–base disorders.

The central focus of treating acid–base disturbances is understanding the biochemistry of the hydrogen ion. Hydrogen ion concentrations in the various body fluid compartments are precisely regulated in the face of enormous variations in local production and clearance. Deviations in hydrogen ion concentrations from the normal range can cause marked alterations in protein structure and function, enzyme activity, and cellular function. Although hydrogen ions are continuously produced in the hydrolysis of adenosine triphosphate, the largest contribution of metabolic acids arises from the oxidation of carbohydrates, principally glucose, to produce carbon dioxide (volatile acid, approximately 24,000 mEq per day). By comparison, the average net production of nonvolatile metabolic acid, such as lactate, is relatively small (approximately 60 mEq per day).

The hydrogen ion concentration is regulated to maintain the arterial blood pH between 7.35 and 7.45. However, expression of the hydrogen ion concentration as pH masks large variations in hydrogen ion concentration despite small changes in pH. For example, a pH range of 7.0 to 7.7 is associated with a fivefold change (100–20 nmol/L) in hydrogen ion concentration. The pH of venous blood and interstitial fluid is lower than that of arterial blood (approximately 7.35).

TABLE 26.1

Basic definitions

p: a mathematical notation for a concentration expressed as the –log to the base 10; useful to describe substances present in the plasma in very low concentrations

pH: the concentration of free hydrogen ions (H^+) in a solution. The pH of water is 7.0 at 25°C and 6.8 at 37°C. The normal pH of most body fluids is 7.4 (range, 7.35–7.45). This means that there are 40 nmol/L of H^+ in plasma (for comparison, there are 140 million nmol/L of Na^+ [140 mmol/L] in plasma).

pH_i: intracellular pH

Acid: a substance that increases the hydrogen ion concentration of a fluid (proton donor)

Alkali (or base): a substance that decreases the hydrogen ion concentration of a fluid (proton acceptor)

Buffer: a substance that reduces the change of pH in a solution when amounts of acid or base are added

K_a: the dissociation constant for a dissolved acid (HA), that is, the equilibrium ratio: $[H^+] [A^-] / [HA]$

pK_a: the –log of K_a for a given acid, for example, for carbonic acid (H_2CO_3), pK_a = 6.2. By convention, “strong” acids (eg, HCl) have a pK_a < –2 (more free H^+ at equilibrium) and “weak” acids (eg, H_2CO_3) have a pK_a –2 to +12 (this is confusing, but due to the negative logarithmic notation, a smaller number indicates a higher concentration of free H^+).

Anions: a negative ionized particle (eg, HCO_3^- , Cl^-), that is, an excess of electrons vs protons

Cations: a positively charged particle (eg, Na^+ , K^+), that is, an excess of protons vs electrons

Strong ions: the ions of substances that are completely dissociated in body fluids (eg, Na^+ , Cl^- , K^+ , SO_4^{2-} , Mg^{2+} , Ca^{2+})

Mole (mol): a fixed number [6.022×10^{23} (Avogadro number)] of elementary entities (atoms, molecules, ions, electrons, etc)

Molecular weight (MW) (actually, the “molecular mass”): the mass of 1 mole of a specific entity

Equivalent (Eq): the amount of a substance that will supply or react with 1 mole of H^+ ions (in acid–base reactions) or supply 1 mole of electrons (in oxidation–reduction reactions) mmol = mol/1,000, mEq = Eq/1,000. For singly charged particles (eg, Na^+), 1 mmol/L = 1 mEq/L; for doubly charged particles (eg, Mg^{2+}), 1 mmol/L = 2 mEq/L

Mole day: an informal annual holiday based on Avogadro number on October 23 (10/23) from 6:02 AM to 6:02 PM

Mechanisms for Regulation of Hydrogen Ion Concentration

Regulation of pH over a narrow range depends on (1) buffer systems, (2) ventilatory responses, and (3) renal responses. The buffer system mechanism is local and immediate but incomplete. Ventilatory responses are slower (minutes) and usually incomplete. Renal responses develop very slowly (hours) but can produce nearly complete pH correction.

Buffer Systems

Body fluids contain acid–base buffer systems that immediately combine with acid or alkali to prevent excessive changes in the hydrogen ion concentration. This ability to neutralize excess protons maintains the local pH near 7.4 in the face of continuous acid generation. The most important buffer systems are (1) bicarbonate and carbonic acid in plasma, interstitial and intracellular fluid, and bone; (2) hemoglobin and other proteins in intracellular fluid; (3) plasma proteins; and (4) phosphates in intracellular and extracellular fluid and the kidney ([Figure 26.1](#)).

FIGURE 26.1 Buffering systems present in the body. Abbreviations: Hb, hemoglobin; Prot, protein.

Bicarbonate Buffering System

The bicarbonate buffering system consists of carbonic acid and sodium bicarbonate. Bicarbonate buffer is primarily a product of the approximately 200 mL of carbon dioxide produced per minute, of which considerably less than 1% dissolves to become carbonic acid. Carbonic acid is a weak acid because of its limited degree of dissociation (<5% at physiologic pH) into hydrogen and bicarbonate ions ([Figure 26.2](#)). Most carbonic acid in solution almost immediately dissociates into carbon dioxide and water, the net result being a very high concentration of dissolved carbon dioxide compared to the concentration of bicarbonate ions. This relationship is described mathematically by the Henderson-Hasselbalch equation, which can be used to calculate the pH of a solution if the concentration of bicarbonate ions and dissolved carbon dioxide is known ([Figure 26.3](#)).

FIGURE 26.2 Hydration of carbon dioxide results in carbonic acid (H_2CO_3), which can subsequently dissociate into bicarbonate and hydrogen ions.

$$\text{pH} = 6.10 + \log \frac{\text{HCO}_3^-}{\text{Paco}_2 (0.03)}$$

FIGURE 26.3 The Henderson-Hasselbalch equation can be used to calculate the pH of blood from the concentration of bicarbonate (HCO_3^-) and the Paco_2 .

The addition of a strong acid such as hydrochloric acid to the bicarbonate buffering system results in conversion of the strong acid to weak carbonic acid (Figure 26.4). Therefore, a strong acid lowers the pH of body fluids only slightly. The addition of a strong base, such as potassium hydroxide, to the bicarbonate buffering system results in the formation of a weak base and water. Buffers are most effective when they operate at a pH that is close to their pK_a (under these circumstances, the buffer system is approximately 50% dissociated). The bicarbonate buffering system is not a powerful buffer because its pK_a of 6.1 differs greatly from the normal pH of 7.4. Physiologically, buffers are most effective when their pK_a is equal to normal pH. However, the bicarbonate system is important because (1) bicarbonate is present in significant quantities in nearly all fluid compartments, (2) the concentration of its components is ultimately regulated by the lungs and kidneys, and (3) in severe acidosis the pH approaches the pK_a of the bicarbonate system thus increasing its efficiency.

FIGURE 26.4 The addition of a strong acid (hydrochloric acid [HCl]) to the bicarbonate buffering system results in the formation of weak carbonic acid (H_2CO_3).

The bicarbonate buffer system accounts for >50% of the total buffering capacity of blood. Approximately one-third of the bicarbonate buffering capacity of blood occurs within erythrocytes. The electrical charge of bicarbonate ions limits their diffusion into cells other than erythrocytes.

Hemoglobin Buffering System

Hemoglobin is a particularly effective buffer because it is localized in quantity in erythrocytes; it has a pK_a of 6.8 and has a buffering capacity that varies with oxygenation. The imidazole ring of the amino acid histidine has a pK_a that is close to the physiologic pH. Thus, hemoglobin and other histidine-containing proteins are excellent physiologic buffers. Furthermore, deoxygenated hemoglobin is a weaker acid (better proton acceptor) than oxyhemoglobin. Thus, in the systemic capillaries, dissociation of oxyhemoglobin to deoxyhemoglobin facilitates the binding of hydrogen ions produced by the dissociation of carbonic acid. This situation is reversed in the pulmonary circulation where the conversion of deoxyhemoglobin to oxyhemoglobin facilitates the release of hydrogen ions.

Protein Buffering System

Like hemoglobin, other histidine-containing proteins are important intracellular buffers. Proteins are localized in high concentrations within the cell where it is estimated that approximately 75% of all the buffering of body fluids occurs, mostly by proteins. Of particular importance is the local buffering of hydrogen ions by proteins in the mitochondria. Although the relatively low concentration of plasma proteins limits their role as extracellular buffers, hypoproteinemia will further reduce buffering capacity, especially in the critically ill patient.

Phosphate Buffering System

The phosphate buffering system is important in most fluid compartments but is especially important in renal tubules, where phosphate is concentrated. Renal tubular fluid is more acidic than extracellular fluid, bringing the pH of renal tubular fluid closer to the pK_a (6.8) of the phosphate buffering system. Phosphate is a very

important intracellular buffer because it is the most abundant intracellular anion. Furthermore, the relatively acidic pH of intracellular fluid is closer to the pK_a of the phosphate buffering system than is the pH of extracellular fluid.

Intracellular pH Regulation

Although blood pH is commonly measured clinically, it is the intracellular pH (pH_i) that is of functional importance. The routine measurement and manipulation of pH_i is not possible in current practice. Indeed, during hypothermic cardiopulmonary bypass and hibernation, the pH_i in heart and brain tissue appears to be highly regulated despite significant deviations in systemic pH. Cellular metabolism, transmembrane transport, membrane potential generation, cell growth and division, cytoskeletal structure, and contractile function are processes that are crucially dependent on pH_i (**Table 26.2**). Furthermore, the optimal function of several organelles, including lysosomes and mitochondria, require that their local pH is significantly different from the general pH_i . Thus, there are highly regulated mechanisms to maintain local pH_i , including intracellular buffer systems and membrane-bound proton transporters. Indeed, the pH_i (7.0) is higher than is predicted by the -90 mV transmembrane potential (pH 6.8). As in the extracellular compartment, intracellular protons are rapidly bound to weak acids and bases resulting in a low free proton concentration.

Cell volume regulation
Intracellular membrane flow

Ventilatory Responses

Ventilation is quantitatively the most important mechanism of acid removal, given the enormous daily production of volatile acid compared to nonvolatile acid. Ventilatory responses cannot return pH to 7.4 when a metabolic abnormality is responsible for the acid–base disturbance. This reflects the fact that the intensity of the stimulus responsible for increases or decreases in alveolar ventilation will begin to diminish as pH returns toward 7.4. As a “buffer,” ventilatory responses are able to buffer up to twice the amount of acids or bases as all the chemical buffers combined. However, compensation for extreme metabolic acidosis imposes a significant respiratory burden. If the bicarbonate is reduced to 10 mmol/L, the carbon dioxide tension must be reduced to 15 mm Hg in order to normalize the pH. Most patients cannot hyperventilate to below 20 mm Hg. Further, it is likely that the insult causing severe metabolic acidosis will also adversely affect respiratory muscle function, thus compromising the respiratory response.

Renal Responses

The day-to-day renal contribution to acid–base regulation is directed toward the conservation of bicarbonate and the excretion of hydrogen ions. Plasma bicarbonate is freely filtered at the glomerulus. Almost all filtered bicarbonate must be reabsorbed from the glomerular filtrate to maintain the normal plasma bicarbonate concentration (25 mEq/L) and plasma pH. Most bicarbonate reabsorption occurs in the proximal convoluted tubule and is facilitated by the presence of carbonic anhydrase in the luminal fluid and is driven by the sodium-potassium-ATPase pump in the peritubular cell membrane. Active sodium ion extrusion from the

renal tubular cell into the peritubular circulation favors sodium diffusion from the tubular lumen into the tubular cell in exchange for hydrogen ions. Hydrogen in the renal tubular fluid then combines with filtered bicarbonate to form carbonic acid. Carbonic anhydrase facilitates the dissociation of carbonic acid into water and carbon dioxide that both enter the renal tubular cell. Carbon dioxide and water generate bicarbonate, which enters the peritubular circulation accompanied by sodium. The remaining hydrogen ions are secreted into the lumen in exchange for sodium (Figure 26.5). Inhibition of carbonic anhydrase by acetazolamide interferes with the reabsorption of bicarbonate ions from renal tubular fluid. As a result, excess bicarbonate ions are lost in the urine and the plasma bicarbonate concentration is decreased.

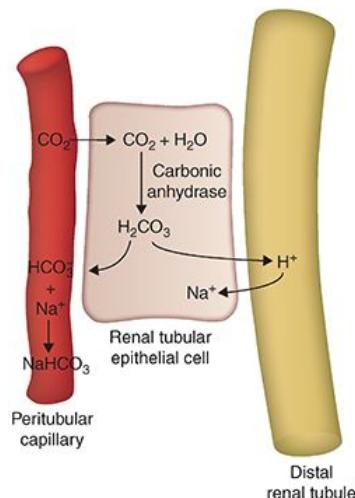

FIGURE 26.5 Schematic depiction of the renal tubular secretion of hydrogen ions, which are formed from the dissociation of carbonic acid in renal tubular epithelial cells.

Hydrogen ions are secreted into renal tubules by epithelial cells lining proximal renal tubules, distal renal tubules, and collecting ducts. At the same time, sodium ions are reabsorbed in exchange for the secreted hydrogen ions and combine with bicarbonate ions in the peritubular capillaries. This process is facilitated by aldosterone. As a result, the amount of sodium bicarbonate in the plasma is increased during the secretion of hydrogen ions into renal tubules. Active hydrogen ion transport is inhibited when the urinary pH drops below 4.0. Thus, hydrogen ions must combine with ammonia and phosphate buffers in the renal tubular lumen to prevent the pH from decreasing below this critical level. Ammonia is generated in the mitochondria of the proximal tubule. Ammonia combines with hydrogen ions to form ammonium, which is excreted in the urine in combination with chloride ions as the weak acid ammonium chloride (Figure 26.6). In renal insufficiency, the capacity to generate urinary ammonia is impaired, thus reducing hydrogen ion excretion.

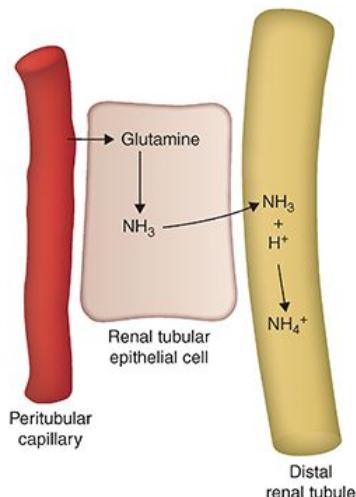

FIGURE 26.6 Ammonia formed in renal tubular epithelial cells combines with hydrogen ions in the renal tubules to form ammonium.

Renal responses that regulate hydrogen ion concentrations do so by acidification or alkalinization of the urine. In the presence of acidosis, the rate of hydrogen ion secretion exceeds the net loss of bicarbonate ion into the renal tubules. As a result, an excess of hydrogen ions is excreted into the urine. In the presence of alkalosis, the effect of the titration process in the renal tubules is to increase the number of bicarbonate ions filtered into the renal tubules relative to the secretion of hydrogen ions. Excess bicarbonate ions are excreted into the urine accompanied by cations, most often sodium.

Extracellular fluid is electroneutral such that the sum of the positive charges of all cations must equal the sum of negative charges of all anions. In the process of altering the plasma concentration of bicarbonate ions, it is mandatory to remove some other anion each time the concentration of bicarbonate ions is increased or to increase some other anion when the bicarbonate concentration is decreased. Typically, the anion that follows changes in the concentration of bicarbonate ions is chloride. As the most abundant extracellular anion, physiologic manipulation of chloride appears to be an important element of pH control. Conceptually, when bicarbonate ions are replaced by chloride ions, the pH will generally tend to decrease as a weak acid (carbonic acid) is replaced by a strong acid (hydrochloric acid).

The value of renal regulation of hydrogen ion concentration is not its rapidity but instead its ability to nearly completely neutralize any excess acid or alkali that enters the body fluids. Ordinarily, the kidneys can remove up to 500 mmol of acid or alkali each day. If greater quantities than this are generated, the kidneys are unable to maintain normal acid–base balance, and acidosis or alkalosis occurs. Even when the plasma pH is 7.4, a small amount of acid is still lost each minute. This reflects the daily production of 50 to 80 mmol of more acid than alkali. Indeed, the normal urine pH of approximately 6.4 is due to the presence of this excess acid in the urine.

Classification of Acid–Base Disturbances

Acid–base disturbances are categorized as respiratory or metabolic acidosis ($\text{pH} < 7.35$) or alkalosis ($\text{pH} > 7.45$) (Table 26.3).¹ An acid–base disturbance that results primarily from changes in alveolar ventilation is described as respiratory acidosis or alkalosis. An acid–base disturbance unrelated to changes in alveolar ventilation is designated as metabolic acidosis or alkalosis. Compensation describes the secondary renal or ventilatory responses that occur as a result of the primary acid–base disturbance.

The principal manifestation of severe respiratory or metabolic acidosis is depression of the central nervous system. For example, coma is a characteristic of severe diabetic acidosis or renal dysfunction leading to uremia. The principal manifestation of respiratory or metabolic alkalosis is increased excitability of the peripheral nervous system and central nervous system. As a result, there may be repetitive stimulation, causing skeletal muscles to undergo sustained contraction known as tetany. Tetany of respiratory muscles may interfere with adequate ventilation of the lungs. Central nervous system excitability may manifest as seizures.

Respiratory Acidosis

Any event (drug or disease) that decreases alveolar ventilation results in an increased concentration of dissolved carbon dioxide in the blood (increased PaCO_2), which in turn leads to formation of carbonic acid and hydrogen ions. By convention, carbonic acid resulting from dissolved carbon dioxide is considered a respiratory acid, and respiratory acidosis is present when the pH is <7.35 and PaCO_2 is >45 mm Hg. It is important to note that although an increase in dissolved carbon dioxide generates an equivalent increase in both the hydrogen ion and bicarbonate ion concentrations, the pH will fall. This is because the relative increase in hydrogen ions is significantly greater than the relative increase in bicarbonate ions because the plasma concentration of hydrogen ion is far lower than the concentration of bicarbonate. An increase in carbon dioxide sufficient to reduce the pH from 7.4 to 7.1 will essentially double the hydrogen ion concentration from 40 to 79 nmol/L, compared to an increase in the bicarbonate ion concentration only from 24.000000 to 24.000039 mmol/L.

Acidosis, respiratory or metabolic, often has profound effects on many drug and enzyme interactions in the body, which function optimally only within normal pH ranges. Of particular importance to the anesthesiologist is the clinical scenario of increasing respiratory acidosis due to inadequate reversal of muscle relaxants and the interaction between anticholinesterases and the enzyme acetylcholinesterase. The commonest method to reverse the muscle relaxant effects of nondepolarizing neuromuscular-blocking agents (NMBAs) is by administering an anticholinesterase, such as neostigmine. Anticholinesterases inhibit normal acetylcholinesterase, increasing the concentration of acetylcholine in the synaptic clefts of the neuromuscular junction and thus antagonizing the neuromuscular block. The concentration of NMBAs remains essentially unchanged at the time of reversal. If the reversal is inadequate due to an excess of NMBAs or due to the limited duration of action of the anticholinesterase (eg, 20-30 minutes for neostigmine), then inadequate alveolar minute ventilation can lead to progressive respiratory acidosis, which will potentiate the NMBAs and weaken the effects of the anticholinesterase. This clinical picture of increasing muscle weakness after a seemingly appropriately reversed neuromuscular block has been termed *recurarization*.² Although this was more of a clinical problem with the older longer acting NMBAs (eg, pancuronium), it can still occur with the newer shorter acting drugs (eg, rocuronium).

Respiratory Alkalosis

Respiratory alkalosis is present when increased alveolar ventilation removes sufficient carbon dioxide from the body to decrease the hydrogen ion concentration to the extent that pH becomes >7.45 . A physiologic cause of respiratory alkalosis is hyperventilation due to stimulation of chemoreceptors by a low PO_2 associated with ascent to altitude. Kidneys compensate with time for this loss of carbon dioxide by excreting bicarbonate ions in association with sodium and potassium ions. This renal compensation is evident in individuals residing at altitude who have a nearly normal pH despite a low Paco_2 . A frequent cause of acute respiratory alkalosis is iatrogenic hyperventilation of the lungs as during anesthesia. Tetany that accompanies alkalosis reflects hypocalcemia due to the greater affinity of plasma proteins for calcium ions in an alkaline, compared with an acidic, solution.

Metabolic Acidosis

The most common and most confusing acid–base disorder that clinicians are required to manage is metabolic acidosis. Any acid formed in the body other than carbonic acid from carbon dioxide is considered a metabolic acid, and its accumulation results in metabolic acidosis. Acidosis impairs myocardial contractility and the responses to endogenous or exogenous catecholamines.³ Hemodynamic deterioration is usually minimal (in the awake state) when the pH remains >7.2 due to compensatory increases in sympathetic nervous system activity. Of great clinical importance are the accentuated detrimental effects of metabolic acidosis in individuals with underlying left ventricular dysfunction or myocardial ischemia or in those in whom sympathetic nervous system activity may be impaired, as by drug-induced β -adrenergic blockade or general anesthesia. Respiratory acidosis may produce more rapid and profound myocardial dysfunction than does metabolic acidosis, reflecting the ability of carbon dioxide to freely diffuse across cell membranes and exacerbate intracellular acidosis.

Acute metabolic acidosis has been treated with intravenous administration of an exogenous buffer, usually sodium bicarbonate, in the hope that normalizing pH will attenuate the detrimental effects of acidosis. The effectiveness of the use of sodium bicarbonate to treat metabolic acidosis is debatable.⁴ Sodium bicarbonate administration increases the carbon dioxide load to the lungs, leading to further increases in arterial and intracellular PCO_2 if alveolar ventilation is not concomitantly increased. It is estimated that 1 mEq/kg sodium bicarbonate, given intravenously, produces approximately 180 mL of carbon dioxide and necessitates a transient doubling of alveolar ventilation to prevent hypercarbia. In the presence of increased dead space ventilation, even greater increases in alveolar ventilation are required for carbon dioxide elimination to equal production. Even if Paco_2 is maintained normal, it is possible that tissue pH_i and the risk of ventricular fibrillation will not be altered by administration of sodium bicarbonate during cardiopulmonary resuscitation. Also, the standard formulation of sodium bicarbonate, 8.4%, is hypertonic, and this will have a plasma-expanding effect that contributes to dilutional acidosis (see the following text). However, if alveolar ventilation can be increased to deal with the increased carbon dioxide load from administration of sodium bicarbonate (initial bolus dose 0.5–1 mEq/kg), then it can be useful as a temporizing measure to help restore hemodynamic stability in shock combined with severe metabolic acidosis.⁵

Lactic Acidosis

Under normal circumstances, lactate is produced at a rate of approximately 1 mmol/kg per hour. Normal clearance of lactate maintains its serum concentration between 0.5 and 1.0 mmol/L. Most lactate is cleared by the liver, where it undergoes oxidation, gluconeogenesis, and eventual conversion to bicarbonate. Lactate undergoes both passive diffusion and active transport into the liver via a monocarboxylate transporter. However, active transport becomes saturated at serum lactate concentrations that exceed 2.5 mmol/L. Severe reductions in hepatic blood flow, which occur during shock, will decrease hepatic lactate clearance. Lactic acid is a strong acid and therefore dissociates almost completely under physiologic conditions into the lactate anion and a hydrogen ion. Although lactate accumulation has classically been taught to occur mainly during anaerobic glycolysis, it is now clear that significant lactate generation occurs under normoxic conditions. Indeed, lactate is an important gluconeogenic precursor and is involved in cell-to-cell signaling. However, in

the critically ill patient, lactate production may increase while lactate clearance is impaired, and lactic acidosis may occur. Point-of-care testing allows almost instantaneous lactate determinations to be performed in the operating room and intensive care unit. A serum lactate >1.5 mmol/L upon admission is an independent predictor of mortality in critically ill patients. Furthermore, failure to decrease lactate concentration to ≤ 1.0 mmol/L 24 hours after admission is also associated with significant mortality.

The investigational drug dichloroacetate decreases lactate concentration in cardiogenic shock, burns, diabetic ketoacidosis, and malaria. Dichloroacetate activates the mitochondrial pyruvate dehydrogenase complex, thus accelerating the irreversible oxidation of lactate via pyruvate to acetyl coenzyme A, which then enters the Krebs cycle. The buffer tris(hydroxymethyl)aminomethane can be used to treat metabolic acidosis and does not generate carbon dioxide. It may be particularly useful, as an alternative to sodium bicarbonate, to treat metabolic acidosis in patients who are hypernatremic.⁶

Dilutional Acidosis

Because the pH of water at 37°C is 6.8, any increase in the free-water volume of the body will contribute to acidosis (eg, administration of 5% dextrose). Dilutional acidosis also occurs when the plasma pH is decreased by extracellular volume expansion with chloride-containing solutions such as normal saline. Clinically, a hyperchloremic metabolic acidosis may accompany large-volume infusion of isotonic saline.⁷ Normal saline is commonly thought of as being a “physiologic” solution because it has an osmolarity close to plasma and does not lyse red blood cells. However, it has a pH (5.7) that is more acidic than plasma and contains significantly more chloride (154 vs 100 mmol/L) and slightly more sodium (154 vs 140 mmol/L) (**Table 26.4**). Thus, infusion of a large volume of normal saline will increase plasma chloride concentration to a relatively greater degree than sodium concentration. Chloride can be thought of as a strong acid (hydrochloric acid-proton donor), just as sodium can be thought of as a strong base (sodium hydroxide-hydroxyl donor).⁸

TABLE 26.4

Electrolytes in plasma and commonly available crystalloid solutions

Solution	Na	Cl	K	Ca	Mg	Lactate	Acetate	Gluconate	pH	mOsm
Plasma	144	107	5	2	1.5				7.4	290

Abbreviations: Ca, calcium; Cl, chloride; K, potassium; Mg, magnesium; mOsm, osmolarity; Na, sodium; NS, normal saline; RL, Ringer lactate.

Other Causes of Metabolic Acidosis

Renal failure prevents excretion of acids formed by normal metabolic processes, and metabolic acidosis occurs. Severe diarrhea and associated loss of sodium bicarbonate rapidly leads to metabolic acidosis, especially in the pediatric age group. Lack of insulin secretion (diabetes mellitus) or starvation impairs glucose utilization, forcing tissues to metabolize fat to meet energy needs. As a result, the plasma concentration of ketones such as acetoacetic acid may increase sufficiently to cause metabolic acidosis.

Differential Diagnosis of Metabolic Acidosis

Several different methods have been developed over the past 60 years to help clinicians in the differential diagnosis and treatment of acid-base disturbances, particularly relating to metabolic acidosis. All of these methods have their strengths and their weaknesses because they are based on theoretical stable states. In clinical practice, these methods have been made less relevant by the ability to get rapid laboratory or point-of-care results for several plasma values such as lactate.

Base Excess

The concept of base excess (BE) and its converse base deficit were developed in the 1940s. This is defined as the amount of strong acid or base to return the plasma pH to 7.4 assuming PaCO_2 40 mm Hg and normothermia. The BE is calculated (not measured) by modern blood gas analyzers from an algorithm based on measured bicarbonate and pH. In isolated acute respiratory acidosis or alkalosis, the BE should not change (normal value = 0). The BE remains useful to alert the clinician to the presence of a concurrent metabolic acidosis ($\text{BE} < 0$) in the presence of a respiratory acidosis ($\text{pH} < 7.35$, $\text{PaCO}_2 > 45$ mm Hg) or to the presence of an underlying metabolic alkalosis ($\text{BE} > 0$). Mixed respiratory and metabolic acidosis is a common clinical problem. Also, it alerts the physician to the severity of the metabolic derangement, which can then be used as a guide to the initial therapy. The weakness of the BE measurement is that it does not distinguish among the possible causes of metabolic acidosis.

Anion Gap

Calculation of the anion gap may assist in the evaluation of acid–base disorders. The anion gap is a derived value based on the principle of electrochemical neutrality such that the sum of the positive (cationic) charges in a solution must equal the sum of the negative (anionic) charges. The major extracellular anions are chloride and bicarbonate. Other significant anions include proteins, phosphate, sulfate, and organic acids (including lactate). The latter are less commonly measured in routine practice and are referred to as *unmeasured anions*. The predominant extracellular cation is sodium. Although potassium is now routinely measured, its inclusion in the anion gap calculation is inconsistent and varies from institution to institution. Potassium is often grouped with the other “unmeasured cations,” calcium and magnesium. Under normal circumstances, the concentration of the predominant cation (sodium) exceeds that of the combined predominant anions (chloride and bicarbonate) [$\text{anion gap} = \text{Na}^+ - (\text{HCO}_3^- + \text{Cl}^-)$] by 9 to 13 mEq/L. For electroneutrality to occur, the concentration of the combined unmeasured anions must therefore exceed that of the unmeasured cations by the same amount. The term *anion gap* refers solely to the difference in concentration between the traditionally measured anions and cations. The anion gap does not imply a true discrepancy between the total positive and negative charges in physiologic solution where the total anion charge must equal the total cation charge.

Metabolic acidosis is most often associated with an increase in the anion gap (**Table 26.5**). An increase in the concentration of unmeasured anions (or a decrease in the concentration of unmeasured cations) will increase the anion gap. Lactic acidosis, ketoacidosis, and renal failure increase the concentration of unmeasured endogenous anions. Exogenous anions will also increase the concentration of unmeasured anions (salicylate toxicity, ethylene glycol, and methanol ingestion). Hyperchloremic acidosis and renal tubular acidosis (bicarbonate loss) will have a normal anion gap. The weaknesses of the anion gap concept include that it does not differentiate between the causes of increased anion gap metabolic acidosis; it does not correct for pH changes due to free-water volume increase or decreases; and it does not correct for changes in serum albumin and phosphate, which have an effect on acid–base balance.

TABLE 26.5

Causes of metabolic acidosis

Increased anion gap	Normal anion gap
<ul style="list-style-type: none">• Lactic acidosis• Ketoacidosis• Chronic renal failure (accumulation of sulfates, phosphates, urea)• Intoxication: organic acids (salicylates, ethanol, methanol, formaldehyde, ethylene glycol, paraldehyde), INH, sulfates, metformin• Massive rhabdomyolysis	<ul style="list-style-type: none">• Hyperchloremic acidosis (excess saline administration)• Diarrhea (long-standing bicarbonate loss)• Pancreatic fistula• Renal tubular acidosis• Intoxication: ammonium chloride, acetazolamide,

Abbreviation: INH, isoniazid.

Strong Ion Gap

The strong ion gap (SIG) method is also based on the concept of electroneutrality of plasma.⁹ The SIG compares the excess measured serum concentrations of strong cations (Na^+ , K^+ , Mg^{2+} , Ca^{2+}) to the calculated total of measurable anions (Cl^- , HCO_3^- , albumin, phosphate); the normal gap is 6 to 10 mEq/L. The SIG can be corrected for changes in plasma free-water volume and may be more useful in combined causes of metabolic acidosis, which are common in clinical practice. Measurement of the plasma lactic acid concentration and calculation of the anion gap from sodium, chloride, and bicarbonate permits differentiation of dilutional acidosis from acidosis due to tissue hypoperfusion.

Simplified Approach to Metabolic Acidosis of Uncertain Etiology

When the cause of a metabolic acidosis is unclear, measure the serum lactate, blood urea nitrogen, creatinine, and glucose. If this does not identify the etiology of the acidosis, then send serum for toxicology to measure salicylates, methanol, ethylene glycol, etc.

Metabolic Alkalosis

Metabolic alkalosis is commonly iatrogenic. Causes include vomiting with excess loss of hydrochloric acid, nasogastric suction, chronic administration of diuretics, hypoalbuminemia, and excess secretion of aldosterone. Excess administration of sodium bicarbonate may be an iatrogenic cause of metabolic alkalosis. A loss of free water (pH 6.8) will cause a volume-contraction alkalosis. Treatment involves treating the underlying cause.

Compensation for Acid–Base Disturbances

Respiratory acidosis is compensated for within 6 to 12 hours by increased renal secretion of hydrogen ions, with a resulting increase in the plasma bicarbonate concentration. After a few days, the pH will be normal despite persistence of an increased PaCO_2 . Sudden correction of chronic respiratory acidosis, by iatrogenic hyperventilation, may result in acute metabolic alkalosis because increased plasma bicarbonate is not promptly eliminated by the kidneys.

Respiratory alkalosis is compensated for by decreased reabsorption of bicarbonate ions from renal tubules. As a result, more bicarbonate ions are excreted in the urine, which decreases the plasma concentration of bicarbonate and returns the pH toward normal despite persistence of a decreased PaCO_2 .

Metabolic acidosis stimulates alveolar ventilation, which causes rapid removal of carbon dioxide from the body and decreases the hydrogen ion concentration toward normal. This respiratory compensation for metabolic acidosis, however, is only partial because pH remains somewhat below normal.

Metabolic alkalosis diminishes alveolar ventilation, which in turn causes accumulation of carbon dioxide and a subsequent increase in hydrogen ion concentration. As with metabolic acidosis, the respiratory compensation for metabolic alkalosis is only partial. Renal compensation for metabolic alkalosis is increased by reabsorption of hydrogen ions. This metabolic compensation is limited by the availability of sodium, potassium, and chloride ions. During prolonged vomiting, there may be excessive loss of chloride ions along with sodium and potassium. When this occurs, the kidneys preferentially conserve sodium and potassium ions and the urine becomes paradoxically acidic. Indeed, the presence of paradoxical aciduria indicates electrolyte depletion.

Effects of Temperature on Acid–Base Status

Temperature changes have several effects on blood and tissue pH and PCO_2 . As blood is cooled, carbon dioxide becomes more soluble. Therefore, for a given carbon dioxide content, the partial pressure will decrease as the temperature falls. The magnitude of this change is approximately 4.5% per degree Celsius and

will tend to increase the pH. The blood pH is further increased as the dissociation of water into protons and hydroxyl ions decreases with cooling, thus decreasing hydrogen ion concentration. In addition, proton buffering by hemoglobin α -imidazole groups is enhanced by hypothermia. The sum of these effects is an increase of 0.015 pH units per degree Celsius decrease in temperature. These changes are probably insignificant within the physiologic temperature range but are important when interpreting blood gas and acid–base data during induced cooling during cardiopulmonary bypass. If the blood temperature is decreased by 10°C to 27°C, the pH will increase to 7.6. Two alternate blood gas management strategies, “ α -stat” and “pH-stat,” are utilized during hypothermia in the operating room ([Table 26.6](#)).

TABLE 26.6

α -Stat versus pH-stat management during hypothermia

	α-Stat	pH-Stat
Carbon dioxide added to oxygenator	No	Yes
Enzyme function	Near normal	Decreased
Cerebral blood flow	Normal	Increased
Blood gas temperature correction required	No	Yes
Hb–O₂ dissociation curve	Marked left shift	Less marked left shift

Abbreviations: Hb, hemoglobin; O₂, oxygen.

pH-Stat Management

During hypothermic conditions, blood pH is increased and PCO₂ is decreased. The pH-stat strategy seeks to return the pH and PCO₂ of hypothermic blood to normal. During hypothermic cardiopulmonary bypass, this strategy usually involves the addition of carbon dioxide via the oxygenator. A purported advantage of this strategy is that cerebral blood flow will be increased because carbon dioxide is a potent cerebral vasodilator. However, delivery of microemboli to the brain may also be increased. Temperature correction of blood gas samples is required to interpret the values obtained from a hypothermic patient but measured at 37°C. The pH-stat strategy is used more often in surgery for pediatric congenital heart disease, especially during cooling and deep hypothermic circulatory arrest.¹⁰ Under these circumstances, enhanced cerebral perfusion that facilitates brain cooling is thought to be desirable. Cerebral injury secondary to global hypoperfusion is thought to be a greater threat than delivery of microemboli in this patient population. Hypothermia, hypocarbia (via the Bohr effect), and alkalosis, all shift the oxyhemoglobin dissociation curve to the left and impair tissue oxygen delivery. The addition of carbon dioxide during pH-stat management will counter these effects and facilitate oxygen unloading from hemoglobin.

α -Stat Management

The α -stat strategy seeks to replicate the alkalinization of blood that occurs during cooling in poikilothermic mammals (eg, naked mole rat). This strategy seeks to optimize enzyme function during hypothermia. The α of α -stat refers to the charged portion of the histidine imidazole residue. The objective is to maintain biologic neutrality by preserving the α -imidazole and protein charge state, the OH[−]/H⁺ ratio, and therefore enzyme function, even though the pH will increase. This strategy is most often used during adult cardiopulmonary bypass and does not generally encourage the delivery of microemboli to the brain because supplemental carbon dioxide is not generally administered. This strategy does not require temperature correction of blood gas results.

There are examples of both strategies in nature. Homeotherms (eg, humans) have homeostatic mechanisms for maintaining the temperature of the internal environment within very narrow limits. Homeotherms and hibernating animals hypoventilate in order to maintain blood pH at 7.4 as their body temperature decreases (pH-stat). The pH_i is low in most tissues under these circumstances and suppresses metabolism and conserves energy stores in nonfunctioning tissues. However, the brain and heart of these

animals employ α -stat strategies to maintain pH_i at α -stat values and to maintain near-normal function. Poikilotherms (eg, snakes) have not developed mechanisms for regulating the temperature of their internal environment that changes with that of the external environment. Poikilotherms use the α -stat strategy and allow their blood pH to increase and PCO_2 to decrease with cooling in order to preserve cellular and enzyme function over wide temperature ranges.

PART V Blood and Hemostasis

Physiology of Blood and Hemostasis

Jerrold H. Levy

Understanding the physiology of blood and its interactions for hemostasis is a critical aspect of managing perioperative bleeding. With the increasing use of anticoagulation therapies for cardiovascular diseases, patients also present with multiple underlying acquired coagulation abnormalities. Further, in an acutely bleeding and hemorrhagic patient, additional coagulation changes occur that are covered in the chapter on physiology and management of massive transfusion. Understanding the physiology of coagulation and blood interactions is important in determining the preoperative bleeding risk of patients and in managing hemostatic therapy perioperatively.

At the center of hemostasis is the ability to generate thrombin, a serine protease. Thrombin plays pivotal roles in the activation of additional coagulation factors as shown in [Figures 27.1](#) and [27.2](#).¹ Most coagulation factors circulate in the body as inactive enzymatic precursors that are called **zymogens**.¹ However, there are multiple critical steps in clot formation that involve additional cofactors, humoral proteins, cellular components, and cell surface receptors. Following tissue injury, thrombin is generated in a highly regulated way that keeps the effects of this activation local to the site of injury and prevents uncontrolled systemic thrombosis. In surgical patients, multiple perturbations occur, and the hemostatic and inflammatory systems are closely related and have significant cross talk. Managing perioperative hemostasis also requires consideration of the postoperative hypercoagulability that may follow, and important advances have been made as new pharmacologic strategies are available and used to treat both procoagulation states and cardiovascular disease. This chapter reviews the physiology of hemostasis, clot formation, and thrombin generation.

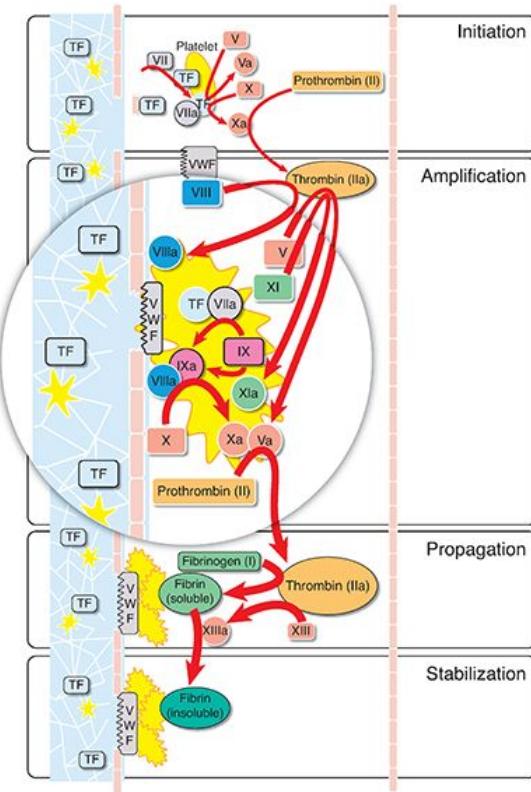

FIGURE 27.1 Initiation, amplification, propagation, and stabilization of hemostasis and clot formation. This describes the complexity of the clotting process and illustrates the interaction between coagulation factors and the cell surfaces of platelets in what has been described as the cellular model of hemostasis. Four sequential and interrelated stages include initiation, amplification, propagation, and stabilization as shown. This model also combines multiple aspects of the classic waterfall/cascade model and further explains additional aspects of hemostasis that the classic acellular model does not. Abbreviations: TF, tissue factor; VWF, von Willebrand factor. *Derived from Monroe DM, Hoffman M. What does it take to make the perfect clot? Arterioscler Thromb Vasc Biol. 2006;26:41-48.*

Hemostasis and History

The term **hemostasis** essentially means to stop bleeding and refers to the physiologic process that keeps blood within damaged blood vessels, the opposite of hemorrhage. Multiple mechanisms are involved in hemostasis, a process critical for survival. The elucidation of models to explain the molecular and cellular interactions of the clotting cascade continue to evolve over time. The best understood clotting cascade is the waterfall/cascade model that most clinicians learned in medical school and was developed about 50 years ago but is still used as an educational tool.¹ However, this acellular model does not tell the entire story and was previously refined by Hoffman and Monroe² in their cell-based model that focuses on both cellular and humoral interactions and (see [Figure 27.1](#)). Hemostasis is also a complex inflammatory response that provides host defense mechanisms to prevent exsanguination following injury, trauma, and/or surgery. Many of the hemostatic factors have complex inflammatory signaling properties that orchestrate further host defense mechanisms, healing, and a multitude of other functions. There are multiple aspects of the physiology of hemostasis and clot formation that will be considered separately.

Initiation of Coagulation

Initiation of coagulation by procoagulant activities has been traditionally separated into extrinsic, intrinsic, and common pathways. However, a better understanding of the complex interactions has created a better conceptual integration of these pathways. Following tissue injury and vascular endothelial disruption, activation of hemostasis occurs by tissue factor (TF) expression on the subendothelial vascular basement of the blood vessel as shown in [Figures 27.1](#) and [27.2](#).¹⁻³ The TF is a transmembrane receptor expressed by

perivascular/vascular cells that binds factor VIIa.⁴ Vascular injury with loss of normal endothelial function allows for expression of extravascular TF and initiation of clotting.⁴ The TF is also present in the circulation as microparticles that are small membrane vesicles that appear following cellular injury or death and may contribute to thrombosis with sepsis or other procoagulant states. Activated factor VII (factor VIIa), a serine protease that circulates in blood in low concentrations, allows for formation of the factor VIIa/TF complex, and conversion of factor X to factor Xa.^{1,3} Subsequently, factor Xa (also a serine protease) generates trace amounts (0.1-1 nM) of thrombin.^{1,3} Thrombin generation is subsequently amplified by other coagulation factors from the intrinsic cascade that includes factor XI-, IX-, and VIII-dependent activities, although both the extrinsic (factor VIIa/TF) and intrinsic (factors IXa/VIIIa) tenase complexes produce factor Xa, which is also an important target for many anticoagulation agents. “Tenase” is a contraction of the words “ten” and the suffix “-ase” and refers to these factor complexes that activate inactive factor X through enzymatic cleavage. Multiple factors influence the degree of activation including the local TF concentration and type of cell surface supporting enzyme/cofactor complex assembly as platelets also will contribute to this response.^{1,3} The interaction of both cellular and plasma-dependent mechanisms generates the prothrombinase complex (factors Xa, Va, and prothrombin) assembly that enzymatically cleaves prothrombin to produce thrombin, another critical factor targeted in anticoagulation therapy. The orchestration of hemostasis and factors influencing its balance are shown in [Figures 27.1](#) and [27.2](#).

As part of the activation, there are also checks and balances in the system to prevent an over exuberant prothrombotic effect from occurring and regulate thrombin generation to localize clot at the site of vascular injury as shown in [Figure 27.2](#). Tissue factor pathway inhibitor (TFPI) neutralizes factor Xa when it is in a complex with TF-factor VIIa.^{1,3} The other regulator of TF-triggered procoagulant response is antithrombin (formerly called antithrombin III; a serine protease inhibitor), which circulates at a high concentration (150 µg/mL, ~2.7 µM) and neutralizes the initially formed factor Xa and thrombin.^{1,3} Overall factor VIIa patrols the circulation in search of sites of vascular injury where TF is exposed, and trace quantities of factor Xa and thrombin initiate a procoagulant response. Plasma levels of the different coagulation proteins are listed in [Table 27.1](#).

TABLE 27.1

Plasma levels and half-lives of coagulation factors^a

Factor	Level (µM)	Half-life (hours)
Fibrinogen	7.6	72-120
Prothrombin	1.4	72
Factor V	0.03	36
Factor VII	0.01	3-6
Factor VIII	0.00003	12
Factor IX	0.09	24
Factor X	0.17	40
Factor XI	0.03	80
Factor XIII	0.03	120-200
von Willebrand factor	0.03	10-24
Protein C	0.08	10
Protein S	0.14	42
Antithrombin	2.6	48-72

Propagation of Coagulation

Platelets further amplify or potentially initiate clot formation at the site of vascular injury. Inflammatory cells all contain adhesion molecules to facilitate binding in the rapid flow of blood vessels as shown in [Figure 27.1](#). Following vascular injury and exposure of the subendothelial vascular basement membrane, von Willebrand factor (vWF) that circulates in a multimeric form binds to the damaged blood vessel. Platelets then adhere to subendothelial collagen-vWF via their glycoprotein Ib receptors and are activated. Thrombin generation that also occurs locally is a potent activator/agonist for platelets by stimulating protease-activated receptor (PAR)-1 and PAR-4.^{1,3} Thrombin activation of platelets further amplifies clot formation by multiple mechanisms. Platelet glycoprotein Ib receptors bind to factor XI, and they also localize factor VIII to the site of endothelial disruption via its carrier protein vWF.⁵ Also, factor V is released from platelet α -granules upon platelet activation, and factors XI, VIII, and V further amplify and sustain procoagulant responses (the “intrinsic pathway”) after thrombin-mediated activation. The serine protease factor XIa mediates the activation of factor IX to factor Xa, and factor VIIIa serves as a cofactor to factor IXa. Factor IXa, a serine protease, activates factor X to factor Xa, and factor Va serves as a cofactor to factor Xa.^{1,3} In the absence of factor VIIIa or factor IXa, as is clinically observed in hemophilia A or B, the initiation of coagulation is normal, but amplification/propagation is altered. Patients with hemophilia clot, but they develop bleeding in muscle and joints due to low TF expression.

Tissue Factor, Thrombin, and Fibrin(ogen) in Clot Formation and Stability

When generated, thrombin facilitates the proteolytic conversion of circulating soluble fibrinogen to an insoluble fibrin meshwork. This complex mechanism involves the cleavage of *N*-terminal peptides from fibrinogen, end-to-end polymerization of fibrin monomers to protofibrils, and lateral aggregation of protofibrils to fibers.^{1,3} Fibrin’s biophysical characteristics provide extensive structural support to the clot; individual fibers can be strained >330% without rupturing. The fibrin network that forms can be influenced by many different factors including fibrin(ogen)-binding proteins (eg, factor XIII), thrombin, and fibrinogen present during fibrin formation.

Role of Fibrinogen

Fibrinogen is a critical protein for clot formation and has a critical role in hemostasis.⁶ Fibrinogen is critical for clot formation and creating the dense lattice structure as shown in [Figure 27.3](#). Fibrinogen also binds to platelet glycoprotein IIb/IIIa receptors to facilitate clot formation and is affected by many antiplatelet agents. In addition, fibrinogen facilitates the cross-linking and network formation for clot and the subsequent fibrin polymerization that is catalyzed by thrombin and thrombin-activated factor XIII that locally at the site of activation. Of all the coagulation factors, fibrinogen circulates at the highest concentration (7.6 μ M, ~200-400 mg/dL). In pregnancy and during acute inflammatory responses that often occur postoperatively, fibrinogen is an acute-phase reactant.⁶ Platelets that are activated by multiple agonists express glycoprotein IIb/IIIa receptors. Thrombin catalyzes the conversion of fibrinogen to fibrin monomers after thrombin cleaves the fibrinopeptides from the fibrinogen Aa and B3 chains. Platelets that are activated release factor XIII A subunits that further polymerize fibrin monomers into fibrin. Activated factor XIII also cross-links α_2 -antiplasmin to fibrin, making fibrin more resistant to degradation. Thrombin released locally modulates the thickness and the fibrinolytic resistance of fibrin fibers.

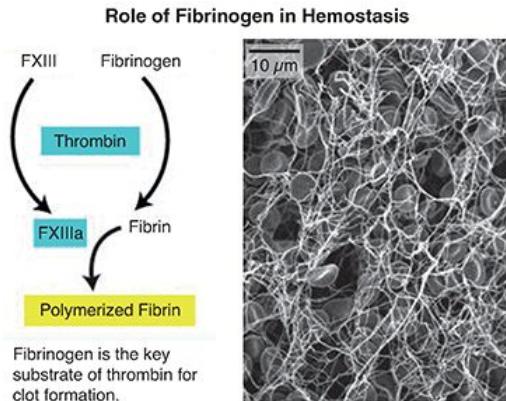

FIGURE 27.3 Fibrinogen is converted to fibrin that polymerizes by the action of thrombin. The electron micrograph shows a fibrin clot with red blood cells trapped. Platelets also are critical to fibrin formation, but they are 8 to 10 microns and not visible in the photo. Fibrinogen receptors on the platelet surface (called **IIb/IIIa receptors**) facilitate the lattice network of fibrin formation. Factor XIII, a transglutaminase, is also important for cross-linking the fibrin clot to create a stronger clot that is resistant to fibrinolysis. *Modified with permission from Tanaka KA, Key NS, Levy JH. Blood coagulation: hemostasis and thrombin regulation. Anesth Analg. 2009;108(5):1433-1446. Copyright © 2009 International Anesthesia Research Society.*

Thrombin generation is critical to clot formation, platelet activation, and fibrinogen cross-linking.^{1,3} With normal hemostatic function, the peak thrombin level reaches 200 to 500 nM, facilitating the formation of a dense fibrin network for normal clot function and hemostasis. However, in patients with hemophilia and other bleeding abnormalities, lower levels of thrombin generation occur, and as a result, clot formation is altered; thus, hemophiliacs commonly bleed into joints. Thrombin generation at the junction of the injured vasculature and subendothelial basement membrane is amplified by platelet activation and release of procoagulant microparticles.^{1,3} Thrombin has a complex effect of releasing tissue plasminogen activator (tPA) to simultaneously initiate fibrinolysis. This occurs not only by binding to thrombomodulin but also by activated factor XIII and activation of thrombin-activatable fibrinolysis inhibitor (also called TAFI). Fibrin polymerization, thrombin, and activated factor X generated at the site of vascular injury site are released systemically.

Critical Factor Levels for Hemostasis

A critical question is what levels of fibrinogen, platelets, and other coagulation proteins are necessary to optimize hemostasis in the surgical patient. Because of the critical role of fibrinogen for clot formation, current guidelines recommend fibrinogen levels of at least 1.5 to 2.0 g/L (150-200 mg/dL) for treating bleeding, and potentially even higher, as further normalization of fibrinogen to levels more consistent with normal circulating concentrations of 2 to 3 g/L (200-300 mg/dL) may be important for adequate hemostasis.⁷

Role of Factor XIII

Factor XIII plays a major role in the terminal phase of the clotting cascade that promotes formation of cross-linked fibrin polymers and generation of a stable hemostatic plug.⁸ Factor XIII exists as a tetrameric precursor (zymogen) of 2A and 2B subunits and is converted into an active transglutaminase (factor XIIIa) by thrombin and calcium.⁸ In this activated form, factor XIIIa mechanically stabilizes fibrin and protects it from fibrinolysis. As a result, patients with a deficiency in factor XIII develop a rare but severe bleeding disorder.⁸ A congenital deficiency in factor XIII is clinically defined as a plasma level of less than 5% of the protein.⁸ Most cases of factor XIII deficiency are due to lack of the A subunit with less than 1% factor XIII activity. Congenital factor XIII deficiency is inherited as an autosomal recessive disease and was first reported in Switzerland in 1960.⁹ The incidence of factor XIII deficiency is currently estimated as 1 in 3 to 5 million

births in the United States.⁸ An acquired deficiency in factor XIII can arise from the development of antibodies against factor XIII.

Role of Platelets and von Willebrand Factor

Platelets adhere to sites of vascular injury and to each other by direct and indirect effects that are part of a complex cellular mechanism required for hemostasis. Although platelet aggregation is mediated in part by bridging/binding of the integrin glycoprotein IIb/IIIa on platelet surfaces by the adhesive protein fibrinogen, this process is far more complex than simple interactions and the lattice formation of the two elements.¹⁻³

There are multistep adhesion processes involving distinct receptors and adhesive ligands that are also dependent on flow conditions, especially with the critical role of platelet function in arterial hemostatic mechanisms. Thus, following vascular injury, the subendothelial surface is exposed which then binds to vWF that is synthesized in the endothelium and critical for platelet adhesion in arteries and arterioles that have high shear rates.^{1,10}

The vWF is critical to facilitate platelet adhesion in rapid blood flow environments. The vWF binds to an adhesion ligand, its platelet membrane receptor, glycoprotein Ib-IX-V. Once platelets adhere, they are activated by a complex series of steps including release of adenosine diphosphate and thromboxane A₂, agonists that activate additional platelets and bind P2Y12 receptors and express IIb/IIIa receptors.¹¹ These important receptors are the target of common pharmacologic agents including clopidogrel, prasugrel, and ticagrelor. Platelets provide a catalytic membrane surface for further thrombin generation and clot formation and mediate additional platelet and leukocyte recruitment by mechanisms that include release of microparticles that mediate leukocyte-leukocyte and leukocyte–endothelial cell interactions. When activated, platelets may also form occlusive thrombi in cardiovascular diseases that result in myocardial infarction, stroke, or other acute ischemic syndromes of other organs.¹¹

Endothelial Regulation of Coagulation

The vascular endothelium provides an extensive interface that is critical for both anticoagulant and procoagulants functions as shown in [Figure 27.2](#).¹²⁻¹⁵ Increased shear forces and flow across the endothelium release important anticoagulation agents ([Table 27.2](#)) that include a diverse series of molecules, including nitric oxide, prostacyclin, and ecto-adenosine diphosphatase that degrade the platelet agonist adenosine diphosphate. Additionally, endothelium-derived TFPI is localized on the surface of vascular endothelium and reduces the procoagulant activities of the TF–factor VIIa initiation step.¹³ Heparin sulfate is located on endothelial surfaces and binds antithrombin in the circulation to further provide anticoagulant activity on the vascular surface. Thrombin is scavenged to keep thrombin activity local at the site of vascular injury by another endothelium-bound protein called **thrombomodulin**.¹³ A recombinant form of thrombomodulin is used clinically in Japan for disseminated intravascular coagulation (DIC) and was studied for the treatment of sepsis. Endothelial activation also provides anticoagulation by releasing tPA from the endothelial stores of the Weibel-Palade bodies. The tPA activates plasmin from plasminogen, which, in turn, promotes fibrinolysis, a critical component of vascular patency.¹³

The endothelium is critical for procoagulant effects as well.¹²⁻¹⁵ Endothelial damage following vascular injury or inflammatory responses initiates an array of procoagulant responses that include release of TF, vWF, plasminogen activator inhibitor 1, and PARs. The TF as discussed is critical for initiation of clot formation and thrombin generation. The vWF allows for platelets to bind and activate locally at the site of vascular injury. Plasminogen activator inhibitor 1 prevents plasmin generation and fibrinolysis or clot cleavage. The PARs further signal platelet and a host of other responses by thrombin and other inflammatory mediators.¹²⁻¹⁵

This complex equilibrium of hemostasis continues and is constantly scavenged by many of these important mechanisms to localize hemostasis to the site of vascular injury through this multitude of regulatory mechanisms. Thrombin that is scavenged and bound to thrombomodulin is an important step in the generation of the anticoagulant protein C and TAFI.¹²⁻¹⁵ Activated protein C has multiple antiinflammatory and cytoprotective functions by modulating endothelial protein C receptor and PAR-1 (thrombin receptor).¹⁶⁻¹⁸ The TAFI also exerts antiinflammatory effects by cleaving bradykinin and C5a. Activated protein C has also seen therapeutic use as a therapy in sepsis, along with antithrombin.

Other important factors in hemostatic regulation include the circulating release of vWF that circulates as a multimer complex and is a key adhesive protein for platelets as further discussed in the following text. The vWF is also increased during inflammation and is downregulated by ADAMTS13 (*a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13*), which is also synthesized by endothelial cells.¹⁹ In addition to von Willebrand disease, other vWF abnormalities can occur due to increased degradation that occurs with ventricular assist devices or aortic stenosis, or decreased regulation due to lack of the cleaving enzyme that can occur with hemolytic uremic syndrome or thrombotic thrombocytopenic purpura.

Antithrombin and Proteins C and S

As discussed earlier, thrombin generation for hemostasis is localized because anticoagulant activities of endothelial cells modulate thrombin and other procoagulant proteases as shown in [Figure 27.2](#).²⁰ Other proteins including antithrombin, protein C, and protein S are also important serine proteases that exert anticoagulant and antiinflammatory activities. Protein C circulates in the inactive state in plasma at concentrations of 4 to 5 µg/mL (~0.08 µM) and is proteolytically activated by thrombin to activated protein C.²⁰ Thrombin is again scavenged by binding to endothelial thrombomodulin, activating protein C. Activated protein C binds protein S, and together, they function as a critical anticoagulant by inhibiting factor Va and factor VIIIa, two cofactors in thrombin generation and clot formation (see [Figure 27.2](#)). Activated protein C has been studied in sepsis but is no longer available for that indication.

Inflammation and Coagulation: An Important Link

Coagulation is closely linked to inflammatory responses through complex networks of plasma and cellular components including proteases of the clotting and fibrinolytic cascades.^{21,22} Hemostatic initiation, contact activation, and other pathways amplify inflammatory responses and can collectively produce end-organ damage in the process of their normal function as host defense mechanisms. Coagulation is activated as a central element of both a local and a systemic response to inflammation.²² Surgical injury and additional activation that can occur following cardiopulmonary bypass produces inflammatory responses initiated by contact of blood with the damaged vasculature and other nonendothelial extracorporeal circuits. In vascular

surgical and trauma patients, ischemia-reperfusion injury of organs can also occur.²³ The TF has important proinflammatory effects mediated by thrombin, plasmin, and other proteases.^{21,22,24}

Coagulation Testing

The two tests most frequently used in the perioperative setting, other than blood counts, include the prothrombin time used to evaluate the extrinsic coagulation cascade and the activated partial thromboplastin time, used to evaluate the intrinsic pathway of the classic coagulation system. The prothrombin time is affected by reductions of factors VII, X, V, and prothrombin and is used to measure the effect of warfarin and other agents with vitamin K antagonist activity or the consequences of decreased synthetic activity resulting from hepatic dysfunction. Although prothrombin time is used commonly for perioperative coagulation screening, its use and target values are still controversial and often based on consensus rather than supportive data. Clinical hemostasis may not be adequately evaluated with prothrombin times alone as is apparent in patients with hemophilia who have isolated factor VIII or IX deficiency despite normal prothrombin times.

The partial thromboplastin time is another widely used coagulation test that assesses the intrinsic coagulation cascade. Most partial thromboplastin times are activated using an agent such as ellagic acid, kaolin, or celite.²⁵ The partial thromboplastin time is used to monitor lower doses of unfractionated heparin (up to ~1.0 unit/mL), argatroban, and bivalirudin. At higher heparin concentrations used during cardiac surgery the activated clotting time is used.

Although these coagulation tests are used to evaluate bleeding, they only examine specific components of the overall coagulation cascade and may not be useful to determine the exact cause of the coagulopathy. As should be apparent from the discussion in this chapter, multiple factors influence normal coagulation and lead to coagulopathy in a perioperative setting including hemorrhage and dilution, fibrinolysis, hypothermia, and vascular injury.²⁶ These in vitro laboratory tests do not include the important interaction of platelets with coagulation factors or measurement of the stability of a hemostatic plug as these tests actually measure initial clot formation alone.

Whole blood viscoelastic tests including thromboelastography and thromboelastometry provide multiple insights into coagulation factor interaction and allow assessment of individual characteristics of either individual limbs of hemostasis or global monitoring of coagulation, and they have been widely used in the perioperative and trauma setting.²⁷ The commonly used thromboelastometric variables include coagulation time (in seconds), clot formation time (in seconds), angle (in degrees), maximum clot firmness (in millimeters), and lysis time (in seconds). Coagulation time represents the onset of clotting, whereas clot formation time and angle both represent the initial rate of fibrin polymerization. Maximal clot firmness is a measure of the maximal viscoelastic strength of clot. Lysis time is used for the diagnosis of premature lysis or hyperfibrinolysis.

Perioperative Changes in Coagulation

In surgical patients, there are multiple perioperative events that influence hemostatic function and produce coagulopathy. Vascular and tissue injury are important contributors to bleeding, but with significant hemorrhage and resuscitation with crystalloids/colloids, a dilutional coagulopathy can occur resulting from significant reductions in platelet counts/dilutional thrombocytopenia and factor deficiencies. The end result is a multifactorial reduction of thrombin generation, hypofibrinogenemia, and lack of other factors that reduce clot formation and this state is accompanied by increased fibrinolysis. The poorly formed fibrin clot contributes to bleeding, and increasing hemodilution simultaneously leads to a reduction in important proteins that balance hemostasis and anticoagulation, including antithrombin, TFPI, protein C, protein S, and thrombomodulin.²⁰ These complex hemostatic changes also contribute to the coagulopathic state.

Hemostatic Therapy

When perioperative bleeding occurs, we use red blood cells and hemostatic factors that include plasma/fresh frozen plasma, platelet concentrates, and cryoprecipitate (see further discussion in [Chapters 28](#) and [29](#)). Postoperatively, an important anabolic state occurs that increases hemostatic factors for several days. Many of the factors that modulate this acute inflammatory response postoperatively will increase cytokines and other

important signaling molecules that will increase cellular and protein synthesis. These changes will increase bone marrow production of red blood cells and platelets; increase fibrinogen and vWF; and create a hypercoagulable, procoagulant response. This is important and also integral to the current practice of use of anticoagulation for postoperative venous thromboembolic prophylaxis because of the increased thrombotic potential postoperatively.

Postoperative Hypercoagulability

The complex balance in hemostatic function can be readily altered in the postoperative setting. Because of loss of vascular endothelial function and other prohemostatic changes, venous and arterial thromboembolic events increase with age.²⁰ Acute myocardial infarction and thrombotic stroke can occur following disruption of atherosomatous plaques in coronary and cerebral arteries. The rupture of a lipid core expresses multiple procoagulant molecules that expose TF, lead to thrombin generation, and activate platelets, all leading to coagulation. Embolic and other thrombotic events occurring locally at the site of an atherosclerotic plaque can result in myocardial infarction and ischemic stroke. Additional abnormalities present in cancer patients can also initiate coagulation and other prothrombotic events that increase the risk of venous thromboembolic events.

Congenital coagulation factor deficiencies or polymorphisms of critical proteins including hemophilia A or B, vWF, antithrombin, protein C, protein S, factor V Leiden, and prothrombin (polymorphisms) are more uncommon in the perioperative period but do occur and often require specific management strategies—these conditions can present with either bleeding or thrombosis. Acquired or congenital absence of the anticoagulant proteins reduces normal clot formation and regulation, and untreated patients are at an increased risk for venous thromboembolic problems, including pulmonary embolism. A more common occurrence is the antiphospholipid syndrome that is caused by the lupus anticoagulant, which is a phospholipid-binding antibody. Of note is that patients may present with prolonged prothrombin times and partial thromboplastin times, but they are actually hypercoagulable.²⁰

Disseminated Intravascular Coagulation

The DIC is a coagulation disorder that occurs when pathologic activation of the hemostatic systems occurs following major tissue injury associated with trauma; sepsis due to bacterial, fungal, or viral causes; or other complex occurrences of vasculopathy that occurs in eclampsia.^{28,29} Activation of the coagulation system occurs; however, the multiple endothelial and circulating anticoagulation mechanisms that are part of hemostatic mechanisms are unable to inhibit systemic thrombin formation. The pathophysiologic changes of DIC include hemostatic activation characterized by microvascular deposition of clot/fibrin and thrombotic microangiopathy. Platelets are also activated and are sequestered into the pulmonary, renal, hepatic, and other organs, depleting platelets, fibrinogen, antithrombin, and other hemostatic factors. The end result is an imbalance, resulting in either a hemorrhagic coagulopathy or procoagulant state. The diagnosis of DIC is based on clinical and laboratory findings that follow.

Thrombocytopenia occurs in DIC due to the mechanisms described; however, in the perioperative setting and in critically ill patients, thrombocytopenia is common. The most common cause of perioperative thrombocytopenia is the dilutional effect following volume resuscitation; nonetheless, current strategy is to treat massive transfusion coagulopathy in the setting of trauma and surgery, and this strategy includes the administration of platelets and other clotting factors (platelets, fresh frozen plasma, and/or cryoprecipitate). Coagulation factors are also decreased in DIC, and this presents clinically with prolonged prothrombin times or activated partial thromboplastin times. In DIC and other similar syndromes, such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome, decreased levels of the protease ADAMTS13 can occur. This protease converts ultralarge von Willebrand multimers in plasma that are otherwise prothrombotic. The uncleaved multimers increase vascular platelet sequestration and the subsequent development of thrombotic microangiopathy and organ dysfunction.^{28,29} Fibrinogen levels are also used in diagnosing DIC, but, despite consumption, plasma levels are affected by multiple factors and may only detect severe cases of DIC.²⁹ D-dimers are also used in the diagnosis of DIC and are fragments of cross-linked fibrinogen that are cleaved by fibrinolysis. D-dimer levels are increased not only in DIC but also with venous

thromboembolism and following any recent trauma or surgery; thus, they may not be helpful in the surgical patient. Finally, antithrombin levels decrease in DIC and have been suggested as a therapeutic target to replete. Overall, in DIC, removal of the underlying source of the problem, treatment with antibiotics for infections, and perhaps instituting anticoagulation in efforts to reduce further consumption of coagulation factors are critical considerations.^{28,29}

Conclusion

The physiology of coagulation and hemostatic regulation are critical homeostatic mechanisms that are critical to survival. The interaction of the vasculature with both circulating plasma proteins and platelets is important for understanding the physiology of the hemostatic system, and the ability to modulate hemostasis and respond to vascular injury. Multiple disease states including atherosclerosis, acquired coagulation deficiencies, and the pharmacologic effects of many therapies used for atherosclerotic vascular disease may contribute to the problems of perioperative hemostatic management. Our goal is to reduce bleeding without the adverse effects of thrombosis. This concern is complicated by the interaction of coagulation and subsequent inflammatory responses. As discussed in the other chapters on coagulation that follow, pharmacologic interventions, based on the authors' understanding of the physiology of hemostasis, it is critical for the perioperative management and further discussed in other chapters.

Blood Products and Blood Components

Jerrold H. Levy

In 2015, 11.3 million whole blood and red blood cells (RBCs), 2.1 million apheresis platelets, and 3.6 million plasma components were transfused.¹ While blood transfusions are considered to be standard of care in perioperative management, overall data supporting their efficacy has never been demonstrated in a prospective controlled clinical trial in the manner that drugs are approved for clinical use. For surgical patients, the relative benefit/risk of transfusions has become part of informed consent because blood products have risks, costs, supply, and inventory considerations.

Reports of adverse events including transfusion fatalities from both the Serious Hazards of Transfusion assessments in the United Kingdom and the U.S. Food Drug Administration (FDA) Center for Biologics Evaluation and Research evaluations in the United States suggest that transfusion-related deaths appear to be declining.^{1,2} Previous hemovigilance reports including the Serious Hazards of Transfusion evaluations reported that transfusion-related acute lung injury (TRALI) was the most common cause of mortality and morbidity associated with transfusion. However, recent data reported from 2013 to 2017 noted that transfusion-associated circulatory overload (TACO) cases caused the highest number of reported fatalities (32%), followed by the combined TRALI and possible TRALI (30%).¹ Less common causes reported included microbial contamination (12%), hemolytic transfusion reactions due to non-ABO incompatibilities (11%) and ABO incompatibilities (7%), anaphylactic reactions (6%), and hypotensive reactions (2%).¹ Of note is that both known risks and ongoing potential for new viral contaminants (unknown risks) are likely associated with transfusion.

However, as reported to the FDA, the blood supply is safer today than at any time in history which is due to ongoing advances in donor screening, improved testing, automated data systems, and efforts at blood conservation and patient blood management that have changed transfusion medicine practices.¹ As a result, in 2015, there was a 14% decrease in transfusions of RBCs and whole blood in the United States since 2013.¹ Nonetheless, despite the relative safety of our blood supply, transfusions have the potential for adverse events including infections and multiple other adverse events that include increased hospital and intensive care unit (ICU) length of stay. Of importance is that most data and studies evaluating transfusions are based on retrospective studies and include observational data from critically ill patients already predestined to adverse outcomes. Other important issues that transfusions pose in addition to the risks are the costs and blood inventory required for managing patients. Patient blood management initiatives have evolved from ongoing work by many different interests to develop evidence-based transfusion practices and strategies to reduce bleeding and the need for allogeneic transfusions. In the perioperative setting, multiple specialties and health care providers influence the decision to transfuse a patient. Most blood conservation strategies focus on RBC transfusions and specific hemoglobin concentration thresholds with far less emphasis on coagulation factors whose effects are more difficult to measure. Because the decision to transfuse a patient is complex, rarely can a single laboratory value be an absolute indicator of the need for transfusion. Decisions to transfuse require multiple clinical considerations including risk factors, comorbidities, hemodynamic stability, and the rate of bleeding, especially in hemorrhagic shock, a common perioperative emergency.

The appropriate use of blood products, including RBCs, fresh frozen plasma (FFP), cryoprecipitate, or platelet transfusions, continues to be defined in surgical and trauma patients. In European countries, purified factor concentrates are increasingly used instead of transfusion factors that include fibrinogen and prothrombin complex concentrates (PCCs). Guidelines for bleeding management and transfusions in surgical and trauma patients have been reported, including those from the American Society of Anesthesiologists as noted in **Table 28.1**.³⁻⁵

As a reminder, before the elective transfusion of RBCs, crossmatching occurs. This process is performed by mixing the patient's blood sample after an antibody screen for blood type with a sample of RBCs from the donor unit using a section of tubing from the blood bag. The blood after mixing is examined for hemolysis and/or clumping (also called agglutination), which would signify a positive test result and the presence of an additional antibody.

Blood products are administered routinely in perioperative bleeding management. Despite guidelines, most physicians either have not read the guidelines or have difficulty following them. Clinicians often resort to empiric therapy because laboratory tests may be difficult to obtain or take too long to obtain results, do not determine platelet defects, or due to concerns about obtaining blood products from the blood bank in a timely fashion for high-risk patients. The role of transfusion in massive transfusion protocols following trauma and/or major hemorrhage will be considered in a separate chapter. However, in a critically ill patient, the importance of a multimodality approach is important rather than focusing on the individual transfused components.

The American Society of Anesthesiologists established the Task Force on Blood Component Therapy to develop evidence-based guidelines for transfusing RBCs, platelets, FFP, and cryoprecipitate in perioperative settings. Specific guidelines were developed according to a defined methodology.⁵ The recommendations of the task force were reported and can be found in [Table 28.1](#). Although these guidelines are reported as recommendations, there are also other important considerations regarding the use of specific blood units in surgical patients that need to be considered. The rationale for transfusion of individual blood components will also be considered.

TABLE 28.1

Recommendations for transfusion of non-red blood cell products****

Platelets

- Platelet transfusion may be indicated despite an apparently adequate platelet count or in the absence of a platelet count if there is known or suspected platelet dysfunction (*e.g.*, the presence of potent antiplatelet agents, cardiopulmonary bypass, congenital platelet dysfunction, and bleeding)[†]
- In surgical or obstetric patients, platelet transfusion is rarely indicated if the platelet count is known to be greater than $100 \times 10^9/l$ and is usually indicated when the count is less than $50 \times 10^9/l$ in the presence of excessive bleeding.

Plasma products (*e.g.*, FFP, PF24, or thawed plasma)[‡]

- FFP is indicated:
 - For correction of excessive microvascular bleeding (*i.e.*, coagulopathy) in the presence of an INR greater than 2.0, in the absence of heparin
 - For correction of excessive microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than one blood volume (approximately 70 ml/kg) and when PT or INR and aPTT cannot be obtained in a timely fashion
 - For urgent reversal of warfarin therapy when PCCs are not available
 - For correction of known coagulation factor deficiencies for which specific concentrates are unavailable
- FFP is not indicated:
 - If PT or INR and aPTT are normal
 - Solely for augmentation of plasma volume or albumin concentration
 - Administer FFP in doses calculated to achieve minimum of 30% of plasma factor concentration. Four to five platelet concentrates, 1 unit single-donor apheresis platelets, or 1 unit fresh whole blood[§] provide a quantity of coagulation factors similar to that contained in one unit FFP

Cryoprecipitate

- Cryoprecipitate is indicated:
 - When a test of fibrinogen activity indicates a fibrinolysis
 - When the fibrinogen concentration is less than 80-100 mg/dl in the presence of excessive bleeding^{||}
 - As an adjunct in massively transfused patients when fibrinogen concentrations cannot be measured in a timely fashion

- For patients with congenital fibrinogen deficiencies
- Whenever possible, decisions regarding patients with congenital fibrinogen deficiencies should be made in consultation with the patient's hematologist
- Transfusion of cryoprecipitate is rarely indicated if fibrinogen concentration is greater than 150 mg/dl in nonpregnant patients.
- Treat bleeding patients with von Willebrand disease types 1 and 2A with desmopressin and subsequently with specific VWF/FVIII concentrate, if available. Cryoprecipitate should be administered if there is no response to or availability of desmopressin or VWF/FVIII concentrate
- Treat bleeding patients with von Willebrand disease types 2B, 2M, 2N, and 3 with specific VWF/FVIII concentrate, if available. If VWF/FVIII concentrate is not available, cryoprecipitate is indicated

Abbreviations: aPTT, activated partial thromboplastin time; FVIII, factor VIII; INR, international normalized ratio; PCC, prothrombin complex concentrate; PT, prothrombin time.

*This table displays some transfusion criteria that may suggest when to transfuse with the above blood products. The decision to apply some or all the criteria shown in this table is dependent upon the clinical context and judgment of the practitioner. The table is not intended as a mandatory or exhaustive list.

Scientific evidence is insufficient to evaluate the perioperative benefit of applying the earlier suggested criteria.

**Note current recommendations for fibrinogen repletion in the bleeding patient are targeting levels of 150–200 mg/dL or higher (as noted in [References 20, 32–35](#)).

†The proper dose of platelets should be based on recommendations of the local institutional transfusion committee.

‡The FFP refers to plasma frozen within 8 h after phlebotomy, PF24 refers to plasma frozen within 24 h after phlebotomy, and thawed plasma refers to FFP stored up to 5 days at 1°–6°C after thawing. In the United States, it is a common practice to use these terms interchangeably. In this table, the term FFP refers to the use of any of these plasma products.

§Many institutions in the United States no longer have fresh whole blood available from the blood bank.

||Cryoprecipitate may be indicated at a higher fibrinogen concentration in actively bleeding obstetric patients. Transfusion Therapy for Bleeding

Volume replacement in the perioperative setting when there is critical bleeding requires the use of replacement therapy. Although crystalloid, colloid, and RBCs may be initially administered, none of these products provide coagulation factors including platelets and can exacerbate coagulopathy. Severe bleeding requires the use of a massive transfusion protocol that includes multiple blood products as whole blood is in nonmilitary settings may not be readily available and includes RBCs, FFP, platelets, and cryoprecipitate. With major bleeding in surgical in trauma patients, the goal is to restore circulating levels of hemostatic factors. The increasing use of point of care testing with viscoelastic assays including rotational thromboelastometry and thromboelastography. Following massive transfusion therapy, hypothermia and acidosis frequently occur, further complicating bleeding. Thus, temperature and pH must be monitored and corrected during any ongoing transfusion effort.

Red Blood Cells

There is no single minimum acceptable hemoglobin level that can be applied to all patients when deciding when to transfuse RBCs. Chronic anemia is better tolerated than acute anemia. However, with acute anemia, compensatory mechanisms that increase cardiac output and improve oxygen transport depend on the patient's cardiovascular reserve. In surgical patients with heart failure and/or flow-restricting lesions, compensation during acute anemia may be limited. Multiple factors should be considered including intravascular volume,

whether the patient is actively bleeding, and the need for improvement in oxygen transport. For instance, the patient receiving multiple inotropic agents and requiring an intra-aortic balloon pump who is anemic following surgery may need RBC transfusion to maintain a higher hemoglobin level than an otherwise healthy and hemodynamically stable patient. The decision to transfuse must weigh the risks of transfusion against the need for improved oxygen-carrying capacity in recovery from trauma, surgery, or illness.⁵ The American Society of Anesthesiologists Task Force on Perioperative Blood Transfusion and Adjuvant Therapies noted in its recommendations that transfusion of RBCs should usually be administered when the hemoglobin concentration is low (eg, <6 g/dL in a young, healthy patient), especially when the anemia is acute. The RBCs are usually unnecessary when the hemoglobin concentration is more than 10 g/dL.⁵ These conclusions may be altered in the presence of anticipated blood loss or active critical (ie, myocardium, central nervous system, or renal) or target organ ischemia. Determining whether intermediate hemoglobin concentrations (ie, 6 to 10 g/dL) justify or require RBC transfusion should be based on any ongoing indication of organ ischemia, potential or actual ongoing bleeding (rate and magnitude), the patient's intravascular volume status, and the patient's risk factors for complications of inadequate oxygenation. These risk factors include a low cardiopulmonary reserve and high oxygen consumption.⁵ Hemoglobin triggers for transfusion are not to be taken as absolute; patients with significant cardiac disease should be transfused if signs or symptoms of inadequate myocardial oxygenation appear.

Patient blood management strategies have increasingly become an area of focus to reduce allogeneic blood exposure.⁶ However, most of these strategies focus primarily on RBC transfusions and specific hemoglobin values without defining a clinically meaningful parameter that includes an appropriate clinical indicator or other meaningful threshold for RBC transfusion. Current studies that address specific hemoglobin thresholds do not examine critical physiologic parameters such as measures of oxygen delivery and/or oxygen debt.⁶ Because clinicians cannot readily measure specific oxygen delivery or oxygen debt, they treat specific hemoglobin thresholds instead. Many reported studies note that restrictive thresholds for transfusions of RBCs are noninferior to liberal thresholds in most clinical scenarios.¹

One important aspect of adverse events associated with RBC transfusion relates to the age of RBCs transfused and changes that occur in stored RBCs as they age (the so-called storage lesion).⁶⁻⁸ Although RBCs are stored for up to 42 days after donation, biochemical changes occur in RBCs as they age. Studies suggest that RBC units stored for long periods (often described as >14-21 days) may lead to adverse effects. The mechanisms for these adverse events include senescent RBC fragments, impaired nitric oxide production, and increased nitric oxide scavenging by stored RBCs, together with reduced nitric oxide synthesis by dysfunctional endothelial cells. However, many of the studies demonstrating adverse outcomes are from large retrospective studies with all of the inherent problems associated with retrospective analyses and not all studies are in agreement.

Red Blood Cell Storage Lesions

The RBCs develop a complex series of biochemical and metabolic changes during storage in the blood bank that include depletion of adenosine triphosphate and of 2,3-diphosphoglycerate, membrane phospholipid vesiculation and shedding, protein oxidation, and lipid peroxidation of the cell membrane. As the blood ages, RBCs undergo shape changes with increased fragility that may impair microcirculatory flow. Because of increased red cell–endothelial cell interaction, bioreactive lipids and other substances are released that may initiate inflammatory responses leading to TRALI, as described in more detail in the following text. These complex changes can also decrease oxygen delivery and increase hemolysis. When free hemoglobin is released from the RBC, it binds to nitric oxide, and this nitric oxide scavenging causes endothelial dysfunction and additional proinflammatory events including generation of oxygen free radicals.⁸

Red Blood Cell Storage and Tissue Oxygenation Parameters

Transfusion of RBCs is used therapeutically to increase the oxygen-carrying capacity of blood and thereby improve oxygen delivery to tissues. Multiple retrospective studies have attempted to evaluate the clinical outcomes of critically ill patients receiving fresh compared to older blood. There are multiple analyses in the

literature that examine the clinical effect of blood storage in multiple patient groups including trauma patients, ICU patients, and patients undergoing cardiac surgery or those with acute heart disease with variable effects. Most of the studies are observational based, and there is clinical equipoise regarding results and previous systematic reviews and a meta-analysis conducted in critically ill patients have been inconclusive.

The Red Cell Storage Duration Study, a prospective, randomized clinical trial of complex cardiac surgical procedures reported red-cell storage was not associated with significant differences in the change in multiorgan function that compared RBC transfusions stored for 10 days or compared to RBCs stored for 21 days or more among patients 12 years of age. Other clinical studies include the TRANSFUSE trial, which reported that the age of transfused red cells did not affect 90-day mortality among critically ill adults. Although RBC transfusions are used extensively in the perioperative setting, all transfusions can be associated with adverse events.

Plasma/Fresh Frozen Plasma

Plasma is transfused for multiple indications, especially in surgical and trauma patients. Plasma use has increased with the increasing understanding of its role in managing the coagulopathy associated with massive transfusion (massive transfusion is covered in detail in a separate chapter). Currently, plasma and FFP are used to replace volume and coagulation factors during massive transfusion, to treat or prevent future bleeding during surgery and invasive procedures, to reverse warfarin therapy in patients, and for treatment of coagulation factor abnormalities where specific concentrates are not available. The FFP is plasma frozen within 8 hours of collection. However, many plasma units transfused in the United States are actually frozen within 24 hours after phlebotomy and called plasma FP24. The difference is that cryoprecipitate can be obtained from FFP but not plasma; nonetheless, experts agree that FFP and plasma can be transfused interchangeably and most clinicians refer to both products as FFP, despite this subtle distinction. Thawed plasma stored for up to 5 days before administration is also commonly used for transfusion. Plasma is used throughout the text to refer to either FFP or thawed plasma, as most scientific evidence supporting and distinctions among different plasma transfusion practices is limited.

Following collection of a unit of blood, FFP is the plasma that remains after RBC and platelet removal and contains blood coagulation factors, fibrinogen, and other plasma proteins in a volume of 170 to 250 mL that is then frozen and can be stored for up to 1 year. Most plasma administered in perioperative settings is actually FP24. Before administration, the plasma must be thawed in a water bath at 37°C, which takes about 30 minutes. After thawing, the units of FFP are stored at 1°C to 6°C and are transfused within 24 hours. The FFP should be administered through a component administration set with a 170-micron filter. If not used within 24 hours, it can be relabeled as “thawed plasma” and stored at 1°C to 6°C for an additional 4 days. Thawed plasma maintains normal levels of all factors except factor V, which falls to 80% of normal and factor VIII, which falls to 60% of normal during storage.² Because these levels are above the in vivo threshold for normal hemostatic function for these factors and factor VIII is an acute phase reactant, thawed plasma can be used as a substitute for FFP.²

The FFP is used for treating bleeding because of coagulopathies that are associated with a prolongation of either the activated partial thromboplastin time (PTT) or prothrombin time (PT)/international normalized ratio (INR) greater than 1.5 times normal, or a specific coagulation factor assay of less than 25%.⁵ The FFP is often used to reverse the effect of warfarin before surgery or during active bleeding episodes (see [PCCs](#) later in this chapter and see also [Chapter 29](#)). When FFP is indicated, it should be administered in a dose calculated to achieve a minimum of 30% of plasma factor concentration. Ten to 15 mL/kg of FFP will generally result in a rise of most coagulation proteins by 25% to 30% (or increases in 0.25-0.3 U/mL), although a dose of 5 to 8 mL/kg may be adequate to urgently reverse warfarin anticoagulation but varies based on the initial levels of the vitamin K-dependent coagulation factors.⁵ The FFP is also an important part of a transfusion algorithm for posttraumatic bleeding that is covered in more detail in the chapter on massive transfusion.

Guidelines exist in many countries for the use of plasma and include active bleeding preoperatively, invasive procedures in patients with acquired coagulation abnormalities, thrombotic thrombocytopenic purpura, and patients with a congenital coagulation factor deficiency where specific factor concentrates are

not available. Published plasma transfusion indications are listed in [Table 28.1](#). However, for immediate correction of vitamin K antagonists (eg, warfarin), four-component PCCs should be used as will be subsequently discussed.

Plasma is overused in surgery most often because of the empirical nature of transfusion therapy. The most common cause of bleeding after surgery is platelet dysfunction. Furthermore, the PT and PTT, which are widely used to evaluate bleeding, have never been demonstrated to accurately reflect the cause of bleeding in surgical patients. Indeed, the PT and PTT can be abnormal in patients who are not bleeding. Despite the widespread use of plasma, there is little evidence for its effectiveness outside of trauma patients requiring massive transfusion.^{10,11} Analyses of randomized controlled trials have been unable to demonstrate consistent evidence of benefit for plasma in most clinical scenarios.^{10–12} The use of plasma in many situations to treat elevated INRs, especially when the INR is less than 1.7 is problematic, as these patients may not be at risk for bleeding and the lowest INR obtainable with plasma is approximately 1.5 because that is the INR of plasma/FFP.¹³ A recent survey evaluating approximately 5,000 plasma transfusions reported that 43% were administered in the absence of bleeding in efforts to correct abnormal coagulation tests preoperatively or before invasive procedures, and in 31% of cases where plasma was given, the INR was 1.5 or less.¹⁴

Plasma transfusions, like all blood products, have the potential for adverse effects. A recent study reported a 6% incidence of TACO in ICU patients, which can occur when patients with heart failure/ventricular dysfunction are given as little as 2 to 4 units of plasma.^{1,15} Both TRALI and TACO are major causes of mortality and morbidity from blood transfusion.^{1,2} However, for TRALI, the incidence has declined with the use of plasma from male donors or female donors who have no history of pregnancy.^{16,17} The TRALI and TACO will be considered in more detail later.

Solvent/Detergent-Treated Plasma

Human pooled plasma that has been solvent/detergent (S/D) treated is now available commercially in a sterile, frozen solution of pooled human plasma from donors that has been treated with an S/D process. This method of preparation not only kills certain viruses and minimizes the risk of serious virus transmission but also removes other agents, including cellular debris and lipid contaminants. This process is thought to reduce the risk of TRALI. The plasma used to manufacture this product is collected from specific pools of US donors who have been screened and tested for diseases transmitted by blood and determined to be suitable donors. Collected donor pools include approximately 500 to 1,600 donors. This product is used extensively in Europe and other countries and approximately 13 million have been administered outside of the United States. In the United States, this product is indicated for replacement of coagulation factors with acquired deficiencies due to liver disease, undergoing cardiac surgery and liver transplantation, and for plasma exchange in patients with thrombotic thrombocytopenic purpura. Administration is based on ABO blood group compatibility.

The collection and testing process for this pooled and treated plasma is extensive; unlike other blood products, it is extensively purified and tested. The product is manufactured from US plasma donations that are extensively tested for viral markers with each pool limited to 630 to 1,520 individual donors. Frozen plasma units are thawed, pooled, filtered through a 1-micron pore membrane, and then treated with S/D reagents (1% tri[n-butyl] phosphate and 1% octoxynol for 1–1.5 hours at +30°C [86°F]) to inactivate enveloped viruses. The S/D reagents are removed by sequential oil and solid phase extraction procedures that also remove prions. After sterile filtration, the product is filled into blood bags, labeled, deep-frozen, and stored at 4°F. The S/D treatment step has been shown to effectively inactivate relevant pathogenic and enveloped viruses.

Leukocyte antibodies are not detected in S/D plasma because the process dilutes white blood cell antibodies and soluble human leukocyte antigens (HLAs) are present in the product, neutralizing the antibodies. This pooled and treated plasma product has not been associated with TRALI, with more than 13 million units transfused to date.

Cryoprecipitate

In the early 1960s, attempts to create an improved factor VIII concentrate led to the development of cryoprecipitate. Cryoprecipitate forms when frozen plasma is allowed to thaw slowly at 1°C to 10°C;

cryoprecipitate is rich in fibrinogen, factor VIII, and factor XIII but also contains other factors. This product was introduced as a therapy for patients with hemophilia A^{18,19}, however, its major use today is to replete fibrinogen levels during coagulopathies. Cryoprecipitate contains fibrinogen and high concentrations of factor VIII, von Willebrand factor, and factor XIII.

Cryoprecipitate is composed of the insoluble proteins that precipitate when FFP is thawed and is named for that process. The residual volume of cryoprecipitate (~15 mL) is refrozen and stored and has a shelf life of ~36 months frozen. However, once thawed, it must be used within 4 hours and cannot be refrigerated. Cryoprecipitate contains therapeutic amounts of factor VIII:C, factor XIII, von Willebrand factor, and fibrinogen. Each bag of cryoprecipitate contains 80 to 100 units of factor VIII:C, 150 to 200 mg of fibrinogen, significant amounts of factor XIII, and von Willebrand factor, including the high-molecular-weight multimers. Cryoprecipitate is used not only to increase fibrinogen levels depleted because of massive hemorrhage or coagulopathy but also for the treatment of congenital or acquired factor XIII deficiency. For fibrinogen replacement therapy, in Europe, specific fibrinogen concentrates are available (see the following text); however, 1 unit of cryoprecipitate per 10 kg body weight increases plasma fibrinogen by roughly 50 to 70 mg/dL in the absence of continuing consumption or massive bleeding.^{19,20} The minimum hemostatic level of fibrinogen is traditionally suggested to be around 100 mg/dL but normal fibrinogen levels are 200 mg/dL and higher, and higher levels of fibrinogen may be important for clot formation (see “[Fibrinogen Concentrates](#)” section). Because cryoprecipitate does not contain factor V, it should not be the sole replacement therapy for disseminated intravascular coagulopathy, which is almost always associated with a variety of factor deficiencies and thrombocytopenia. Because fibrinogen is an important determinant of hemostatic function and clot strength, fibrinogen levels should be routinely evaluated in bleeding patients especially following multiple transfusions. Hypofibrinogenemia itself can cause a prolonged PT and PTT, and FFP transfusion alone may not provide sufficient repletion. Cryoprecipitate is likely underused in cardiac surgical patients who are bleeding and “refractory” to standard FFP and platelets. Cryoprecipitate has been withdrawn from many European countries due to safety concerns, primarily the transmission of pathogens, and because it is a multidonor blood product. Instead, commercial fibrinogen preparations are available for fibrinogen replacement therapy. The fibrinogen concentrates used for repleting fibrinogen levels are free of known pathogens, stored as a lyophilized product, and can be readily administered when required. Nevertheless, cryoprecipitate remains available for hemostatic therapy in several countries, including the United States, Canada, and the United Kingdom. An adult dose of cryoprecipitate is ~10 units obtained from 10 different donors, and is equivalent to ~2 g fibrinogen.

Platelet Concentrates

Platelets that are used clinically are either pooled random-donor platelet concentrates or single-donor apheresis and can be stored for up to 5 days. In medical patients, a platelet count of 10,000/ μ L is a typical threshold for prophylactic platelet transfusion (normal platelet count ranges from 150,000 to 400,000 platelets per μ L), but the optimal platelet count or dose is still being evaluated. Consensus descriptions suggest the platelet count for therapeutic transfusions to control or prevent bleeding with trauma or surgical procedures requires a higher transfusion trigger of 100,000/ μ L for neurosurgical procedures and between 50,000/ μ L and 100,000/ μ L for other invasive procedures or trauma. Many transfused products, including platelets, undergo leukoreduction to reduce alloimmunization rates, cytomegalovirus transmission, and febrile transfusion reactions. Whether leukoreduction reduces immunomodulatory effects of transfusion (ie, decreases infection rates and cancer recurrence) is still controversial, as is the use of universal leukoreduction as the procedure, is associated with significant cost.

Platelet concentrates can be prepared either from whole blood or by apheresis. For many years, the use of platelet concentrates was the standard for platelet administration, and this required exposure to multiple donors, as 10 units of platelets required 10 different donors. An important advantage of platelets collected by apheresis is that a sufficient enough number can be collected from a single donor while an equivalent number of platelets require pooling of at least 4 to 6 whole blood-derived platelets concentrates. Reducing donor exposures by using apheresis platelets also has the potential advantages of reducing transfusion-transmitted infections and platelet alloimmunization where antibodies form because platelets have many antigens besides

ABO.^{21,22} Testing has reduced the infectious risk to low levels. The quality of apheresis platelets is similar to pooled random-donor platelets concentrates, these two products can be used interchangeably based on availability and cost considerations.^{21,22} Platelets are stored at 22°C rather than at the 4°C storage used for red cell storage and have a shelf life of ~5 days. However, there remains significant risk of bacterial infection with platelet administration because storage at 22°C is permissive for bacterial growth. Some studies have suggested a reduction in bacterial transmission by transfusion with the use of single-donor platelets.^{21,22} However, both the American College of Pathologists and the American Association of Blood Banks (AABB) have mandated testing of all platelet products for bacteria.^{21,22}

A summary of platelet transfusion recommendations as reported by the AABB are listed in [Table 28.2](#).

TABLE 28.2

Recommendations for platelet transfusions

Recommendation 1

The AABB recommends that platelets should be transfused prophylactically to reduce the risk for spontaneous bleeding in hospitalized adult patients with therapy-induced hypoproliferative thrombocytopenia. The AABB recommends transfusing hospitalized adult patients with a platelet count of 10×10^9 cells/L or less ($100,000/\mu\text{L}$) to reduce the risk for spontaneous bleeding. The AABB recommends transfusing up to a single apheresis unit or equivalent. Greater doses are not more effective, and lower doses equal to one-half of a standard apheresis unit are equally effective. (Grade: strong recommendation; moderate-quality evidence)

Recommendation 2

The AABB suggests prophylactic platelet transfusion for patients having elective central venous catheter placement with a platelet count less than 20×10^9 cells/L ($20,000/\mu\text{L}$). (Grade: weak recommendation; low-quality evidence)

Recommendation 3

The AABB suggests prophylactic platelet transfusion for patients having elective diagnostic lumbar puncture with a platelet count less than 50×10^9 cells/L ($50,000/\mu\text{L}$). (Grade: weak recommendation; very-low-quality evidence)

Recommendation 4

The AABB suggests prophylactic platelet transfusion for patients having major elective nonneuraxial surgery with a platelet count less than 50×10^9 cells/L ($50,000/\mu\text{L}$). (Grade: weak recommendation; very-low-quality evidence)

Recommendation 5

The AABB recommends against routine prophylactic platelet transfusion for patients who are nonthrombocytopenic and have cardiac surgery with cardiopulmonary bypass. The AABB suggests platelet transfusion for patients having bypass who exhibit perioperative bleeding with thrombocytopenia and/or evidence of platelet dysfunction. (Grade: weak recommendation; very-low-quality evidence)

Recommendation 6

The AABB cannot recommend for or against platelet transfusion for patients receiving antiplatelet therapy who have intracranial hemorrhage (traumatic or spontaneous). (Grade: uncertain recommendation; very-low-quality evidence)

Abbreviation: AABB, American Association of Blood Banks.

Data from Kaufman RM, Djulbegovic B, Gernsheimer T, et al. Platelet transfusion: a clinical practice guideline from the AABB. *Ann Intern Med.* 2015;162(3):205-213.

Alloimmunization

Allogeneic blood transfusions are in many ways similar to organ transplantation. Transfusing cells from one patient (the donor) to the recipient introduces multiple foreign cells, antigens, and other potential contaminants. An immunocompetent recipient often develops variable immune responses to the transfused

agents that include graft versus host disease (to be considered later in this chapter). Multiple other antigens that are not routinely crossmatched for platelets and responsible for alloimmunization include HLAs, class I shared by platelets and leukocytes and class II present on some leukocytes; granulocyte-specific antigens; platelet-specific antigens (human platelet antigen); and RBC-specific antigens. Platelets are crossmatched only to RBC-specific antigens. The spectrum of additional antigenic components in platelets is why leukoreduction is part of an important management strategy.

Leukoreduction

Leukoreduced platelet and RBC products have many potential benefits. By reducing additional leukocyte exposure, sensitization and antibody formation to different white blood cell antigens (alloimmunization) is reduced.^{21,23} Cytomegalovirus transmission is also reduced by reducing leukocyte burden, and as a result, there is also a reduction in febrile transfusion reactions.^{22,23} Other potential benefits of leukoreduction include decreased exposure to white cells that potentially contribute to immunomodulatory effects of transfusion (transfusion-related immunomodulation) that may present as increased risk for postoperative infections and tumor metastasis formation in cancer surgery. There is extensive controversy about the immunomodulatory effects of transfusions as patients often have multiple other risk factors that contribute to outcomes.^{21,23} Several countries including Canada and many medical centers have instituted universal leukoreduction of the blood supply.

Graft Versus Host Disease

In cancer patients and certain pediatric populations, platelets are irradiated to prevent transfusion-related graft versus host disease, a potentially fatal complication of transfusion. Graft versus host disease occurs more commonly after a bone marrow or stem cell transplant, or following platelet transfusions where viable white cells from the donor regard the recipient's body as foreign and create acute inflammatory responses and tissue and organ injury by attacking the recipient's body. For platelet transfusions, γ -irradiation is performed for patients receiving allogeneic stem cell transplants, for patients receiving blood products from related donors, and for patients who are severely immunocompromised, usually because of their disease or its treatment (eg, patients with Hodgkin disease or other lymphomas).^{21,22,24}

Indications for Platelet Transfusions and Transfusion Triggers

In medical patients, a platelet transfusion trigger of approximately 10,000 platelets/ μ L in efforts to prevent bleeding is often described. However, data and prospective studies to evaluate the effects of platelet dose on hemostasis and rates of platelet use overall for perioperative management are often based on consensus guidelines rather than clinical studies. There are three important areas of controversy regarding the use of platelet transfusions without active bleeding.²³ First, the optimal prophylactic platelet dose to prevent thrombocytopenic bleeding even in medical patients is not well known. Second, the exact platelet count threshold that requires transfusion of platelets is not known. Finally, whether prophylactic platelet transfusions are superior to therapeutic platelet transfusions in surgical patients is not known.

A review of clinical trials²⁵ suggests that in hematologic malignancies, a target platelet count of more than 10,000 platelets/ μ L is acceptable in preventing spontaneous bleeding caused by thrombocytopenia alone, although platelet dosing was not found to influence bleeding when administered prophylactically.^{26,27}

Guidelines for platelet transfusions exist in many countries.²⁶⁻²⁹ Hematology patients receive about two-thirds of all platelet concentrates, depending on the medical center. Additional studies are needed to determine the optimal transfusion practice; however, the clinical use of platelet transfusions to obtain hemostasis is complicated because direct platelet function testing is rarely possible in the bleeding or coagulopathic patient. For instance, after cardiopulmonary bypass, platelet counts may be normal, but platelets are functioning poorly (qualitative platelet defect). Most recommendations are to maintain platelet counts of greater than 50,000/ μ L in surgical patients; however, this is also dependent on whether the circulating platelets are functional. Although definitive data for the most effective platelet dosing strategy for maintaining perioperative hemostasis is not available, following platelet numbers is our only practical guide. However, clinicians must bear in mind that patients with abnormal platelet counts and/or hemostasis may not

bleed at the same time that patients with normal platelets counts may bleed based on the platelet dysfunction that appears in many surgical settings.

In most surgical patients, there is little data to support prophylactic platelet transfusions; the exceptions are massive transfusion coagulopathy and certain closed surgical procedures where bleeding may be highly problematic such as intracranial hemorrhage. Dilutional thrombocytopenia often occurs as an early manifestation of massive transfusion. However, studies also suggest thrombocytopenia may not always correlate with abnormal bleeding. In cardiac surgical patients, defective platelet function is part of the clinical problem, and the inability to have suitable platelet function testing for postoperative use complicates our ability to decide when to transfuse platelets.

Studies in chronic thrombocytopenic patients suggested that significant spontaneous bleeding with an intact vascular system does not occur until the platelet count is 5,000 platelets/ μ L or less.^{30,31} Previously, a platelet count of less than or equal to 20,000/ μ L was considered to be an indication for a prophylactic platelet transfusion. However, four randomized prospective transfusion trials comparing prophylactic platelet transfusion triggers of 10,000 versus 20,000 platelets/ μ L showed no differences in hemorrhagic risks. Current recommendations are that a threshold of 10,000 platelets/ μ L for prophylactic platelet transfusion be used in hematology patients who are chronically thrombocytopenic.

Platelet Counts for Surgery and Invasive Procedures

For surgery or following trauma, expert recommendations suggest that a platelet count of greater than or equal to 50,000/ μ L be maintained, although there is little data to support these recommendations. In neurosurgical patients or patients with intracerebral bleeding and for neurosurgical procedures, expert recommendations suggest that platelet counts should be maintained at greater than 100,000/ μ L. With platelet counts between 50,000 and 100,000/ μ L, clinical decisions to transfuse platelets should be based on the type of surgery, trauma, rates of bleeding, risk of bleeding, use of platelet inhibitors, and other potential coagulation abnormalities. An assessment of whether platelet function is normal should also weigh in to the decision about when to transfuse platelets.

Abnormal platelet function can arise from numerous causes, including multiple medications, sepsis, malignancy, tissue injury following trauma, obstetric issues including eclampsia, cardiopulmonary bypass, or hepatic or renal failure with azotemia/uremia. In the bleeding patient, laboratory testing can determine platelet counts but not platelet function, so bleeding due to tissue injury may occur at higher platelet counts. If platelet dysfunction is present in the face of trauma or surgery, platelet transfusions may be necessary, even in the presence of a normal platelet count. Unfortunately, there is little data to help clinicians manage these complex but common occurrences, and as a result, platelet transfusions must be guided by a logical approach that weighs each of these factors.

Purified Factor Concentrates

Fibrinogen Concentrates

Fibrinogen is a critical clotting protein, with increasing data further reporting its importance for perioperative hemostasis.^{20,32-35} Cryoprecipitate is routinely administered as the source of fibrinogen in many countries, while fibrinogen concentrates are also used in some countries. Although any biologic agent can potentially produce an adverse event, current reviews of published clinical data and pharmacovigilance reporting have not demonstrated significant thrombogenic concerns with fibrinogen concentrate to date.^{20,34,35} However, fibrinogen concentrate administration in patients with hypofibrinogenemia and disseminated intravascular coagulation should be avoided and the focus placed on treatment of the underlying disease (ie, sepsis).

The advantage of factor concentrates is that the risk of viral infection is significantly reduced due to viral inactivation and removal that minimize the risk of transmitting viruses. Although fibrinogen concentrate is manufactured using human plasma from a large pool of donors, the production processes involved remove antibodies and antigens, largely mitigating the risk of immunologic and allergic reactions resulting from its administration, and provide a pure product without other cellular and protein contaminants.

Prothrombin Complex Concentrates

The PCCs are highly purified, lyophilized coagulation factors derived from plasma that include coagulation factors II, VII, IX, and X in concentrations that vary depending upon the lot and the manufacturer.³⁶ The PCCs initially available were developed for hemophilia management and included factor IX specific products such as Bebulin VH (Baxter Health Care Corp, Westlake Village, CA), Profilnine SD (Grifols, Barcelona, Spain), and FEIBA (Factor Eight Inhibitory Bypassing Activity) VH (Baxter Health Care Corp, Westlake Village, CA).³⁶ Bebulin and Profilnine contain low levels of factor VII, whereas FEIBA contains the activated form of VII (VIIa). Three-factor PCCs are still available in the United States and, in some countries, represent the only PCC available and, in the United States, used for off-label indications including bleeding in surgical patients.

However, four-factor PCCs are currently the PCC recommended for urgent vitamin K antagonist reversal (eg, warfarin) in all recently published guidelines. Four-factor PCCs contain the four critical vitamin K-dependent coagulation factors but also proteins C and S. Kcentra (CSL Behring, King of Prussia, PA) is the only four-component PCC available in the United States but is called Beriplex P/N (CSL Behring GmbH, Marburg, Germany) in other countries. Other four-component PCCs available in other countries include Octaplex (Octapharma, Vienna, Austria).

Despite the previous use of FFP for warfarin reversal, current guidelines recommend four-component PCC administration as a primary treatment for emergent reversal.³⁶⁻³⁹ There are multiple advantages of PCCs for urgent warfarin reversal when compared to FFP, including rapid acquisition, no need for crossmatching, rapid INR correction, small infusion volume (~20 mL per 500 IU), and purification by viral inactivation/nanofiltration to remove potential pathogenic viruses. Kcentra is FDA approved for vitamin K antagonist reversal in the setting of coagulopathy or significant bleeding in combination with vitamin K and can be used prior to urgent surgery in patients taking warfarin. Although a four-component PCC was only approved the United States in 2013, these factor concentrates have been available in mainland Europe and other countries and are increasingly administered to facilitate factor repletion in perioperative bleeding.

Use of Prothrombin Complex Concentrates for Perioperative Bleeding

Algorithms for managing perioperative bleeding especially using viscoelastic methods of point-of-care monitoring have routinely included PCC administration.^{34,36} However, in bleeding patients, a multimodal approach to managing bleeding includes fibrinogen repletion, correction of thrombocytopenia and/or platelet dysfunction following cardiopulmonary bypass, use of antifibrinolytic agents, and evaluating surgical sources of bleeding. Many of these topics will be covered in other chapters. However, PCCs therapy for factor depletion and as part of management strategies in treatment algorithms has become common. In patients with major hemorrhage, the critical role of massive transfusion protocols with blood product administration in addition to potential adjunct therapies, including PCCs, are important to consider. Coagulation management algorithms have been published using PCCs, and other potential coagulation factor concentrates in cardiac surgical patients and trauma.³⁴⁻³⁶ In many of these patients, tranexamic acid is also concomitantly administered along with fibrinogen repletion.

von Willebrand Factor

Human antihemophilic factor/von Willebrand factor complex is commercially available in the United States and is indicated for treatment and prevention of bleeding in adult patients with hemophilia A (classical hemophilia). This agent is also indicated in adult and pediatric patients with von Willebrand disease (VWD) for (1) treatment of spontaneous and trauma-induced bleeding episodes and (2) prevention of excessive bleeding during and after surgery. This applies to patients with severe VWD and patients with mild and moderate VWD for whom use of desmopressin is known or suspected to be inadequate. This agent is not indicated for the prophylaxis of spontaneous bleeding episodes.

This product is the first plasma-derived von Willebrand factor/factor VIII-containing concentrate that was pasteurized to reduce the risk of virus infection and approved for use in Germany in 1981, and it is now available in many countries worldwide for on-demand treatment and long-term prophylaxis in patients with VWD or hemophilia A (factor VIII deficiency). This agent is used off-label for bleeding with acquired VWD due to ventricular assist devices or aortic stenosis.³⁴

Hereditary Angioedema and C1 Esterase Inhibitor Concentrates

Hereditary angioedema (HAE) is a life-threatening disease resulting from the absence or genetic mutation of a complement component inhibitor called C1 esterase inhibitor (C1 INH). Although there are several variants of HAE, they share a final common pathway following tissue injury, intubation, or other inciting events, leading to unopposed activation of multiple inflammatory pathways and mediators including kallikrein and bradykinin that increase vascular permeability.⁴⁰ Angioedema produces increased permeability of submucosal or subcutaneous capillaries and postcapillary venules leading to plasma extravasation and subsequent swelling of critical airway structures and other systemic effects. The C1 INH concentrates have been used since 1974 in Europe and now are available in the United States for both preventing and terminating attacks. Two of these have now been licensed in the United States for use in HAE patients, one for prophylaxis (Cinryze [Shire, Lexington, MA]) and the other for treating acute abdominal and facial HAE attacks (Berinert-P [CSL Behring, King of Prussia, PA]). The use of C1 INH concentrates is critical in the perioperative management of HAE patients.⁴¹

Adverse Effects of Transfusions

The risks of allogeneic transfusion extend beyond viral transmission and include allergy, alloimmunization, anaphylaxis, bacterial sepsis, graft versus host disease, TRALI, TACO, renal failure, volume overload, and immunosuppression.⁴²⁻⁴⁴ Platelet transfusions also carry the added risk of bacterial contamination and they contain a high concentration of donor white blood cells. Transfusion of donor white blood cells has the potential to produce multiple adverse effects. Cytokines, such as interleukins 6 and 8, tissue necrosis factor alpha, and other inflammatory mediators are especially concentrated in platelet products and could contribute to adverse outcomes.

Transfusion as an Inflammatory Response

Transfusions of allogeneic blood is reported to have multiple immunomodulatory effects including immunosuppression; they contain bioactive substances that cause febrile reactions, and they release inflammatory mediators.⁴⁵ Inflammatory responses to cardiac surgery are affected by giving packed RBCs during surgery as displayed by neutrophil activation.⁴⁶ Neutrophils in allogeneic cellular blood components are associated with adverse effects in the recipient.⁴⁷ In cardiac surgical patients who are already immunosuppressed by surgical trauma, added inhibition of immunomodulation may have harmful effects.

Because of increasing awareness and identification of TRALI and decreases in the incidence of infectious and hemolytic complications of transfusions, TRALI is now a primary cause of transfusion-associated mortality reported to the FDA and has become a frequent cause of transfusion-related morbidity and mortality.⁴⁸ The TRALI can be confused with other transfusion and non-transfusion-related events such as anaphylaxis, hemolysis, circulatory overload, and cardiac failure and present with acute shock, florid pulmonary edema, and pulmonary hypertension.^{47,49} Because TRALI is a major cause of mortality resulting from transfusion, strategies have evolved to reduce its incidence and will be considered in more detail later.

Transfusion-Associated Circulatory Overload

The TACO is simply a volume overload state, where the rate of volume infusion of blood products is in excess of what the patient's cardiovascular status can handle. An example is the transfusion of 4 units of FFP to reverse warfarin in a patient with heart failure; in such a patient who can barely manage his or her own intravascular volume, he or she may well go on to develop orthopnea and paroxysmal nocturnal dyspnea following transfusion. The TACO is characterized by the acute onset of dyspnea and is typically associated with hypertension, tachypnea, and tachycardia—an exacerbation of heart failure as shown in **Table 28.3**. Sometimes, it can be difficult clinically to differentiate TRALI from TACO, but use of echocardiography, transthoracic or transesophageal, will reveal hypervolemia, ventricular dysfunction, and potentially reveal exacerbation of valvular dysfunction. In a TRALI patient, volume overload is not the cause of pulmonary edema, rather left ventricular size should be normal or low, and often, the right ventricle is dilated. Alternately, attesting for brain-type natriuretic peptide is another approach, and this should be greatly

elevated, usually several folds above a baseline of 100 to 200 in patients with TACO. The TACO incidence ranges from approximately 1% to 8% of transfusions. The TACO is increasingly reported as a common cause of morbidity and mortality associated with transfusion, especially with the use of FFP.

TABLE 28.3

Presentation of transfusion-associated circulatory overload

Dyspnea
Elevated jugular venous pressure
Hypertension or hypotension
Tachycardia
Rales on lung auscultation
Pulmonary edema
Increased brain natriuretic peptide
Echocardiography: hypervolemia, mitral regurgitation due to volume overload

Transfusion-Related Acute Lung Injury

The term *transfusion-related acute lung injury* was initially reported as the clinical presentation of hypoxia and bilateral noncardiogenic pulmonary edema within 6 hours of a transfusion.⁵⁰ Initially, this pathologic response was thought to be produced by donor immunoglobulin G antibodies against recipient neutrophils, called leukoagglutinins. The TRALI is secondary to TACO for transfusion-related deaths in the United States reported to the FDA.¹ The most widely accepted current concept is that TRALI results from neutrophil and/or endothelial activation via multiple mechanisms in the lung, resulting in pulmonary vascular injury and pulmonary edema.⁵⁰ Multiple pathogenic transfused factors are associated with TRALI and predisposing events that may prime the response as will be covered in more detail later and as summarized in [Figure 28.1](#).

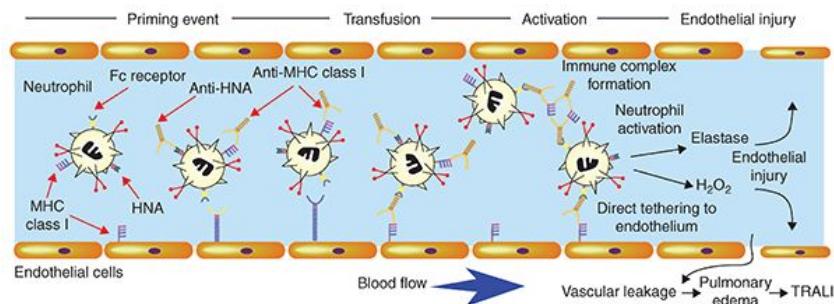

FIGURE 28.1 Transfusion-related acute lung injury (TRALI). Multiple priming events may or may not be required for TRALI but appear to be important factors in the inflammatory process that causes TRALI and may significantly potentiate the acute vasculitis that occurs. Transfusion of blood products from multiparous donors or other donors containing antibodies against white blood cell antigens that include human neutrophil antigen and major histocompatibility complex (MHC) class I can result in direct binding and activation of intravascular polymorphonuclear leukocytes. These antibodies may also directly bind and tether neutrophils to the endothelium independent of the adhesion molecules, selectin and integrin. The antigen-antibody binding also produces immune complexes of multiple white blood cell antigens that may also be recognized by the Fc receptors (tail receptors of antibodies) resulting in neutrophil activation. The activated neutrophils bind to the pulmonary vascular endothelium, and aggregated clumps of neutrophils may lodge in the pulmonary microcirculation. Activated neutrophils release multiple proinflammatory substances including proteolytic enzymes, oxygen free radicals, thromboxane, and other inflammatory mediators both locally at the site of vascular injury and systemically. This complex series of events results in damage to endothelial cells, vascular leakage, and pulmonary edema.

Clinical History of Transfusion-Related Acute Lung Injury

Initially, in the 1980s, this reaction was termed *pulmonary hypersensitivity reaction* and thought to be associated with leukocyte antibodies in the donor against the recipient, or in the recipient against the donor. In 1985, a series of 36 cases of TRALI were reported with acute respiratory failure characterized by hypoxemia and pulmonary edema occurring within 4 hours of transfusion. Granulocyte or lymphocytotoxic antibodies were detected in the donor of 89% of blood products. By 2006, more than 50% of transfusion-related fatalities reported to the FDA were due to TRALI. A National Heart, Lung, and Blood Institute working group defined TRALI as new acute lung injury (ALI) occurring within 6 hours of the end of transfusion of one or more plasma-containing blood products in patients without other risk factors for ALI. Patients with preexisting ALI and ALI occurring more than 6 hours after transfusion are excluded.

Clinical presentation of TRALI, in its severe form, is indistinguishable from adult respiratory distress syndrome and is characterized by acute-onset (within minutes to 6 hours after transfusion), bilateral pulmonary infiltrates and hypoxia without evidence of heart failure.^{42,51,52} Because reports use different definitions of TRALI, the information on incidence, outcome, and blood product association are variable. In German hemovigilance data of 44 cases of TRALI, the fatal 18% of cases were antibody-mediated from female donor blood. However, from multiple reports and European countries, the rates vary from approximately 1:11,363 (Finland) to 1:250,000. Five of the blood products implicated in TRALI, 49% were FFP, 29% RBCs, 13% platelet concentrates, 2% whole blood, 0% S/D plasma, and 7% mixed products. The American Red Cross–estimated risk of fatal TRALI per distributed component was 1:202,673 for plasma, 1:320,572 for apheresis platelets, and 1:2,527,437 for RBC units.⁵⁰ The TRALI mortality rates range from 5% to 35% in case series while leukocyte antibodies were identified in the implicated donor in 65% to 90% of TRALI cases.⁵⁰ **Table 28.4** lists clinical presentation of TRALI.

TABLE 28.4

Presentation of transfusion-related acute lung injury

Onset within 6 hours, usually more acute, following transfusion

Bilateral infiltrates seen on frontal chest radiograph

Hypoxemia/ratio of $\text{PaO}_2/\text{FiO}_2$ 300 mm Hg regardless of positive end-expiratory pressure level, or oxygen saturation of 90% on room air

Pulmonary artery occlusion ≤ 18 mm Hg when measured or lack of clinical evidence of left atrial hypertension (volume overload)

Pathophysiologic mechanisms: human neutrophil antigen (HNA) and human leukocyte antigen (HLA) class I and II antibodies, CD40 ligand (CD40L), biologically active lipids

Abbreviation: FiO_2 , fraction of inspired oxygen.

Multiple Factors Influence Transfusion-Related Acute Lung Injury

Although multiple factors may produce TRALI, priming events that occur before actual blood product administration may also be needed in what is termed the *two-hit model*.⁵⁰ First, an inciting inflammatory event may be required to activate and upregulate inflammatory cells and vascular endothelium (see “[Role of Neutrophils and Other Inflammatory Cells](#)” section), followed by a second, transfusion event that actually triggers an acute inflammatory response and injury. The initial priming event may be caused by lipids generated during prolonged storage of blood, recent infection including viral illnesses, and other events such as cardiopulmonary bypass that can trigger inflammatory responses and cytokine generation. Because neutrophils and endothelial cells are activated by multiple inflammatory events, there may be different thresholds for TRALI development in distinct settings from infection, lipid exposure, or extracorporeal circulation. Additional factors that likely contribute to the development of TRALI include complex factors such as antibody specificity and titer, antigen density, and the patient’s underlying condition.⁵⁰

Acute Pulmonary Edema and Management

The multiple signaling mechanisms and inflammatory mediators in TRALI promote priming and activation of a patient's granulocytes leading to their pulmonary sequestration and release of proteases, oxidants, and leukotrienes, which cause alveolar epithelial and microvascular endothelial damage resulting in increased permeability and the eventual development of noncardiogenic pulmonary edema. The two-hit model of TRALI is similar to pathophysiology of acute respiratory failure/syndrome. With TRALI, several reactive lipid-like substances that accumulate in RBCs or platelets during storage, referred to as biologic response modifiers, can act as the first pulmonary insult but are more likely the second. The first insult is generally a systemic inflammatory condition resulting from major surgery, sepsis, trauma, or pulmonary aspiration that causes activation of the pulmonary endothelium and priming of polymorphonuclear lymphocytes leading to their sequestration in the pulmonary vasculature. The second hit occurs when the primed polymorphonuclear lymphocytes are activated by the biologic response modifiers in the transfused component. Therapy for TRALI is supportive. Suspected cases of TRALI should be reported to the hospital transfusion service to assure a suitable investigation including testing of associated donors for antileukocyte and antiplatelet antibodies and typing recipients for HLA (ie, via leukocytes in a pretransfusion blood specimen or buccal swab technique). If donor leukocyte antibodies that react specifically to the patient's leukocytes are found, avoiding future transfusion of plasma-containing components from this donor is recommended. The patient, however, is not at an increased risk for future TRALI reactions with future transfusion.

A retrospective study of the incidence of acute pulmonary edema after transfusion in 8,902 ICU patients demonstrated 25 cases of TACO (incidence 1:356 units transfused), 7 cases of suspected TRALI (1:1,271 units transfused), and 14 cases of possible TRALI (1:534 units transfused).⁵³ Patients who developed suspected or possible TRALI received larger amounts of plasma, especially plasma from female donors. In addition, the mortality rate was 67% for suspected or possible TRALI, compared with 20% for TACO and 11% for matched controls.⁵³

Decreasing the Incidence of Transfusion-Related Acute Lung Injury

Because antibodies are present in most TRALI cases, especially severe and fatal cases, most policy changes made to mitigate TRALI have targeted antibody-mediated TRALI. Decreasing TRALI through changes in blood product policies is supported through biovigilance data and includes use of plasma from men only, resuspending pooled buffy coat platelets in plasma from men only, and screening female donors (either all or only those donors with a history of pregnancy, transfusion, or both) for leukocyte antibodies.⁵⁰ Recommendations for screening donors for leukocyte antibodies point to the need for screening patients at risk, including parous women and patients following transplantation and/or transfusion. Blood components with high plasma fractions that contain antibodies such as plasma, apheresis platelets, and whole blood should not be prepared from these donors.⁵⁰ The AABB also recommends implementing measures to minimize the preparation of high plasma-volume components from donors known to be leukocyte-immunized or at increased risk for immunization.

Plasma From Male Donors

Because TRALI is usually secondary to donor HLA or human neutrophil antigen antibodies, which are more common in females than males, the United Kingdom began using male donor plasma and resuspension of buffy coat-derived platelets in male-donated plasma. Since 2003, 80% to 90% of the United Kingdom FFP has been male-donated plasma. In 2004, the United Kingdom started using S/D plasma for plasma exchange procedures in thrombotic thrombocytopenic purpura patients. These changes resulted in a decrease in number of TRALI reports and deaths in the United Kingdom with a reduction from 1:65,000 to 1:317,000 ($P < .001$) for FFP, and 1:71,000 to 1:173,000 ($P = .068$) for platelets; the risks for RBCs (1:949,000) and cryoprecipitate (1:104,000) remained similar. Likewise, the American Red Cross reported a decrease in fatal and nonfatal TRALI cases after using only male-donated plasma in 2007 (from 26 cases in 2006 to 7 in 2008).⁵⁴

Transfusion-Related Acute Inflammatory Responses and Immunomodulation

Although TRALI is an important example of the complex inflammatory responses associated with transfusions, multiple blood products have the potential for proinflammatory responses including acute hypersensitivity responses and anaphylaxis that may not affect the lung. Inflammatory mediators including cytokines, tissue necrosis factor alpha, interleukin 6, and interleukin 8 are increased 100- to 1,000-fold over baseline in platelets and are also potentially elevated in other blood products.⁵⁵ Even though white cells are responsible for forming the high levels of inflammatory mediators including complement and cytokine factors, leukoreduction may be only partially effective in reducing the immunosuppressive effects of platelets.⁵⁶ Other mechanisms of immunosuppression not affected by leukoreduction may come into play.

Role of Neutrophils and Other Inflammatory Cells

Polymorphonuclear leukocytes are an important element of the innate immune response for host defense and are critical to controlling microbial pathogens after tissue injury following surgery or trauma. As part of all inflammatory responses, neutrophil-mediated events produce inflammatory responses that often become systemic producing widespread tissue damage and adverse sequelae. Neutrophils release multiple factors that kill both pathogens and surrounding tissue. Neutrophil activation is responsible for multiple inflammatory events, including reperfusion injury, a common issue following restoration of blood flow in occluded vessels. Following inflammatory insults, neutrophils and other inflammatory cells have important mechanisms of activation and recruitment and interact with vascular endothelial cells for further activation, localization, and extravasation/transmigration to areas of tissue injury or actual microbial invasion. Important inflammatory mediators and interactions with endothelial cells orchestrate these events by upregulating adhesion molecules after hypoxic challenge and production of inflammatory cytokines or pathogen metabolites that facilitate margination of leukocytes. Cytokines liberated as part of the inflammatory response induce changes in integrins and increase adhesion to the vascular wall followed by transmigration across the vessel wall. Chemotactic factors released locally further attract neutrophils to areas of primary tissue damage to kill invading organisms and remove necrotic tissue.

Summary

Blood and blood products are used extensively in the perioperative setting in surgical and trauma patients. Blood products and transfusions should be considered in the same manner that we consider use of other drug therapies by carefully weighing their risks and benefits. The complex environment in which we transfuse patients, the wide range of reasons to transfuse, and the different indications for blood product administration all further emphasize the importance of considering risk and benefit for each unique patient. The TACO and TRALI are major causes of morbidity and mortality associated with transfusions, and many therapeutic approaches have been adopted to decrease the risk. Both purified and recombinant therapeutic proteins will have an important role to play in the perioperative management of patients; despite their cost, these products do not need crossmatching and are likely to play an increasing role as alternatives to many blood products currently in use.

Procoagulants

Jerrold H. Levy

Bleeding that occurs in surgical patients perioperatively or following trauma can arise from numerous causes beyond surgical factors that include activation of the coagulation, fibrinolytic, and inflammatory pathways, dilutional changes, and hypothermia.¹⁻³ Bleeding may be further exacerbated by the increasing use of multiple agents that affect coagulation, including oral and parenteral anticoagulants and platelet inhibitors. Hemostatic function and coagulation are complex and often altered in by multiple events that occur in the perioperative setting.¹⁻³ As a result, when patients bleed following surgery and trauma, multiple therapeutic approaches are often required in addition to blood transfusion, and procoagulants are now increasingly used to treat bleeding in the perioperative setting. This chapter focuses on the role of procoagulants used in a perioperative setting.

Antifibrinolytic Agents: Lysine Analogs

The two synthetic antifibrinolytic agents available are the lysine analogs epsilon aminocaproic acid (EACA) and tranexamic acid (TXA). These agents competitively inhibit activation of plasminogen to plasmin, an enzyme that degrades fibrin clots, fibrinogen, and other plasma proteins. Antifibrinolytic agents are not prothrombotic per se rather are clot stabilizers and prevent compensatory responses of inflammatory injury and clot lysis. The TXA also inhibits plasmin at higher doses,³ and most of the efficacy data are reported with TXA. The EACA does not consistently reduce transfusion requirements or surgical reexploration, especially in cardiac surgery, where these agents are best characterized.^{3,4} Multiple meta-analyses examining the use of antifibrinolytic agents consistently report a decrease in bleeding with use of these agents as measured by chest tube drainage, but data are limited for any conclusions about safety. The EACA has been removed from many European countries due to concerns about safety.³ Most studies reporting the use of antifibrinolytic agents are in cardiac surgical patients, but use in other patients, including orthopedic patients have also been reported. Aprotinin, a polypeptide protease inhibitor, is described later.

A meta-analysis of cardiac surgical patients compared aprotinin, TXA, and EACA.⁵ From 49 trials, 182 deaths among 7,439 participants were reported, and the relative risk for mortality with aprotinin versus placebo was 0.93. In the 19 trials that included TXA versus placebo, there were 24 deaths in 1,802 patients, yielding a relative risk of mortality of 0.55. To calculate direct estimates of death for aprotinin versus TXA, 13 trials with 107 deaths among 3,537 patients were evaluated. The relative risk was 1.43. Among 1,840 patients, the calculated estimates of mortality for aprotinin compared directly to EACA yielded a relative risk of 1.49. There was no evidence of an increased risk of myocardial infarction with aprotinin compared with TXA or EACA in either direct or indirect analyses, and all three drugs were effective in reducing the need for red blood cell transfusion.⁵ A more recent randomized study of 4,631 patients in coronary artery surgery compared TXA to placebo. The primary outcome was a composite of death and thrombotic complications within 30 days postoperatively. A primary outcome event occurred in 16.7% of TXA patients and in 18.1% of placebo ($P = .22$), and 4,331 allogeneic blood products were transfused in TXA patients compared to 7,994 in placebo ($P < .001$). A total of 1.4% of the TXA group required reoperation for bleeding compared to 2.8% of patients in placebo ($P = .001$), and seizures occurred in 0.7% and 0.1%, respectively ($P = .002$).⁶

One of the potential complications of TXA in cardiac surgery is seizures.³ The incidence of postoperative convulsive seizures at one institution was reported to increase from 1.3% to 3.8% following cardiac surgery, temporally coincident with high-dose TXA.⁷ In 24 patients who developed perioperative seizures, all had received high doses of TXA intraoperatively ranging from 61 to 259 mg/kg, had a mean age of 69.9 years, and 21 of 24 had undergone open chamber cardiac procedures.⁷ The ability of TXA to block γ -

aminobutyric acid receptors in the frontal cortex is a suspected mechanism, although other factors are likely involved that are specific to cardiac surgical patients.³

Antifibrinolytic agents also have been studied in other procedures, including orthopedic surgery, and all three agents reduce blood loss. Although most of the reported studies included small numbers of patients and lacked sufficient power, larger meta-analysis and more recent data suggest that these agents represent an important adjunct for reducing bleeding and the need for allogeneic transfusions. Multiple studies have examined the use of intravenous antifibrinolitics compared with placebo on transfusion requirement in orthopedic surgery and the safety of these agents, including venous thromboembolic risk.^{3,8} Zufferey et al⁸ evaluated 42 randomized trials in total hip and knee arthroplasty, spine fusion, musculoskeletal sepsis, or tumor surgery performed up to 2004. There were 22 trials with 1,238 participants for aprotinin, 20 trials with 1,096 participants for TXA, and 3 trials with 141 participants for EACA. Aprotinin and TXA both significantly reduced allogeneic blood transfusions compared to placebo. There was a dose-effect relationship with TXA, but EACA did not show any efficacy; antifibrinolytic use was not associated with an increased risk of venous thromboembolic events.

The TXA has also been studied in trauma patients and is being used more commonly for this application. Much of this increase in use is based on the Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage study, a study of the effects of early administration of TXA on death, vascular occlusive events, and blood transfusion in trauma patients conducted in 274 hospitals in 40 countries.⁹ A total of 20,211 adult trauma patients with (or at risk for) significant bleeding were randomly assigned within 8 hours of injury to receive either TXA (loading dose 1 g over 10 minutes and then infusion of 1 g over 8 hours) or placebo. The primary outcome was in-hospital death within 4 weeks of injury and was described as bleeding, vascular occlusion (myocardial infarction, stroke, and pulmonary embolism), multiorgan failure, head injury, or other causes. A total of 10,096 patients were allocated to TXA and 10,115 to placebo, of whom 10,060 and 10,067, respectively, were analyzed. All-cause mortality was significantly reduced with TXA (1,463 [14.5%] TXA group vs 1,613 [16.0%] placebo group; relative risk, 0.91; $P = .0035$). The risk of death due to bleeding was significantly reduced (489 [4.9%] TXA group vs 574 [5.7%] placebo group; relative risk, 0.85; $P = .0077$).

In the United States, clinicians often use EACA instead of TXA; however, most of the efficacy and safety data with antifibrinolytic use is TXA and not EACA. Furthermore, TXA is also approved in an oral form in the United States for the treatment of heavy menstrual bleeding. The recommended dose for women with normal renal function is two 650-mg tablets taken three times daily (3,900 mg per day) for a maximum of 5 days during monthly menstruation.

Antifibrinolytic Agents: Aprotinin

Aprotinin, a polypeptide serine protease inhibitor, inhibits plasmin and other serine proteases and has had a long history of use in different clinical applications. In cardiac surgery, multiple randomized, placebo-controlled trials reported aprotinin as effective in reducing bleeding and allogeneic transfusions.^{10,11} However, reports from observational databases^{12–15} and one randomized study¹⁶ questioned the safety of aprotinin. Following publication of the *Blood Conservation Using Antifibrinolitics: A Randomized Trial in a Cardiac Surgery Population* (BART) study,¹⁶ Bayer Pharmaceuticals removed the drug from the market in the United States, but it is currently available in Europe.¹⁷ A recent retrospective, single-center cohort study reports on 15,365 cardiac surgical patients, of which 1,017 received aprotinin and 14,358 received TXA. They noted aprotinin had a better risk-benefit profile than TXA in high-risk patients, but not in low- to moderate-risk patients and suggested its use in high-risk cases may be warranted.¹⁸

On September 21, 2011, Health Canada concluded that the benefits of aprotinin outweigh the risks when used as authorized by Health Canada. Aprotinin is authorized for patients undergoing coronary artery bypass graft surgery. The evidence evaluated did not suggest any increased risk of death associated with use of this agent. Health Canada's decision was based on a comprehensive review of the totality of evidence, which included an evaluation of BART study data, other clinical trial data, postmarket studies, and information from Bayer as well as an Expert Advisory Panel that was convened by Health Canada. One of the aspects

considered was that data suggesting an increased risk of death involved the use of aprotinin in complex, higher risk surgeries for which it is not authorized, such as valve replacement/repair. The precise nature of this risk remains unclear and merits further study. They also noted with respect to the BART study, Health Canada concluded that the study was not designed to reliably determine the risk of death (either within or outside of coronary artery bypass graft surgery) relative to the two drugs it was being compared against and that the increased number of deaths in aprotinin patients could have been due to chance.¹⁹

Protamine

Protamine is a polypeptide containing approximately 70% arginine residues and the only available agent to reverse unfractionated heparin. This basic protein inactivates the acidic heparin molecule via a simple acid–base interaction.²⁰ Protamine does not reverse low-molecular-weight heparin. Most patients receive too much protamine for anticoagulation reversal because plasma levels of heparin decrease over time, and most fixed-dose regimens for reversal give protamine based on the initial or total heparin dose and do not account for elimination.

Excess protamine should be avoided when reversing heparin as it can contribute to coagulopathy, as shown in [Figure 29.1](#).²¹ Protamine inhibits platelets and serine proteases involved in coagulation. Data suggests that maintaining heparin levels during cardiopulmonary bypass (CPB) and administering protamine based on the correct dose of circulating heparin reduces postoperative bleeding and the need for hemostatic factors.²² Part of this efficacy may be related to the finding that excess protamine prolongs the activated clotting time (ACT) and causes additional platelet dysfunction. When protamine is dosed based on the exact amount needed to reverse circulating heparin levels, it produces the lowest ACT values.²¹ Others have also reported lower protamine doses reduce bleeding and transfusion requirements.²³

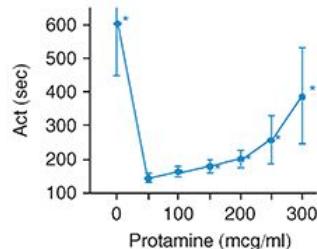

FIGURE 29.1 Excess protamine contribute to elevations in the activated clotting time (Act), at excesses of the exact dose required to reverse systemic anticoagulation. Thus, overdosage of protamine should be strictly avoided. *From Mochizuki T, Olson PJ, Szlam F, Ramsay JG, Levy JH. Protamine reversal of heparin affects platelet aggregation and activated clotting time after cardiopulmonary bypass. Anesth Analg. 1998;87(4):781-785.*

Heparin rebound can occur after initial reversal and is generally observed 2 to 3 hours after the first dose of protamine, when the patient is in the intensive care unit.²⁴ Heparin levels at this time may range from 0.1 to 0.3 IU/mL, equivalent to circulating levels of heparin, based on a 5 L blood volume, of 500 to 1,500 units. Protamine doses of 5 to 15 mg at this time may be effective at reversing heparin rebound rather than the dose of 50 mg commonly administered.²⁵ Studies have evaluated rotational thromboelastometry (ROTEM [Instrumentation Laboratory, Bedford, MA]) assay for determining the need for additional protamine administration and note that most patients do not need additional protamine administration within 30 minutes of initial administration. The ACT is not a sensitive indicator of low heparin concentrations because platelet counts and fibrinogen levels may also affect values.

Protamine can cause adverse reactions, including anaphylaxis, acute pulmonary vasoconstriction, right ventricular failure, and hypotension.²⁰ Patients at an increased risk for adverse reactions are sensitized, often from exposure to neutral protamine Hagedorn (NPH), which contains insulin and protamine.²⁰ In a study of 1,551 cardiac surgery patients, the incidence of protamine reactions was 1 out of 50 in insulin-dependent diabetics receiving NPH-insulin and 1 out of 501 among other patients.²⁶ A subsequent prospective study

found that reactions occurred in 0.6% (1 out of 160) of patients with NPH-insulin-dependent diabetes.²⁷ Other individuals reported at risk for protamine reactions include patients with vasectomy, multiple drug allergies, and prior protamine exposure.²⁰ Despite the potential for anaphylaxis, there are no currently available alternatives to protamine.

Desmopressin

Desmopressin (DDAVP) is the V2 analog of arginine vasopressin that stimulates the release of ultra-large von Willebrand factor (vWF) multimers from endothelial cells.²⁸ The vWF mediates platelet adherence to vascular subendothelium by functioning as a protein bridge between glycoprotein Ib receptors on platelets and subendothelial vascular basement membrane proteins. The DDAVP shortens the bleeding time of patients with mild forms of hemophilia A or von Willebrand disease (VWD).²⁹ The specific surgical patients who might benefit from the use of DDAVP are not clear. The DDAVP is administered intravenously at a dose of 0.3 mg/kg and should be given over 15 to 30 minutes to avoid hypotension.³⁰ Most studies have not confirmed the early reported efficacy during complex cardiac surgery. There have been 18 trials of DDAVP in 1,295 patients undergoing cardiac surgery that show a small effect on perioperative blood loss (median decrease, 115 mL).³¹⁻³² Because critically ill patients are often receiving vasopressin, which also has V2- and V1-mediated effects, there may not be a benefit to adding DDAVP to these patients.

The DDAVP is also used to treat VWD; there are multiple types of this deficiency, and therapy for each type varies. The DDAVP is most useful in type 3 (typically considered mild); in severe forms of types 1 and 2 VWD, DDAVP is not effective and vWF concentrates are available.³³ The VWD is the most frequent inherited bleeding disorder and is due to quantitative (types 1 and 3) or qualitative (type 2) defects of vWF.³³ The DDAVP is the treatment for type 1 VWD. In type 3 and in severe forms of types 1 and 2 VWD, DDAVP is not effective, and virally inactivated plasma vWF concentrates should be used in bleeding, surgery, and secondary long-term prophylaxis.³³

The DDAVP should be administered by slow intravenous infusion to avoid hypotension because it stimulates endothelial cells releasing vasoactive mediators in addition to vWF.³⁴⁻³⁵ Prior reports that DDAVP reduced blood loss and transfusion needs approximately 30% during complex cardiac surgery³⁶⁻³⁸ have not been confirmed.^{30,35} There have been 18 trials of DDAVP in 1,295 patients undergoing cardiac surgery that show a small effect on perioperative blood loss (median decrease, 115 mL). Although DDAVP may stimulate the release of vWF, its effect is likely minimal compared to multiple other factors involved in hemostasis. Also, DDAVP may be associated with other adverse effects as myocardial infarction was twofold higher compared to placebo with no improvement in clinical outcomes.⁶ However, in another review evaluating 16 trials of DDAVP in cardiac surgery and in other high-risk operations, the rate of thrombosis did not differ significantly between patients who received DDAVP and patients who received placebo (3.4% vs 2.7%).³⁹

Fibrinogen

Fibrinogen is a 340-kDa plasma glycoprotein synthesized in the liver and a critical component of effective clot formation.⁴⁰ It is the substrate of three important enzymes involved in clot formation: thrombin, factor XIIIa, and plasmin, as previously reviewed. The half-life is ~3.7 days. For clot formation, thrombin cleaves the fibrinogen molecule, producing a soluble fibrin monomer, which polymerizes to form a loose network in trapping red blood cells, and a clot begins to form. Cross-linking of the fibrin polymers, induced by factor XIIIa, is fundamental to the coagulation process, increasing the elasticity of the clot and its resistance to fibrinolysis. Fibrinogen also acts as the binding site (ligand) for glycoprotein IIb/IIIa receptors, found on the platelet surface, which are responsible for platelet aggregation. These platelets then become enmeshed within the fibrin strands, stabilizing the growing clot, and create the ability to cross-link and expand the clot and seal the bleeding site. During major hemorrhage, hemodilution after blood loss and subsequent volume replacement leads to reduced fibrinogen levels impairing fibrin polymerization and reduces clot stability. Thus, fibrinogen supplementation to restore plasma fibrinogen is key to normalizing clotting function.

Fibrinogen is a critical coagulation factor required for effective clot formation in surgical patients, and data supports hypofibrinogenemia as a predictor of perioperative bleeding.⁴¹⁻⁴³ Normal fibrinogen levels are

200 to 400 mg/dL, although, during the third trimester of pregnancy, fibrinogen levels are elevated to greater than 400 mg/dL. Although the optimal fibrinogen level needed in a bleeding patient is not known, bleeding increases for each 100 mg/dL decrease in fibrinogen level in parturients.⁴⁴ Low fibrinogen levels can predict bleeding after prolonged CPB.^{45,46} Treatment of fibrinogen deficiency is important for survival, and the amount of fibrinogen administered to trauma patients has been positively correlated with reductions in mortality.⁴⁰

In a bleeding patient, fibrinogen is an important factor to both measure and replete. Over the years, transfusion algorithms have targeted increasing levels of ~150 to 200 mg/dL (1.5-2.0 g/L), or potentially higher.⁴¹⁻⁴³ It is important to consider that low fibrinogen levels (<100 mg/dL) can increase laboratory measures of hemostasis, including prothrombin time (PT) and partial thromboplastin time, that may not be corrected with transfusing fresh frozen plasma. In this situation, cryoprecipitate or fibrinogen concentrates are a better option to restore adequate plasma levels and need to be considered when treating life-threatening bleeding. Fibrinogen can be repleted by cryoprecipitate; 1 unit per 10 kg increases fibrinogen by 50 to 70 mg/dL. In Europe, fibrinogen concentrates are available, and cryoprecipitate is not used. Fibrinogen concentrates are available (RiaSTAP [CSL Behring, King of Prussia, PA]), although approved for patients with congenital afibrinogenemia or hypofibrinogenemia.

Recombinant Coagulation Products and Factor Concentrates

Purified and recombinant proteins are becoming more readily available for managing bleeding, topical hemostasis, and for other therapeutic interventions.^{47,48} Factor concentrates are increasingly used in perioperative settings of bleeding and include fibrinogen, prothrombin complex concentrates, hemophilia factors VIII and IX, and XIII. Recombinant proteins can also be modified to alter specific characteristics that may be important in therapeutic effects or provide quantities that can be administered as a therapeutic agent to treat bleeding in hemophilia, VWD, and in patients with acquired antibodies/inhibitors, but also used off-label for refractory or life-threatening bleeding.

Recombinant Activated Factor VIIa

Recombinant activated factor VIIa (rFVIIa; NovoSeven [Novo Nordisk, Princeton, NJ]) is the activated form of factor VII (FVII) approved for treatment of bleeding episodes and perioperative management in patients with hemophilia A or B with inhibitors, congenital FVII deficiency, and Glanzmann thrombasthenia (the congenital absence of glycoprotein IIb/IIIa receptors) with refractoriness to platelet transfusions. Previously, rFVIIa has been extensively studied and continues to be used off-label as a prohemostatic agent for life-threatening hemorrhage.⁴⁹⁻⁵²

Recombinant FVIIa produces a prohemostatic effect by multiple mechanisms that include complexing with tissue factor (TF) expressed at the site of vascular injury to locally produce thrombin and amplify hemostatic activation.⁵⁰ Circulating FVIIa accounts for approximately 1% of circulating FVII and has no effect until bound with TF.⁵⁰ An increasing number of publications report the off-label use of rFVIIa in cardiac surgical patients. The therapeutic dose of rFVIIa in nonhemophilia patients has not been established.⁵¹ However, guidelines, as reported by Goodnough et al,⁵¹ for off-label use in patients with life-threatening hemorrhage have been reported.

Controlled clinical trials report the incidence of thrombotic complications among patients who received rFVIIa for bleeding and not hemophilia was relatively low, but due to the large number of patients reported, it was statistically significant compared to patients who received placebo.^{52,53} However, most case reports giving rFVIIa as rescue therapy include patients who have impaired coagulation, have received multiple transfusions, and are at a high risk for adverse events.

The complex role that both bleeding patients and transfusion therapy has in producing adverse outcomes is emerging in the scientific literature.⁵⁴⁻⁵⁶ A report using the U.S. Food and Drug Administration MedWatch database noted thromboembolic events in patients with diseases other than hemophilia in whom rFVIIa was used on an off-label basis and included 54% of the events as arterial thrombosis (eg, stroke or acute myocardial infarction).⁵⁷ Venous thromboembolism (mostly, venous thrombosis or pulmonary embolism)

occurred in 56% of patients. In 72% of the 50 reported deaths, thromboembolism was considered the probable cause. It is not clear to what extent the clinical conditions requiring the use of rFVIIa may have contributed to the risk of thrombosis.³¹ Other major issues about rFVIIa include costs and dosing. This drug has also seen widespread use in treating battlefield injuries ([Table 29.1](#)).

TABLE 29.1

Prohemostatic agents

Prohemostatic agent(s)	Specific drugs	Mechanism of action
Antifibrinolytics	Aprotinin, epsilon aminocaproic acid, tranexamic acid	Inhibition of plasminogen/plasmin-induced clot factor lysis
V2 agonists	Desmopressin (DDAVP)	Release of von Willebrand factor stored in the vascular endothelial storage sites (Weibel-Palade bodies)
Anticoagulant reversal agents/antidotes	Andexanet alfa, idarucizumab, protamine	Specific or nonspecific binding to anticoagulants to antagonize their effects
Factor concentrates	Fibrinogen, hemophilia factors (factor VIII, IX), factor XIII, prothrombin complex concentrates	Increase circulating levels of procoagulant proteins
Recombinant activated factor(s)	Activated factor VIIa	Specific single-protein activated factors that are considered bypassing agents to directly activate thrombin generation; currently approved for hemophilia with inhibitors, Glanzmann thrombasthenia, and used off-label for refractory bleeding
Topically applied hemostatic factors	Topical thrombin, microfibrillar collagen, fibrin glues	Applied directly to potential or active bleeding sites in an attempt to minimize or prevent potential bleeding; used extensively in surgical procedures and for microvascular bleeding

In the most recent cardiac surgical study,⁵⁸ patients bleeding postoperatively >200 mL per hour were randomized to placebo (n = 68), 40 µg/kg rFVIIa (n = 35), or 80 µg/kg rFVIIa (n = 69). The primary end points were the number of patients suffering critical serious adverse events. Secondary end points included rates of reoperation, blood loss, and transfusions. Although more adverse events occurred in the rFVIIa groups, they did not reach statistical significance (placebo, 7%; 40 µg/kg, 14%; P = .25; 80 µg/kg, 12%; P = .43). However, after randomization, significantly fewer patients in the rFVIIa group underwent a reoperation because of bleeding (P = .03) or needed allogeneic transfusions (P = .01).⁵⁸

One of the difficulties in using rFVIIa is that it can normalize elevated international normalized ratio (INR)/PT values without actually correcting the coagulation defect, especially in patients receiving warfarin and other vitamin K antagonists.⁵⁹ The use of currently approved component for prothrombin complex concentrates (PCCs) (Kcentra [CSL Behring, King of Prussia, PA]) is recommended in the guidelines and offers an important approach for the urgent reversal of warfarin.⁴⁸

Factor XIII

Plasma FXIII is a transglutaminase that cross-links fibrin, an important final step in clot formation that stabilizes the initial clot.⁶⁰ Congenital deficiency is rare but presents with spontaneous intracranial hemorrhages. In clinical studies, the addition of a plasma-derived FXIII (Fibrogammin [CSL Behring, King of Prussia, PA]) at the end of CPB with concurrent antifibrinolytic therapy reduced postoperative hemorrhage and transfusion requirement in cardiac surgery trial,⁶¹ and there was no reduction in bleeding in a larger randomized placebo-controlled clinical trial using a recombinant form of FXIII.⁶²

Prothrombin Complex Concentrates

The PCCs are concentrates of coagulation factors that include factors II, VII, IX, and X in variable concentrations.⁴⁸ Two agents (eg, Kcentra [CSL Behring, King of Prussia, PA] and Octaplex [Octapharma, Vienna, Austria]) are used worldwide for vitamin K antagonist-induced (ie, warfarin) reversal. Other PCCs available in the United States include FEIBA VH (Baxter, Vienna, Austria), Profilnine SD (Grifols, Barcelona, Spain), and Bebulin VH (Baxter, Vienna, Austria). They are approved for use in hemophilia and contain mainly factor IX.⁴⁸

The three-component and activated PCCs available in the United States are indicated for prevention/control of bleeding in patients with hemophilia B, although they are used extensively off-label for other indications. Only FEIBA contains FVII in an activated form, and Profilnine and Bebulin contain only low levels of FVII.⁴⁸ In general, it is considered preferable to give a PCC containing all four vitamin K-dependent coagulation factors and the natural anticoagulants antithrombin and activated protein C for warfarin reversal. Of note is that the PCCs are also increasingly being used off-label for managing bleeding in patients receiving the non–vitamin K oral anticoagulant direct factor Xa inhibitors (ie, rivaroxaban and apixaban).⁴⁸

Although clinicians continued to attempt warfarin reversal in the United States with fresh frozen plasma, in patients requiring urgent reversal for surgery or procedural interventions, PCCs are recommended.⁴⁸ These recommendations include reversal in patients with life-threatening bleeding and an increased INR when urgent reversal is required. Compared with fresh frozen plasma, PCCs provide quicker INR correction, have a lower infusion volume, and are more readily available without crossmatching without risk of volume overloading.^{63,64} The PCC consistently reduces the INR more rapidly than plasma with 55% of patients treated with four-factor PCC achieving a target INR of ≤ 1.3 versus 10% of patients in the plasma group at 30 minutes after the end of infusion.⁶⁴

Topical Hemostatic Agents

Topical hemostatic agents are used intraoperatively to promote hemostasis at the site of vascular injury and are classified based on their mechanism of action. They include physical and mechanical agents, caustic agents, biologic agents, physical agents, and physiologic agents.⁶⁵ The agent to use depends on the type of bleeding, the agent's specific mechanism of action, its interaction with the environment, and the underlying coagulopathy.⁶⁵ Absorbable agents include gelatin sponges (Gelfoam [Pfizer, New York, NY]), derived from purified pork skin gelatin that increases contact activation to help create topical clot. Surgicel or Oxycel is oxidized regenerated cellulose that works like Gelfoam (Pfizer, New York, NY). Avitene (Bard Davol, Warwick, RI) is microfibrillar collagen derived from bovine skin. Collagen sponges are available in different commercial forms and are derived from bovine Achilles tendon or bovine skin. Gelatin foam should not be used near nerves or in confined spaces but can be administered topically with thrombin. CoSeal (Baxter, Deerfield, IL) is used where swelling and expansion are not a concern. BioGlue (CryoLife, Kennesaw, GA) has been used in cardiac surgery, but it contains a glutaraldehyde component that cross-links proteins to fix tissues it is applied to.^{65–67}

Topically applied thrombin preparations are also used extensively. The first available thrombin was derived from bovine plasma (Thrombin JMI [Pfizer, New York, NY]). Although still available, bovine thrombin has been replaced in most clinical use by human thrombin due to its potential for antibovine thrombin antibody formation and immune-mediated coagulopathy.⁶⁶ Currently, there are two human thrombins available for clinical use, including plasma-derived thrombin (Evithrom [Ethicon, Summerville, NJ]) and recombinant human thrombin (RECOETHROM [Baxter, Deerfield, IL]).

Fibrin sealants, also referred to as **biologic glue** or **fibrin tissue adhesives**, are component products that combine thrombin (mostly human) and fibrinogen (usually plasma derived).⁶⁵ The first commercial fibrin sealant, Tisseel (Baxter, Deerfield, IL), was approved in 1989. Additional fibrin sealants are currently in use and include Crosseal (Ethicon, Summerville, NJ), E vicel (Ethicon, Summerville, NJ), and FloSeal (Baxter, Deerfield, IL). They are packaged with a dual-syringe delivery system that combines the components to form a fibrin clot.⁶⁷ The thrombin concentration determines the onset and the tensile strength fibrin seal.⁶⁷ Crosseal

(Ethicon, Summerville, NJ) contains human fibrinogen, human thrombin, and TXA. E vicel (Ethicon, Summerville, NJ) does not contain any fibrinolytic inhibitors. Several of these agents have been studied in cardiac surgical patients including FloSeal (Baxter, Deerfield, IL) and are the subject of a recent review.⁶⁷

Summary

The potential for bleeding in surgical patients represents an ongoing problem for clinicians. The increasing use of oral anticoagulation agents creates a need for multiple pharmacologic approaches as reviewed in the chapter on anticoagulation. Newer therapies, including purified factor concentrates such as the PCCs and potential recombinant therapies under development, will provide clinicians with the ability to administer key coagulation proteins to treat hemorrhage when standard therapies are ineffective, unavailable, or for other reasons that include no need for crossmatching. Therapy should be multimodal when managing perioperative hemostasis (**Figure 29.2**).⁶⁸ Understanding the complex physiology of hemostatic function is an important part of therapy, and procoagulation agents are part of a multimodal approach.

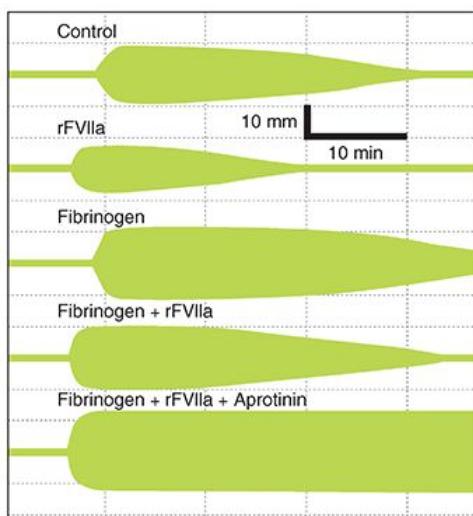

FIGURE 29.2 Thromboelastography recordings obtained with the ROTEM (Instrumentation Laboratory, Bedford, MA) device after the addition of recombinant activated factor VIIa (rFVIIa) and/or fibrinogen in the presence of tissue-type plasminogen activator in volunteer plasma. Tissue-type plasminogen activator was added to stimulate fibrinolysis, followed by rFVIIa in a final concentration 1.5 µg/mL and fibrinogen in a final concentration 100 mg/dL. The maximum clot firmness (the width of clot tracing) was only improved after the addition of fibrinogen. The onset of clotting was shorter after the addition of rFVIIa, but the extent of lysis (ie, decreased clot firmness) was increased in contrast to the samples with fibrinogen. Fibrinolysis was observed after the addition of rFVIIa and fibrinogen, and the clot structure was improved after the addition of an antifibrinolytic aprotinin. Reprinted with permission from Tanaka KA, Taketomi T, Szlam F, et al. Improved clot formation by combined administration of activated factor VII (NovoSeven) and fibrinogen (Haemocomplettan P). Anticoagulants

Jerrold H. Levy

Anticoagulants are drugs that delay or prevent the clotting of blood. In a perioperative setting, patients receive anticoagulation for cardiovascular procedures, for thromboprophylaxis, or for cardiovascular disease and/or atrial fibrillation. The therapeutic potential of anticoagulation must be considered against risks for increased bleeding. Many agents are also used in the perioperative setting that may not be routinely monitored, including drugs such as low-molecular-weight heparin (LMWH), non–vitamin K oral anticoagulants that include direct thrombin inhibitors (dabigatran [Pradaxa] and factor Xa inhibitors rivaroxaban [Xarelto], apixaban [Eliquis], edoxaban [Savaysa], or P2Y₁₂ platelet inhibitors [clopidogrel and ticagrelor]). This chapter reviews the different anticoagulation agents, including antiplatelet agents, and considerations for their use in the perioperative use. The agents most commonly used will be considered in detail. Guidelines for management from different societies and journals are published and updated over time including American College of Chest Physicians and other societies that should be referred to for more detail.^{1–9}

Heparin

Unfractionated heparin (UFH) is an extract of porcine intestine or bovine lung, where heparin is stored in the mast cells. It is a mixture of highly sulfated glycosaminoglycans with molecular weights ranging from 3,000 to 30,000 Da that produce their anticoagulant effects by binding to antithrombin (AT) (previously known as antithrombin III), a circulating serine protease. Heparin acts as an anticoagulant by binding to AT, enhancing the rate of thrombin-AT complex formation by 1,000 to 10,000 times. Other factors in the clotting cascade, including not only factor Xa but also factors XII, XI, and IX, are also inhibited by AT.¹⁰ Anticoagulation thus depends on the presence of adequate amounts of circulating AT as shown in [Figure 30.1](#).

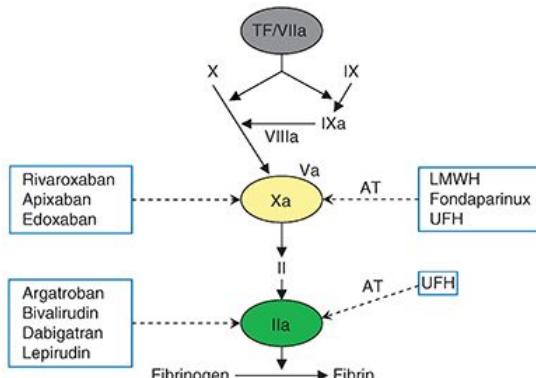

FIGURE 30.1 The major targets for anticoagulants in the coagulation pathway are directed against either factor Xa or thrombin (IIa). Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) require circulating antithrombin (AT) as a cofactor, and only UFH will inhibit thrombin. Fondaparinux is a synthetic pentasaccharide and, like LMWH, indirectly inhibit factor Xa, requiring AT as a cofactor. The direct factor Xa inhibitors are AT-independent and include rivaroxaban, apixaban, and edoxaban. Both oral direct thrombin inhibitors (dabigatran) and intravenous agents directly inhibit thrombin. Vitamin K antagonists, such as warfarin, inhibit the activation of factors II, VII, IX, and X, as factors are made but are not activated by the posttranslational carboxylation that is inhibited (mechanism not shown). *Derived from Levy JH, Key NS, Azran MS. Novel oral anticoagulants: implications in the perioperative setting. Anesthesiology. 2010;113:726-745.*

Standardization of heparin potency is based on in vitro comparison with a known standard. A unit of heparin is defined as the volume of heparin-containing solution that will prevent 1 mL of citrated sheep blood from clotting for 1 hour after the addition of 0.2 mL of 1:100 calcium chloride. Heparin must contain at least 120 United States Pharmacopeia units per milliliter. Because the potency of different commercial preparations of heparin may vary greatly, the heparin dosing should always be prescribed in units, and most heparin is porcine in origin.

Pharmacokinetics

Heparin is a highly charged acidic molecule administered by intravenous (IV) or subcutaneous (SC) injection. The pharmacokinetics of heparin is based on measurements of its biologic activity using an anti-Xa assay. Over the range of heparin concentrations used clinically, the dose-response relationship is not linear for multiple reasons, including the need for AT to potentiate its effect, the effects of temperature, its highly charged nature that causes protein binding, and the variability of anticoagulation responses. The precise pathway of heparin elimination is uncertain, and the influence of renal and hepatic disease on its pharmacokinetics is less than with other anticoagulants. Heparin binds to many different proteins, which can affect its anticoagulant activity and contributes to heparin resistance.¹¹

Laboratory Evaluation of Coagulation

The anticoagulant response to heparin varies widely, especially in critically ill patients with alterations in AT and other plasma proteins. Different tests are used to monitor UFH and other anticoagulants as follows.²

Activated Partial Thromboplastin Time and Anti-Factor Xa

Heparin treatment is usually monitored to maintain the ratio of the activated partial thromboplastin time (aPTT) within a defined range of approximately 1.5 to 2.5 times normal values, typically 30 to 35 seconds. The aPTT has traditionally been the most commonly used test to monitor heparin, but certain factor deficiencies, including hemophilia and inhibitors of contact activation (eg, factor XII) can increase aPTT but may not increase the risk of bleeding. As a result, some hospital laboratories have changed to anti-Xa assays instead of aPTT monitoring because of the variability of responses, with low-dose regimens targeting levels of 0.3 to 0.5 unit/mL and high-dose regimens targeting levels 0.5 to 0.8 unit/mL. The aPTT is also used to measure the effects of direct thrombin inhibitors, including bivalirudin and argatroban, and is relatively sensitive to heparin levels up to approximately 1 unit/mL. At higher heparin concentrations, the activated clotting time (ACT) is used as follows.

Activated Clotting Time

The ACT is used primarily to determine anticoagulation for higher heparin concentrations, like those typically used during cardiopulmonary bypass. The ACT is performed by mixing whole blood with an activating substance that has a large surface area, such as celite (diatomaceous earth—silicon dioxide) or kaolin (clay—aluminum silicate). This is a contact activation through the classic intrinsic pathway where factor XII initiates activation of the clotting cascade. The activator speeds up the clotting time to normal values of approximately 100 to 150 seconds, depending on the device. Several commercially available timing systems used clinically to measure the ACT are based on detecting the onset of clot formation. Nevertheless, results between different commercial devices to measure the ACT may not be interchangeable, especially if the type of activator (celite or kaolin) is different.

Heparin effect and its antagonism by protamine are commonly monitored in patients undergoing cardiovascular procedures by measuring the ACT. Because the ACT is easy to use and reliable for high heparin concentrations (>1.0 unit/mL), it has become the mainstay of heparin anticoagulation monitoring in perioperative management and for cardiac catheterization. In addition to the presence of a heparin effect, the ACT may be influenced by hypothermia, thrombocytopenia, presence of contact activation inhibitors (aprotinin), and preexisting coagulation deficiencies (fibrinogen, factor XII, factor VII). With aprotinin

therapy, the recommendation is to use kaolin-ACT rather than a celite-ACT determination as kaolin binds to aprotinin to minimize its effect.

For cardiac surgery, a baseline value for the ACT is determined (1) before the IV administration of heparin, (2) 3 to 5 minutes after administration, and (3) at 30-minute intervals, thereafter. The ACT response to heparin is not linear for multiple reasons, including the need for AT for its effectiveness and because of several other factors that affect ACT. During cardiopulmonary bypass, the target ACT value is still controversial but often considered adequate if the ACT is longer than 350 seconds, although most cardiac surgical centers target an ACT of longer than 400 seconds. The need to measure ACT repeatedly is emphasized by the fourfold variation in heparin sensitivity between patients and the threefold variation in the rate at which heparin is metabolized. Furthermore, ACT values can be misleading during cardiopulmonary bypass with respect to heparin-induced anticoagulation because of the effects of hypothermia and hemodilution on the measurement system.¹²

Clinical Uses

Heparin is used extensively for multiple purposes, including the prevention and treatment of venous thrombosis and pulmonary embolism (PE), for acute coronary syndromes, and perioperative anticoagulation for extracorporeal circulation and hemodialysis. When administered intravenously, heparin has an immediate onset of action, whereas SC administration results in variable bioavailability with an onset of action in 1 to 2 hours.

Heparin-Induced Thrombocytopenia

Thrombocytopenia due to UFH is common and can begin within hours in patients exposed to heparin. However, a more severe and even life-threatening syndrome develops in 0.5% to 6.0% of patients, manifesting as severe thrombocytopenia (50% drop in platelet count or <100,000 cells/ μ L), that can be associated with thrombotic events (heparin-induced thrombocytopenia [HIT] with thrombosis). This severe response typically develops after 4 to 5 days of heparin therapy and is caused by heparin-dependent antibodies to platelet factor IV that trigger platelet aggregation and result in thrombocytopenia (see the more detailed discussion in physiology of hemostasis under [Chapter 27](#)).¹³

Allergic Reactions

Heparin can also cause allergic reactions, but these are rare and present in a manner typical of other hypersensitivity reactions. In patients who do experience immediate reactions, HIT should also be suspected due to the presence of preformed antibodies. The rapid IV infusion of large doses of heparin usually causes minimal hemodynamic changes.¹³

Reversal of Heparin-Induced Anticoagulation With Protamine

Protamine is one of the few agents available for reversing anticoagulation. Protamine is a strongly alkaline (nearly two-thirds of the amino acid composition is arginine), polycationic, low-molecular-weight protein found in salmon sperm. The positively charged alkaline protamine combines with the negatively charged acidic heparin to form a stable complex that is devoid of anticoagulant activity. These heparin-protamine complexes are removed by the reticuloendothelial system. Clearance of protamine by the reticuloendothelial system (within 20 minutes) is more rapid than heparin clearance and that may explain, in part, the phenomenon of heparin rebound. The dose of protamine required to antagonize heparin is typically 1 mg for every 100 units of circulating heparin activity. A more specific dose of protamine is calculated by heparin-protamine titration. Most clinicians give too much protamine because they reverse based on the total dose of heparin administered without accounting for heparin elimination prior to the administration of protamine. Heparin has a half-life of approximately 1 hour, so determinations of protamine dosing should include considerations of the circulating heparin level for reversal (see also “[Protamine](#)” in [Chapter 29](#)).

Low-Molecular-Weight Heparins

Enoxaparin and dalteparin are two commonly administered LMWHs derived from standard commercial-grade UFH by chemical depolymerization to yield fragments with a mean molecular weight of 4,000 to 5,000 Da. Depolymerization of heparin results in a change in its anticoagulant profile, pharmacokinetics, and effects on platelet function. Compared with heparin, which has an anti-Xa to anti-IIa activity of about 1:1, enoxaparin has a corresponding ratio that varies between 4:1 and 2:1.¹⁴ The pharmacokinetics of enoxaparin and dalteparin between patients are more consistent than heparin because these drugs bind less avidly to proteins than heparin. This contributes to better bioavailability at low doses. Although protection against venous thromboembolism (VTE) in high-risk medical and surgical patients is often thought to be better with LMWH than with heparin, LMWH's effect is considerably prolonged with renal failure and anticoagulants such as UFH should be used in this population. Therefore, care should be taken to delay surgery for 12 hours after the last dose of LMWH in patients with normal renal function and longer with renal dysfunction. Protamine does not neutralize LMWH.^{1-3,14}

Spinal and Epidural Hematomas

The risk of spontaneous hematoma formation may be increased in the presence of LMWH and indwelling epidural catheters for administration of postoperative analgesia and by concomitant use of other drugs that affect hemostasis (nonsteroidal antiinflammatory drugs, platelet inhibitors) and by traumatic or repeated attempts to accomplish entry into the epidural or subarachnoid space. This increased risk of hematoma formation is a consideration when selecting regional anesthesia in patients being treated with LMWH preparations. Recommendations for the management of patients for regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy are reported in the *American Society of Regional Anesthesia and Pain Medicine Evidence-Based Guidelines* (fourth edition).¹⁵

Fondaparinux

Fondaparinux is a synthetic anticoagulant composed of the five saccharide units that make up the active site of heparin that binds AT, such as LMWH, to inhibit factor Xa but has no direct activity against thrombin. Administered subcutaneously, fondaparinux is rapidly absorbed and has an elimination half-time of 15 hours, allowing for once daily administration. Metabolism does not occur, and the drug is eliminated by the kidneys and should not be used in patients with renal failure. Clinical uses of fondaparinux include prevention of deep vein thrombosis (DVT) and PE and as an alternative anticoagulant in patients with HIT. Because of its long duration of action, it is used primarily in patients with HIT or concerns about sensitization.¹⁶

Danaparoid

Danaparoid is a glycosaminoglycan that is derived from porcine intestinal mucosa and consists of a mixture mostly of dermatan sulfate and chondroitin sulfate. This low-molecular-weight heparinoid compound attenuates fibrin formation principally by binding AT. Elimination of danaparoid is predominately through the kidneys. Danaparoid is effective in decreasing the incidence of DVT following total hip arthroplasty and was used for the treatment of HIT. Although not currently available in the United States, it is used in other countries and being studied again for HIT management in clinical trials.

Prophylaxis Against Venous Thromboembolism

Surgical procedures have been associated with a 20-fold increase in risk for VTE, which is understandable, considering that the majority of surgical patients have one or more risk factors for developing VTE.² The incidence of DVT is 10% to 40% among general surgery patients and higher still in high-risk surgery patient populations (eg, orthopedic, thoracic, cardiac, and vascular surgery).^{2,3} Fortunately, thromboprophylaxis is known to effectively reduce VTE.¹⁻⁶

To prevent VTE, patients are treated with anticoagulants. Although SC heparin and LMWH are commonly used, multiple novel agents are also approved for different indications, including fondaparinux, rivaroxaban, and dabigatran with different indications depending on the country. Enoxaparin and dalteparin are commonly used LMWHs. Before the availability of LMWH, low-dose heparin, 5,000 units

subcutaneously every 8 to 12 hours, was a common regimen. In those with renal failure or renal dysfunction, heparin and warfarin are the only drugs minimally affected because of nonrenal clearance.

Among surgical patients, those undergoing total hip replacement are at a unique risk for developing DVT, and many of the studies for approval of new anticoagulants have focused on this group and other orthopedic patients. The risk of DVT is more protracted after hip surgery than after general surgery, when it usually develops during the first few postoperative days. The surgical technique for hip surgery, which kinks the femoral vein, seems to stimulate proximal DVT in the operated leg, whereas calf vein thrombosis is more likely to develop in either leg. Another effect unique to hip surgery is the impairment of venous hemodynamics, which may last several weeks in the operated leg. Indeed, there are significantly fewer venous thromboembolic complications in patients undergoing elective hip replacement when prophylaxis with LMWH is given for 1 month rather than only during the hospitalization. The VTE is also a common, life-threatening complication of major trauma. A PE has been observed to occur in 2% to 22% of patients with major trauma, and fatal PE is the third most common cause of death in patients who survive the first 24 hours.^{1–9,17}

Direct Thrombin Inhibitors: Parenteral Agents

An important class of anticoagulants that high-risk surgery patients at risk for or with HIT may receive are the direct thrombin inhibitors that include bivalirudin and argatroban (**Table 30.1**). Bivalirudin is also commonly used for cardiac interventional procedures and in an intensive care unit setting. The direct thrombin inhibitors also vary in their binding affinities for thrombin. Bivalirudin and other similar agents, including desirudin, bind in a bivalent manner to thrombin by interacting with both the catalytic site and fibrinogen-binding site. Bivalent direct thrombin inhibitors show higher affinity and specificity for thrombin compared with univalent direct thrombin inhibitors, which bind to the catalytic site only. Direct thrombin inhibitors vary substantially in their pharmacokinetic properties in terms of half-life and metabolism. The original direct thrombin inhibitors were modifications of the Leach protein hirudin and included desirudin and lepirudin, drugs that were the first agents of this class approved but no longer use or available.

TABLE 30.1

Direct thrombin inhibitors currently available

Drug	Dose	Clinical status	Indications current (future)	Recommended monitoring	Time to stop before surgery
Bivalirudin	Intravenous	Available in United States, Europe, and Canada	<ul style="list-style-type: none"> • PCI in patients with HIT • PTCA • Cardiac surgery (Canada) • Acute coronary syndromes (Europe) 	ACT	~4–6 hours
Argatroban	Intravenous	Available in United States and Europe	<ul style="list-style-type: none"> • Prophylaxis and treatment of thrombosis in HIT • PCI in patients with HIT 	aPTT ACT (PCI)	~4–6 hours
Desirudin	Subcutaneous	Not widely available	<ul style="list-style-type: none"> • Total hip arthroplasty • HIT 	aPTT	~24 hours
Dabigatran etexilate	Oral	Available in United States for stroke prevention for atrial fibrillation; approved in Europe and Canada for hip and knee arthroplasty	<ul style="list-style-type: none"> • Atrial fibrillation • DVT treatment and prevention • PE treatment and 	Not for routine: thrombin times — qualitative assay; diluted thrombin time and ecarin clotting time sensitive also for levels; aPTT to determine effect but not sensitive at low drug levels	~48 hours with normal renal function; ~72–96 hours or more if abnormal renal function. Drug effects can actually be measured as noted and potentially can be used to guide decision making.

			prevention after 5-10 days Rx with parenteral agent		
--	--	--	---	--	--

Abbreviations: ACT, activated clotting time; aPTT, activated partial thromboplastin time; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; PCI, percutaneous coronary intervention; PE, pulmonary embolism, PTCA, percutaneous transluminal coronary angioplasty; Rx, prescription.

Bivalirudin

Bivalirudin, a synthetic analogue of hirudin with a half-life of 25 minutes, has been widely studied in patients with and without acute coronary syndromes undergoing percutaneous coronary intervention (PCI). This agent is indicated for use in patients with unstable angina undergoing percutaneous transluminal coronary angioplasty; in patients with or at risk for HIT or HIT undergoing PCI; and with provisional use of glycoprotein (GP) IIb/IIIa inhibitors in patients undergoing PCI. Although it is a polypeptide, bivalirudin is considered a safe anticoagulant in patients with HIT. In patients with HIT antibodies undergoing cardiopulmonary bypass, bivalirudin provided safe and effective anticoagulation, with a 94% success rate for the procedures.¹⁸ Further, multiple studies have demonstrated its application as a heparin replacement in patients who are HIT-positive and require on or off-pump cardiac surgery, although this is an off-label use for the drug.¹⁸⁻²⁰

Argatroban

Argatroban is an injectable, synthetic, univalent direct thrombin inhibitor indicated for prophylaxis or treatment of thrombosis in patients with or at risk for HIT undergoing PCI. It has a relatively short half-life of 40 to 50 minutes, and anticoagulation returns to baseline when stopping it after approximately 4 hours.²¹ Patients with HIT are likely to have renal dysfunction, and most of the agents used for HIT are all primarily renally eliminated. Argatroban is hepatically eliminated; thus, no dose adjustments are required in patients with renal impairment. As lepirudin is renally eliminated and bivalirudin is partially (~20%) renally eliminated, their use may require dose adjustment in renally impaired patients to avoid accumulation. Antibodies to argatroban have not been detected after prolonged or repeated use due to its low molecular weight.²²

Lepirudin and Desirudin

Lepirudin and desirudin are synthetic analogues of hirudin, the direct thrombin inhibitor first isolated from leeches as *Hirudo medicinalis* is the name of the leech. These drugs were the first direct thrombin inhibitors that were originally approved for use in patients with HIT and associated thromboembolic disease. Lepirudin was initially reported for cardiac surgical patients; however, bleeding was a major problem due to its ability to irreversibly inhibit thrombin.^{16,22} Desirudin (another recombinant hirudin) was originally approved for the prevention of VTE after total hip or knee replacement surgery and was studied in cardiovascular patients undergoing percutaneous transluminal coronary angioplasty. With the advent of all of the newer direct thrombin inhibitors, and non-vitamin K oral anticoagulants, these drugs are either no longer available or used clinically.

Oral Anticoagulants

Vitamin K Antagonists—Warfarin

Oral anticoagulants are derivatives of 4-hydroxycoumarin (coumarin). Warfarin is the most frequently used anticoagulant because of its predictable onset and duration of action and its excellent bioavailability after oral administration ([Table 30.2](#)). Treatment usually begins with an oral warfarin dose of 5 to 10 mg, and the average maintenance dose is 5 mg; however, the dose varies widely among individuals due to pharmacogenetic differences. Warfarin has been the only oral agent available until the recent approval of new

agents that are described in the sections that follow. Disadvantages of warfarin include delayed onset of action, the need for regular laboratory monitoring, and difficulty in reversal should a surgical procedure create concern about bleeding.^{3,16}

TABLE 30.2

Current and emerging factor Xa inhibitors and vitamin K antagonist

Drug	Administration	Clinical status	Indications: current	Monitoring	Time to stop before elective surgery
Apixaban	Oral	Available most countries	Atrial fibrillation DVT treatment and prevention PE treatment and prevention	None	Low-risk bleeding: 1-2 days High-risk bleeding: 2-3 days
Danaparoid	Intravenous or subcutaneous	No longer available	Treatment of HIT; thromboprophylaxis in HIT patients	Calibrated plasma anti-Xa activity	No longer available
Low-molecular-weight heparin	Intravenous or subcutaneous	Available in most countries	Multiple: thromboprophylaxis Acute coronary syndromes	Plasma anti-Xa activity	At least 24-36 hours before Longer if renal dysfunction as elimination is prolonged; not reversible
Fondaparinux	Intravenous or subcutaneous	Available in most countries	Thromboprophylaxis and treatment of pulmonary embolism	Calibrated plasma anti-Xa activity	Long half-life of 17-21 hours; should be stopped at least 2 days; longer if renal dysfunction
Rivaroxaban	Oral	Available in Canada, Europe, and United States	Atrial fibrillation DVT treatment and prevention PE treatment and prevention With ASA to reduce CV events with CAD or PAD	None current	Low-risk bleeding: 1-2 days High-risk bleeding: 2-3 days
Heparin (UFH)	Intravenous or subcutaneous			aPTT, heparin levels (plasma anti-Xa)	4-6 hours before the procedure if possible but may need to continue for cardiovascular surgery; also reversible with protamine
Warfarin	Oral and intravenous		Anticoagulation for multiple reasons and treatment of thrombophilia	PT/INR	~5 days before procedure to allow INR <1.5 ? Bridging: depends on patient

Abbreviations: aPTT, activated partial thromboplastin time; CAD, coronary artery disease; CV, cardiovascular; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; PAD, peripheral arterial disease; PE, pulmonary embolism; PT, prothrombin time; UFH, unfractionated heparin.

Mechanism of Action

Warfarin inhibits vitamin K epoxide reductase that converts the vitamin K-dependent coagulation proteins (factors II [prothrombin], VII, IX, and X) to their active form, a posttranslational modification. The anticoagulant effect of oral or IV warfarin is delayed for 8 to 12 hours, reflecting the onset of inhibition of clotting factor synthesis and the elimination half-time of previously formed clotting factors that are not altered by the oral anticoagulant. Peak effects of warfarin do not occur for 36 to 72 hours.³

Pharmacokinetics

Warfarin is rapidly and completely absorbed, with peak concentrations occurring within 1 hour after ingestion. It is 97% bound to albumin, and this contributes to its negligible renal excretion and long elimination half-time of 24 to 36 hours after oral administration. Warfarin, however, does cross the placenta and produces exaggerated effects in the fetus, who has limited ability to synthesize clotting factors. Warfarin is metabolized to inactive metabolites that are conjugated with glucuronic acid and ultimately excreted in bile (enterohepatic circulation) and urine.

Laboratory Evaluation

Treatment with oral anticoagulants is best guided by measurement of the prothrombin time. The prothrombin time is particularly sensitive to three of the four vitamin K-dependent clotting factors (prothrombin and factors VII and X). Commercial prothrombin time reagents vary markedly in their responsiveness to warfarin-induced decreases in clotting factors. Therefore, prothrombin time results obtained with different reagents are not interchangeable between laboratories. This problem of variability in the responsiveness of prothrombin time reagents has been overcome by the introduction of a standardized system of reporting known as the international normalized ratio (INR). Each manufacturer assigns a specific value that indicates how a particular batch of tissue factor compares to an international reference tissue. The INR is the ratio of a patient's prothrombin time to a normal (control) sample, adjusted by the factor assigned by the manufacturer for the batch of factor being used in the assay. For most indications, a moderate anticoagulant effect with a targeted INR of 2.0 to 3.0 is appropriate, including prosthetic valve prophylaxis. An excessively prolonged prothrombin time is not readily shortened by omitting a dose because of the long elimination half-time of oral anticoagulants. Likewise, an inadequate therapeutic effect is not readily corrected by increasing the dose because of the delayed onset of therapeutic effect.

Unexpected fluctuations in the dose response to warfarin may reflect changes in diet, undisclosed drug use, poor patient compliance, surreptitious self-medication, or intermittent alcohol consumption. Concomitant medication with over-the-counter and prescription drugs can augment or inhibit the anticoagulant effect of coumarin drugs on hemostasis or interfere with platelet function. Patients receiving coumarin drugs are sensitive to fluctuating levels of dietary vitamin K, which is obtained predominantly from leafy green vegetables. The effect of coumarin can be potentiated in sick patients with inadequate vitamin K intake, particularly if they are treated with antibiotics and IV fluids without vitamin K supplementation. Preexisting liver disease and advanced age are associated with enhanced effects of oral anticoagulants.^{3,23}

Clinical Uses

Vitamin K antagonists (VKAs) are effective in the prevention of VTE, the prevention of systemic embolization and resultant stroke in patients with prosthetic heart valves or atrial fibrillation, and for treatment of patients with thrombophilia who are hypercoagulable. Because of the extensive new range of oral anticoagulants for perioperative VTE prophylaxis, these agents are used less and less for this indication.

Management Before Elective Surgery

In patients receiving a VKA, the INR should be checked preoperatively. Although minor surgical procedures can be safely performed in patients receiving oral anticoagulants, for major surgery, discontinuation of oral anticoagulants 1 to 3 days preoperatively is recommended to permit the prothrombin time to return to within 20% of its normal range. This approach, followed by reinstitution of the oral anticoagulant regimen 1 to 7 days postoperatively, is not accompanied by an increased incidence of thromboembolic complications in vulnerable patients. However, patients at high risk, such as those with prosthetic heart valves, may require bridging with UFH.³

Bleeding is the main complication of any anticoagulant therapy, including the VKAs. The risk of bleeding is influenced by the intensity of the anticoagulant therapy, the patient's underlying disorder, and the concomitant use of aspirin. Bleeding that occurs when the INR is less than 3.0 is frequently associated with an underlying cause (neoplasm, peptic ulcer). Anticoagulation drugs may increase the incidence of intracranial hemorrhage after a cerebrovascular accident. Compression neuropathy has been observed in treated patients after brachial artery puncture to obtain a sample for blood gas analysis. Treatment of bleeding depends on the severity and underlying patient and location. In emergency situations, oral or IV administration of vitamin K is used but will not immediately reverse the anticoagulant effect. If the immediate reversal is needed, for performance of high-risk surgical procedures such as craniotomy, administration of prothrombin complex concentrates (PCCs) is needed if available or other reversal strategies, as defined in Chapter 29.^{3,24} Guidelines for perioperative management are available.¹⁻⁷

Direct-Acting Non-vitamin K Oral Anticoagulants

For many years, warfarin has been the only oral anticoagulant available but has variabilities regarding dosing and effects and requires frequent monitoring and may take up to 5 days before therapeutic levels can be obtained. The newer therapeutic agents have a rapid onset with therapeutic anticoagulation within hours of administration and do not need routine monitoring. Dabigatran is an oral direct thrombin inhibitor, and rivaroxaban is a direct factor Xa inhibitor, similar to LMWH.¹⁶ Both of the newer agents require dose adjustments for renal failure and will be considered separately, along with agents still under investigation (see [Table 30.2](#)).^{9,16}

Direct Factor Xa Inhibitors

Rivaroxaban (Xarelto)

Rivaroxaban is an oral, direct factor Xa inhibitor with >10,000-fold greater selectivity for factor Xa than for other related serine proteases. In contrast to LMWH and similar agents, rivaroxaban does not require AT as a cofactor. Direct factor Xa inhibitors, including rivaroxaban, can inhibit free factor Xa, clot-bound factor Xa, and factor Xa bound to the prothrombinase complex, unlike indirect factor Xa inhibitors, such as fondaparinux, which are unable to inhibit factor Xa within the prothrombinase complex. Rivaroxaban is also a non-heparin-like molecule that may be suitable for the management of patients with HIT. Rivaroxaban is approved for prophylaxis of VTE during hospitalization and posthospital discharge to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, treatment of DVT, PE, and reduction in the risk of recurrence of DVT and/or PE, prophylaxis of DVT in knee or hip replacement surgery, and in combination with aspirin, to reduce the risk of major cardiovascular events in patients with chronic coronary artery disease or peripheral artery disease.^{9,16}

When used with neuraxial anesthesia, an epidural catheter should not be removed earlier than 18 hours after the last administration of rivaroxaban, and the next rivaroxaban dose should be administered no earlier than 6 hours after the removal of the catheter and as noted in the manufacturer's package insert and in American Society of Regional Anesthesia and Pain Medicine guidelines.

Apixaban (Eliquis)

Apixaban is another oral, direct factor Xa inhibitor administered twice daily. Apixaban is approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation; in patients with prophylaxis of DVT, which may lead to PE; in patients who have undergone hip or knee replacement surgery; and for the treatment of DVT and PE and to reduce the risk of recurrent DVT and PE following initial therapy.

When used with neuraxial anesthesia, indwelling epidural or intrathecal catheters should not be removed earlier than 24 hours after the last administration of apixaban, and the next dose of apixaban should not be administered earlier than 5 hours after the removal of the catheter as noted in the manufacturer's package insert and 4 to 6 hours in American Society of Regional Anesthesia and Pain Medicine guidelines.

Edoxaban (Savaysa)

Edoxaban is also an oral, direct factor Xa inhibitor administered once daily. Current indications are to reduce the risk of stroke with nonvalvular atrial fibrillation and for the treatment of deep DVT and PE following 5 to 10 days of initial therapy with a parenteral anticoagulant.

Direct Thrombin Inhibitors

Ximelagatran

Ximelagatran is an oral, direct thrombin inhibitor that was approved in Europe for the VTE prophylaxis but later withdrawn from the market in 2006 due to concerns over potential liver toxicity. However, ximelagatran provided proof of principle that oral agents that act via direct inhibition of thrombin were an effective mode of action for new anticoagulants.¹⁶

Dabigatran Etxilate (Pradaxa)

Dabigatran etexilate is an oral, direct thrombin inhibitor approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, for the treatment of DVT and PE in patients who have been treated with a parenteral anticoagulant for 5 to 10 days, and to reduce the risk of recurrence of DVT and PE in patients who have been previously treated. Dabigatran's effects can be best measured by thrombin times, diluted thrombin times, and ecarin clotting times, although aPTT values can be used for screening.²⁵ Administration of the first dose should occur a minimum of 2 hours after the catheter is removed, and patients should be observed for neurologic signs and symptoms.^{9,16} Dosing should also be adjusted for patients with renal dysfunction.

Perioperative Management of the Direct-Acting Non–vitamin K Oral Anticoagulants

The newer therapeutic agents have a rapid onset with therapeutic anticoagulation within hours of administration and do not need routine monitoring. Dabigatran is an oral direct thrombin inhibitor, and rivaroxaban is a direct factor Xa inhibitor, similar to LMWH.¹⁶ Both of the newer agents require dose adjustments for renal failure.¹⁶ One of the new challenges with use of these agents is how to effectively manage patients perioperatively. In the United States, PCCs are recommended in guidelines for immediate INR reversal along with vitamin K administration.²⁴ Vitamin K, however, without PCCs takes days to reverse and synthesize new active coagulation factors. Although fresh frozen plasma (FFP) is still often used, it is associated with transfusion risk, volume overload, and FFP does not restore the INR to <1.3 but usually to approximately 1.4 to 1.6, which is the baseline INR for FFP.²⁴ The PCCs are also used increasingly off-label for managing bleeding in patients receiving the Xa inhibitors including apixaban, edoxaban, and rivaroxaban. Although andexanet alfa is currently approved in the United States for life-threatening bleeding, it has not been studied in surgical patients, has a short duration of effect of several hours, and is expensive, costing \$25,000 per gram.²⁶ For the reversal of dabigatran, there is a specific antidote called idarucizumab, a monoclonal antibody fragment that has been extensively studied in surgical patients; however, dabigatran is not widely used in the United States.²⁶

Although routine monitoring of the new anticoagulants is not standard, if needed, they are best evaluated with specialized tests. For dabigatran, thrombin clotting time, ecarin clotting time, and aPTT can measure its effects.²⁶ Prothrombin time (INR) is not recommended. The aPTT, a standard test, can provide a useful qualitative assessment of anticoagulant activity but is less sensitive at supratherapeutic dabigatran levels, and limited data exists for ACT. Overall, the aPTT and thrombin clotting time are the most accessible qualitative methods for determining the presence or absence of anticoagulant effect.²⁶ For rivaroxaban, prolongation of most standard hemostatic tests are too variable and specialized tests evaluating anti-Xa are required.²⁶

Two important recent studies have been published to guide management. In the BRIDGE study, Douketis et al. randomized atrial fibrillation patients to bridging anticoagulation therapy with LMWH (dalteparin) or placebo from 3 days before the procedure until 24 hours before the procedure and then for 5 to 10 days after the procedure.²⁷ Warfarin treatment was stopped 5 days before the procedure and was resumed within 24 hours after the procedure and included 1,884 patients. Arterial thromboembolism was 0.4% in the no-bridging group and 0.3% in the bridging group ($P = .01$ for noninferiority); however, major bleeding was 1.3% in the no-bridging group and 3.2% in the bridging group ($P = .005$ for superiority).²⁷

Another important report is the Perioperative Anticoagulation Use for Surgery Evaluation cohort study that included 3,007 nonvalvular atrial fibrillation patients who were long-term users of apixaban, dabigatran, or rivaroxaban, scheduled for an elective surgery or procedure. The protocol was designed with a strategy based on direct-acting non–vitamin K oral anticoagulant pharmacokinetic properties, procedure-associated bleeding risk, and creatinine clearance levels. The direct-acting non–vitamin K oral anticoagulants were stopped 1 day before a low-bleeding risk procedure and 2 days before a high-bleeding risk procedure, and resumed 1 day postoperatively after a low-bleeding risk procedure and 2 to 3 days after a high-bleeding risk procedure. Major bleeding and arterial thromboembolic events were determined, and the minimal residual anticoagulant level was considered to be <50 ng/mL) at the time of the procedure. There were ~42% apixaban, ~22% dabigatran, and 36% rivaroxaban-treated patients of which 33.5% were undergoing a high-bleeding risk procedure. The 30-day postoperative rate of major bleeding was 1.35% in the apixaban, 0.90%

in the dabigatran, and 1.85% in the rivaroxaban cohorts. Arterial thromboembolism was low with 0.16% in the apixaban, 0.60% in the dabigatran, and 0.37% in the rivaroxaban cohorts. In patients with a high-bleeding risk procedure, the rates of major bleeding were ~3% per group.²⁵

In summary, for those who require emergency urgent surgery, warfarin can be rapidly reversed with PCCs, and dabigatran with idarucizumab and has been studied in this indication. Andexanet has only been studied for life-threatening bleeding and not in all patients and is costly. For elective surgery, growing data as reviewed suggests bridging it is not required, especially in patients with atrial fibrillation, but patient should be considered on a case-to-case basis, and risk versus benefit should be considered in logical decision making.

Platelet Inhibitors

Aspirin

Antiplatelet agents are the mainstay therapy for patients with atherosclerotic vascular disease and coronary artery disease, therapy consistent with the role of platelets in atherosclerosis.²⁸ Treatment with aspirin reduces the incidence of occlusive arterial vascular events. Aspirin irreversibly acetylates cyclooxygenase and thereby prevents the formation of thromboxane A₂. Despite rapid clearance from the body, the effects of aspirin on platelets are irreversible and last for the life of the platelet, 7 to 10 days. Guidelines suggest in patients who require temporary interruption of aspirin- or clopidogrel-containing drugs before surgery or a procedure, stopping this treatment 7 to 10 days before the procedure is recommended over stopping this treatment closer to surgery. In patients who have had temporary interruption of aspirin therapy because of surgery or a procedure, resuming aspirin approximately 24 hours (or the next morning) after surgery when there is adequate hemostasis is recommended instead of resuming aspirin closer to surgery.

Thienopyridines: Clopidogrel, Prasugrel, and Ticagrelor

Currently approved thienopyridines include clopidogrel (Plavix), prasugrel (Effient), and ticagrelor. The first two agents are prodrugs requiring *in vivo* metabolism each to an active metabolite, as shown in [Table 30.3](#). Ticlopidine is now rarely used clinically and will not be considered. Thienopyridines irreversibly bind to P2Y₁₂ receptors, thereby blocking adenosine diphosphate (ADP) binding. This P2Y₁₂ receptor antagonism inhibits ADP-mediated platelet activation and aggregation due to the critical role ADP plays in platelet function. When ADP is secreted from internal stores, it amplifies platelet responses induced by other platelet agonists to increase activation, an internal to external signaling mechanism.²⁹ The ADP-induced signal is again mediated by P2Y receptors, which are G-coupled 7-membrane-spanning proteins that are present in many different cells.^{28–30} There are multiple other P2Y receptor subgroups, but the G_i-coupled P2Y₁₂ receptor mediates inhibition of adenylyl cyclase and amplifies the platelet aggregation response.

TABLE 30.3

Current oral antiplatelet agents

	Clopidogrel	Prasugrel	Ticagrelor	Aspirin
Drug class	Thienopyridine	Thienopyridine	Thienopyridine	Acetylsalicylate
Mechanism of action	Selective, irreversible binding to and inhibition of P2Y ₁₂ receptor on platelets	Selective, irreversible binding to and inhibition of P2Y ₁₂ receptor on platelets	Selective, reversible binding to and inhibition of P2Y ₁₂ receptor on platelets	Cyclooxygenase inhibition
Comments	Prodrug, metabolized to active form by two different metabolic steps; resistance due to metabolism	Prodrug, metabolized to active form one metabolic step; more potent and resistance rare	Direct-acting agent	Active drug but resistance can occur; likely due to absorption and other factors

Cangrelor

Cangrelor is another ATP analogue that blocks P2Y₁₂ receptor-mediated platelet activation and is the only IV P2Y₁₂ inhibitor available for clinical use. Cangrelor has a rapid onset and offset, a 3- to 6-minute plasma half-life, and platelet function recovery within 30 to 60 minutes after stopping the infusion. Cangrelor is

approved for clinical use by the U.S. Food and Drug Administration as an adjunct to PCI to reduce the risk of myocardial infarction, repeat coronary revascularization, and stent thrombosis in patients who have not been treated with a P2Y₁₂ platelet inhibitor and are not being given a GP IIb/IIIa inhibitor. As a short-acting platelet inhibitor, cangrelor has been studied as a potential agent to maintain therapeutic antiplatelet effects for patients receiving clopidogrel or ticagrelor up to the time of their surgical procedure, when their oral agents cannot be stopped the standard recommended times of 5 days.

Dual antiplatelet therapy—a thienopyridine (ADP P2Y₁₂ receptor antagonist) coadministered with aspirin—is commonly used for improving clinical outcomes in patients with acute coronary syndrome and undergoing percutaneous intervention. New agents include prasugrel and ticagrelor. Ticagrelor is a reversible, direct-acting P2Y₁₂ receptor antagonist. The P2Y₁₂ is a G_i-coupled platelet receptor for ADP that plays a central role in platelet function. Drugs that inhibit P2Y₁₂ are potent antithrombotic drugs. Clopidogrel is the most widely used agent, but resistance, as defined as its inability to inhibit adequately P2Y₁₂-dependent platelet function, occurs in 20% to 30% of patients. Prasugrel and ticagrelor appear to be more effective than clopidogrel in preventing thrombosis, although they increase the incidence of major bleeding, a problem with the efficacy of all anticoagulants.

Current recommendations are to discontinue thienopyridines 5 to 7 days before elective surgery and to avoid regional anesthesia until the effects of these drugs have dissipated. Guidelines for the management of patients with coronary stents on antiplatelet agents have been proposed and are often elaborate ([Figure 30.2](#)). The guidelines take into consideration the type of coronary stent used, and the interval since the stent was placed as well as the urgency of need for surgery in decision making.

Dipyridamole

Dipyridamole is an agent that increases cyclic adenosine monophosphate in platelets to inhibit their function. This agent was also used for cardiac stress testing because of its coronary vasodilatory effects (dipyridamole-thallium stress test). Currently, it is most frequently administered in combination with aspirin to prevent stroke in patients who cannot take a thienopyridine. It can increase bleeding and should be stopped preoperatively, but the aspirin component has a longer half-life than dipyridamole.

Dextran

Dextran 70 (70,000 Da) binds to platelets and inhibits their function. This agent was used clinically to reduce thrombosis after carotid surgery and a few other indications but is now rarely used for this indication.

Platelet Glycoprotein IIb/IIIa Antagonists

An important advance in managing ischemic cardiovascular disease was the development of platelet GP IIb/IIIa receptor inhibitors, although these agents are now often replaced with newer therapies. The IIb/IIIa receptor antagonists (abciximab, tirofiban, eptifibatide) either bind or competitively inhibit the corresponding fibrinogen receptor that is important for platelet aggregation. These drugs block fibrinogen binding to platelet GP IIb/IIIa receptors that are a common pathway of platelet aggregation. In multiple clinical trials, they have provided proof of concept on the critical role that platelet inhibition has in reducing ischemic events associated with acute coronary syndrome and PCIs. In recent years, thienopyridines and direct thrombin inhibitor (bivalirudin) in addition to PCIs, including stenting have had a significant impact; nonetheless, inhibiting platelet function has been critical to prevent platelet responses to vascular injury and clot formation. These agents prevent thrombus formation initiated by platelets in the pathogenesis of acute coronary syndrome (unstable angina, myocardial infarction), angioplasty failure, and stent thrombosis but are decreasingly used with oral P2Y₁₂ therapies in the advent of cangrelor.^{[30](#) [31](#)}

Various antagonists of GP IIb/IIIa are available. The first of these agents, the monoclonal antibody abciximab (ReoPro), was approved for use in PCI. Tirofiban (Aggrastat), a nonpeptide, for treatment of acute coronary syndromes (unstable angina or non–Q-wave myocardial infarction) and eptifibatide (Integrilin), a peptide, for use both in PCI and acute coronary syndromes. New nonpeptide oral antagonists of GP IIb/IIIa intended for long-term use are in various stages of clinical development and may find application in a broad

spectrum of atherothrombotic disease. Although GP IIb/IIIa antagonists are indicated for the acute coronary syndrome and in patients undergoing interventional cardiology procedures, thienopyridines have largely replaced these agents due to cost and increasing clinical data favoring the thienopyridines. Abciximab has the longest half-life of all these agents as a monoclonal antibody, whereas the other agents have shorter half-lives. All of three agents can cause thrombocytopenia.³¹

Perioperative Management of Patients on Platelet Inhibitors

Perioperative management of patients on various platelet inhibitors is complex and requires careful coordinated care with multiple specialties. The risks and benefits of discontinuing antiplatelet therapy must be carefully considered for each individual patient, especially prior to elective surgery. Recent guidelines are listed in [Figures 30.2](#) and [30.3](#).

Thrombolytic Drugs

Pharmacologic thrombolysis is produced by drugs that act as plasminogen activators to convert the endogenous proenzyme plasminogen to the fibrinolytic enzyme plasmin that lyses clot and other proteins. The goal of thrombolytic therapy is to restore circulation through a previously occluded artery or vein, most often a coronary artery. Fibrinolytic therapy was used previously in the treatment of acute coronary syndrome, but current American College of Cardiology and American Heart Association published evidence-based guidelines for the management of patients depend on whether a conservative (ie, noninvasive) approach or an invasive strategy (ie, PCI with possible angioplasty or coronary artery bypass graft surgery) is possible, specifically whether cardiac catheterization is available. Tissue plasminogen activator (tPA) is indicated for the treatment of acute ischemic stroke, acute myocardial infarction to reduce mortality and incidence of heart failure with the limitation the risk of stroke may be greater than the benefit in patients at low risk for death from cardiac causes, and acute massive PE for lysis.

Acute interventions with fibrinolytic agents can be lifesaving in patients with pulmonary emboli,³² ischemic stroke (eg, middle cerebral arterial occlusion),^{6,33} and in patients suffering acute myocardial infarction without immediate access to PCIs.³⁴ Bleeding complications (5%-30%) may occur whether fibrinolytics are injected systemically or directly into the affected arterial lesion.³⁵ Currently available fibrinolytics include streptokinase, urokinase, and tPA. These agents activate plasminogen to plasmin, the major enzyme responsible for clot breakdown. Plasmin is a serine protease that degrades fibrin(ogen) and multiple hemostatic factors and proteins. In clinical practice, tPA is most commonly used because of its localized catalytic effect on plasminogen activation in the presence of fibrin.^{36,37} Blood flow to the thrombus is vital for the delivery of tPA, and thus, localized activation of fibrinolysis via catheter-directed drug delivery is theoretically more favorable than systemic administration.

Thrombolytic agents have an associated risk of bleeding (particularly intracranial hemorrhage), and hemorrhagic complications occur more often in trauma, surgery, or following invasive diagnostic procedures. Intracranial hemorrhage occurs in 1.7% to 8.0% of treated patients.³⁷ Following lytic therapy, hemorrhagic

transformation of ischemic infarcts can occur. The recommended treatment of intracranial or serious systemic bleeding after thrombolytic therapy is administration of cryoprecipitate and platelets, although evidence-based guidelines for such an approach are lacking.³⁷ Angioedema occurs in 1% to 5% of patients receiving recombinant tPA, and the use of angiotensin-converting enzyme inhibitors is strongly associated with this complication.³⁷

Physiology and Management of Massive Transfusion

Jerrold H. Levy

Hemorrhage due to uncontrolled bleeding is a clinical problem commonly faced by clinicians managing traumatic injury, surgical patients, and obstetric patients. There are many terms used to describe this life-threatening problem, including **massive transfusion coagulopathy** or **trauma-induced coagulopathy (TIC)**. The complex coagulopathy that occurs in these situations further compromises the efficacy of subsequent hemostatic treatments. Tissue injury due to trauma, surgical interventions, following delivery in obstetric patients, or associated with extracorporeal circulation during cardiopulmonary bypass or extracorporeal membrane oxygenation may also contribute to the coagulopathic state.

Hemostasis is a physiologic response to vascular injury and disruption of the vascular endothelium and has been described in earlier chapters. Following surgery or trauma where there is extensive tissue injury, in addition to massive loss of blood, the endothelial integrity is compromised; the coagulopathy that follows tissue injury and blood loss produces a complex alteration in the vasculature often described as an **endothelialopathy**. Loss of the critical aspects of vascular regulation can also manifest as disseminated intravascular coagulation, a perturbation of the balance between anticoagulant and procoagulant effects.

TIC also has some unique characteristics due to two major causes that include hypovolemic shock that results from blood loss and extensive tissue disruption. Additional important considerations are the traumatic injury and extent of tissue injury, other underlying factors based on the potential for multiorgan dysfunction, and the resuscitation used, including fluids versus blood components, use of pharmacologic approaches such as antifibrinolytics and/or factor concentrates. Thus, the extensive blood loss and potential for multiorgan tissue injury and/or dysfunction distinguishes TIC from other coagulopathic states.

In addition, the management of hemostasis following traumatic injury and life-threatening hemorrhage has significantly changed over the years from initial resuscitation with crystalloid/colloids and red blood cells (RBCs) to routine administration of plasma/fresh frozen plasma (FFP) and platelets in addition to red cells, and currently goal-directed management based on point-of-care testing including viscoelastic measurements. Experiences learned from the battlefield and civilian studies have been critical for developing multiple therapeutic approaches that have been combined in a rational massive transfusion protocol. Retrospective studies have reported improved survival with the initial use of plasma and platelets as part of these protocols. This chapter reviews the physiology of massive transfusion and modern therapeutic approaches.

Pathophysiology of Hemostatic Abnormalities Associated With Trauma

Hemorrhage is a major cause of mortality following traumatic injury and responsible for approximately 50% of deaths within 24 hours of injury and approximately 80% of intraoperative trauma deaths.¹ The evolution of fluid resuscitation initially included crystalloid, followed by RBC transfusions, and the addition of FFP/plasma, platelets, and cryoprecipitate either empirically or as guided by additional laboratory testing. Therapy in the past was based on treating coagulopathy after the initial resuscitation and stabilization of the patient. More recent observations in trauma victims and on the battlefield found that early administration of plasma resulted in earlier improvement, whereas several studies reported that use of large crystalloid volumes was associated with increased bleeding and lower survival.^{1–3}

Trauma and Endothelial Dysfunction

The effects of hemorrhagic shock on endothelial function have been described, and the term **endotheliopathy of trauma** has been proposed to describe the systemic endothelial injury and dysfunction that contributes to

coagulopathy, inflammation, vascular permeability, tissue edema, and multiorgan system dysfunction.^{1,2} The endothelial dysfunction is secondary to vascular injury and other factors that result from shock, ischemic injury, and the release of inflammatory mediators. Plasma repletion is thought to have a restorative function on endothelial tight junctions to better modulate vascular integrity compared to crystalloid studying in vitro models. Plasma contains multiple serine protease inhibitors that may have antiinflammatory effects. The endothelium becomes permeable with hemorrhagic shock, and extravascular fluid is mobilized intravascularly. Plasma contains proteins for osmotic maintenance, but there are also multiple serine protease inhibitors that include antithrombin (also called **antithrombin III**), C1 esterase inhibitor, tissue factor pathway inhibitor, plasminogen activator inhibitor-1 (PAI-1), α_2 -antiplasmin, and other inhibitors that may be critical for antiinflammatory responses. Crystalloids lack these factors and are thought to increase interstitial edema, increase lung injury, and promote multiorgan system dysfunction.^{1,2}

Inflammatory activation following tissue injury contributes to the endothelial dysfunction, as does the critical role of fibrinolysis. With tissue injury, the fibrinolytic system is activated converting plasminogen to plasmin, a critical enzyme that cleaves fibrin. Plasmin and its generation are inhibited by plasminogen activator inhibitor-1, by thrombin-activatable fibrinolysis inhibitor, and by α_2 -antiplasmin. Thus, fibrinolysis is regulated by multiple circulating serine protease inhibitors under physiologic conditions that can be depleted with massive hemorrhage. As a result of this pathologic activation, antifibrinolytic therapy is a critical component of a multimodal approach, the success of which has been reported in multiple patient populations undergoing surgery. In addition to contributing to a bleeding diathesis, plasmin generation causes a multitude of other effects, including cell signalling, proinflammatory responses, and activation of the complement cascade.⁴

Massive Transfusion

Massive transfusion is defined as greater than 10 units of RBCs within 24 hours after initiating treatment and occurs in approximately 10% of military trauma and approximately 5% of civilian trauma patients.¹⁻³ Patients who acutely bleed and receive greater than 10 units of RBCs within 6 hours of a trauma have a higher mortality. However, the massive transfusion itself is likely a marker for more severe injury rather than a direct effect of the transfusions. The development of massive transfusion strategies and use of specific protocols improve survival and have been an important evolution in the management of trauma patients, wartime injuries, and even massive hospital bleeds that occur following postpartum hemorrhage or massive surgical bleeding. Other important clinical indicators of massive transfusion as reported by Cap et al³ include systolic blood pressure <110 mm Hg, heart rate >105 beats per minute, hematocrit <32%, pH <7.25, injury pattern (above-the-knee traumatic amputation especially if pelvic injury is present, multiamputation, clinically obvious penetrating injury to chest or abdomen), >2 regions positive on focused assessment with sonography for trauma scan, lactate concentration on admission >2.5, admission international normalized ratio \geq 1.2 to 1.4, near-infrared spectroscopy-derived tissue oxygen saturation <75% (in practice, rarely available), and base deficit >6 mEq/L.

Therapeutic Approaches for Massive Transfusion and Coagulopathy

Transfusion services, blood bankers, clinicians, and hospitals have developed and implemented protocols to rapidly provide blood products for patients suffering acute and massive hemorrhage. Observational studies and retrospective analyses of military and civilian trauma initially reported improved outcomes with the administration of whole blood or whole blood equivalents with massive transfusion that include transfusion ratios of 1:1:1 for RBCs, plasma, and platelets.^{1,2}

Additional recommendations suggest adding cryoprecipitate to the component mix to create a 1:1:1:1 ratio of products in order to adequately supply fibrinogen and other clotting factors (factors VIII and XIII and von Willebrand factor) and again in an effort to reconstitute fresh whole blood. However, point-of-care monitoring, and other goal-directed therapy can follow with fibrinogen levels and facilitate additional potential therapeutic approaches.³

Adverse Effects of Transfusions

All transfusions have risk, and certain concerns regarding plasma are important. Major life-threatening risks of plasma administration include transfusion-related acute lung injury, transfusion-associated circulatory overload, hemolytic transfusion reactions, and anaphylaxis (these phenomena have been discussed in an earlier chapter, [Chapter 28, Blood Products and Blood Components](#)). Deciphering the causes of adverse outcomes following transfusions can be difficult because more critically injured patients who have worse outcomes will also require more transfusions, and the reason underlying the need for transfusion will invariably cloud any interpretation of the clinical outcomes.

Hemostatic Changes Associated With Massive Transfusion Coagulopathy

Hemostatic abnormalities following massive transfusions and/or trauma can develop as a result of multiple factors not necessarily directly related to blood administration. Along with coagulopathy, hypothermia and acidosis complete the triad that results in higher mortality in the management of acute trauma. These factors may play a role in the localized depletion or decreased function of hemostatic factors through blood loss, tissue injury, and/or consumption of factors. Volume resuscitation with crystalloids, colloids, and RBCs or the use of cell salvage systems following blood loss can lead to dilutional coagulopathy. The hemostatic balance between anticoagulant and procoagulant activity may be lost due to tissue injury following trauma (including head trauma), tissue hypoxia/acidosis, burns/sepsis, or other physical events especially in an intraoperative setting from suction and reinfusion of debris.

Hypothermia can be a critical factor that precipitates or worsens coagulopathy, as enzymatic cascades are impaired; this impairment may appear beginning at even small drops in core body temperatures, even as high as 35°C. Platelet function may also be impaired with hypothermia, and platelet dysfunction can also occur due to fibrinolysis that increase fibrinogen degradation products, including D-dimer levels.⁴ Other important considerations include anemia-related factors, that is, decreased RBC adenosine diphosphate and decreased platelet diffusivity; and the effects of acidemia, which may include hypocalcemia with massive transfusions.

Perioperative Hemostatic Changes

Trauma and surgical patients have varied degrees of vascular injury, coagulopathy, and exsanguination.⁵ Blood loss up to 30% of total blood volume is generally well tolerated with the fluid resuscitation alone. Coagulation factors are progressively diluted to 30% of normal after a loss of one blood volume and down to 15% after a loss of two blood volumes.⁶ With severe hemodilution, thrombin generation, a critical step in clot formation is impaired by a reduction in procoagulant levels. Thrombin generation is also impaired by thrombocytopenia. Additionally, fibrinogen and factor XIII, critical substrates for clot formation, also decrease without appropriate factor replacement during volume resuscitation. Although clot may form, low levels of fibrinogen and/or factor XIII will result in reduced clot strength, a finding that is often monitored with viscoelastic blood monitoring using thromboelastography (TEG) or rotational thromboelastometry (ROTEM). Low levels of clotting proteins affect the ability of fibrin to polymerize.⁶

Massive Transfusion Coagulopathy

Because standard laboratory tests often take too long to obtain, and with severe hemorrhage, several blood volumes may be replaced by the time the results are available, laboratory testing plays an uncertain role in decision making in many settings where massive transfusion is necessary. Thus, transfusion protocols have been developed where fixed doses of FFP and platelets are administered after a specific number of RBC units have been given, often in a 1:1:1 ratio.^{1-4,6-8} Whether these fixed ratios prevent the development of coagulopathy or improve bleeding is not well established in cardiac surgery, but in trauma patients and in noncardiac surgical battlefield conditions, multiple previous reports suggested that fixed ratios improve survival.^{7,8}

With life-threatening bleeding, as seen in trauma patients, transfusion of fixed ratios of RBCs, FFP, and platelets should be administered.⁶ Transfusion with fixed plasma/FFP:platelet:RBC ratios reports a survival

benefit. As a result, the Army Surgeon General established a clinical policy of 1:1:1 (plasma/FFP:platelets:RBCs) for combat casualties expected to receive massive transfusion. One large study of civilian massive transfusion patients demonstrated improved survival with increased use of platelets.⁸ The current U.S. military resuscitation practice is to use a balanced approach, using 1:1:1 as the primary resuscitation fluid for the most seriously injured casualties. Current studies are underway to determine what the optimal ratios should be in a variety of clinical settings.

Role of Red Blood Cells and Anemia

Anemia may also contribute to bleeding as reported in nonsurgical patients due to multiple mechanisms that include nitric oxide scavenging, margination of platelets, and contributions to the hemostatic processes, although the ideal hematocrit to minimize this risk is not clear. RBC transfusions are administered for multiple reasons, and they are increasingly recognized for their critical role in hemostasis. RBCs can release adenosine diphosphate, an important activator of platelets. Platelets also contribute a surface for clot initiation by facilitating thrombin generation.⁶ Studies suggest that the factor XIII activation and fibrin cross-linking may play an important role in mediating RBC retention within clots.

Causes of Bleeding in the Setting of Massive Transfusion Coagulopathy

Risk factors for developing massive transfusion coagulopathy are often related to the surgical or traumatic injury that causes the hemorrhage. Patients should be evaluated for use of additional medications that can affect coagulation, including antiplatelet agents (clopidogrel, prasugrel, ticagrelor), anticoagulation agents (dabigatran, rivaroxaban, apixaban, warfarin), or parenteral agents such as low-molecular-weight heparin.⁹ Monitoring these agents has been reviewed in other chapters. Many of the standard coagulation tests used for evaluating hemorrhage cannot adequately determine the effects of antiplatelet agents (eg, aspirin, clopidogrel, prasugrel, or ticagrelor) as the complex platelet function tests used clinically are usually ineffective with significant bleeding (see [Chapter 30, Anticoagulants](#)).

Hypothermia, Acidosis, and Coagulopathy

Hypothermia has multiple effects because coagulation is an enzymatic process. As patient temperature decreases, the enzymatic processes that function maximally at normal body temperature are impaired. Hypothermia can produce multiple hemostatic defects that include reversible platelet dysfunction and increased fibrinolysis.¹ In addition, prothrombin time (PT) and activated partial thromboplastin time are prolonged at temperatures of 34°C or less when compared with measurements at 37°C.¹ When blood is sampled from a hypothermic patient, the test is actually conducted at 37°C, so the influence of hypothermia on coagulopathy and bleeding may not be readily appreciated by clinicians. Overall, hypothermia is an important contributing factor to the bleeding defect in coagulopathy in trauma patients and is part of the lethal triad defined as hypothermia, acidosis, and coagulopathy. Hypothermia and acidosis can also prevent thrombin generation, a critical component of clot formation. Hypothermia is thought to inhibit the initiation phase, whereas acidosis severely inhibits the propagation phase of thrombin generation.¹⁰ Maintenance of normothermia is important as part of a multimodal therapeutic plan for minimizing blood loss with significant hemorrhage in trauma, surgery, or coagulopathy of any cause. In a perioperative setting, blood warmers and other warming devices should be used to prevent and treat hypothermia.

Dilutional Coagulopathy

Before the development of massive transfusion protocols, dilutional coagulopathy was a common cause of bleeding in the actively hemorrhaging patient. Bleeding and coagulopathy associated with massive transfusions in 21 acutely traumatized soldiers that occurred after transfusion of 20 to 25 units of stored whole blood was described.¹¹ In this report, dilutional thrombocytopenia was a primary cause of the bleeding and was thought to be due to decreased platelet levels in stored blood. Transfusion of approximately 15 to 20 units caused significant dilution of blood volumes, and critical decreases in platelet count to approximately 20,000 to 30,000/ μ L, far below the recommended platelet target goals in actively bleeding patients.¹¹

Fibrinolysis

Fibrinolysis is a critical component of preventing excessive clot formation and balances for hemostasis, but excessive fibrinolysis as occurs commonly in trauma patients can cause bleeding. Fibrinolysis is initiated by mechanisms that include stimulating tissue plasminogen activator release in response to vascular endothelial damage, stress responses, and other mechanisms.⁴ Plasmin degrades fibrinogen and von Willebrand factor, cleaves receptors from platelets (glycoprotein Ib), and creates degradation products that bind glycoprotein IIb/IIIa receptors, thus interfering with platelet function. Contact activation associated with tissue injury and hemostatic activation also activates kallikrein that initiates plasmin generation but also is involved in other proinflammatory steps including neutrophil chemotaxis and chemokinesis.⁴ Contact activation leads to the cleaving of glycoprotein Ib receptors from platelets, and generation of FDP resulted in the creation of multimers that bind with glycoprotein IIb/IIIa receptors to prevent platelet-fibrinogen cross-linking, alterations in fibrinolysis adversely affect platelet function.⁴

Hypofibrinogenemia

Fibrinogen is a critical component in clot formation and an acute-phase reactant protein. Fibrinogen circulates in the highest concentration of all of the coagulation factors, and normal values for plasma levels are approximately 200 to 400 mg/dL but increase in pregnancy and as a nonspecific anabolic postoperative response following tissue injury.^{12,13} In the late stages of pregnancy, the normal physiologic response is hypercoagulability to reduce the risk of bleeding complications during birth. Although benign dilutional thrombocytopenia often develops, with a platelet count of 80,000 to 150,000/ μ L, fibrinogen levels increase to approximately 400 to 600 mg/dL. During delivery, a systemic hemostatic state develops with consumption of platelets and coagulation factors (including fibrinogen) to allow clotting to occur; hemostasis then normalizes within 4 to 6 weeks postpartum.¹³

If fibrinogen levels fall to approximately 80 to 100 mg/dL, standard clot-based coagulation tests including PT and partial thromboplastin time, can be affected. These changes may not be corrected by transfusion of FFP/plasma; however, cryoprecipitate is used or fibrinogen concentrates in countries that do not have cryoprecipitate (see [Chapters 27-30](#)). Current transfusion algorithms and guidelines are focused on targeting normal fibrinogen levels (\sim 200 mg/dL = 2 g/L) in the bleeding patient with either cryoprecipitate or fibrinogen concentrates depending upon the availability.^{12,13}

Monitoring Hemostasis During Massive Transfusion

PT and activated partial thromboplastin time are often used for monitoring coagulopathy during massive transfusion. The PT is considered proportional to coagulation factor loss and/or hemodilution, but other factors may also be responsible. These standard coagulation tests have limitations for evaluating bleeding because of the multiple coagulation defects that occur. Standard plasma-based coagulation tests also do not provide information about platelet function or interactions with coagulation factors and can be prolonged even with normal clotting factor levels due to protein C deficiency. As a result, other coagulation tests are being used more and more for managing massive transfusions.

Whole blood viscoelastic measurements continue to expand for management of trauma, perioperative bleeding, and massive transfusion coagulopathy and include either TEG (Haemonetics Corp, Braintree, MA) or Rotational thromboelastometry (ROTEM) (Instrumentation Laboratory, Bedford, MA). Some of the advantages of using these systems include the ability to rapidly have information for the diagnosis and management of coagulopathy and also provide methods for algorithm- and goal-directed management. ROTEM provides information about clot formation and fibrin polymerization, and its use is recommended in multiple guidelines to assess and treat TIC. The clot strength, as determined by maximal amplitude on TEG and maximal clot firmness on ROTEM, is influenced not only by fibrinogen levels but also by platelet contributions to the clot. In addition, using the ROTEM fibrinogen-FIBTEM assay, systemic fibrinogen levels can be rapidly determined. The role of these advanced tests during massive transfusion continues to evolve as therapeutic strategies for transfusion and treatment algorithms are developed. In European countries where

cryoprecipitate may not be available, these assays are used as therapeutic guides for both fibrinogen concentrate and prothrombin complex concentrate administration.⁶

Treatment of Coagulopathy During Massive Transfusion

A flow chart and example for the activation and institution of a massive transfusion protocol are shown in **Figures 31.1** and **31.2**. Specific considerations for the management have been discussed and are also included in the following perspectives regarding individual component therapy.

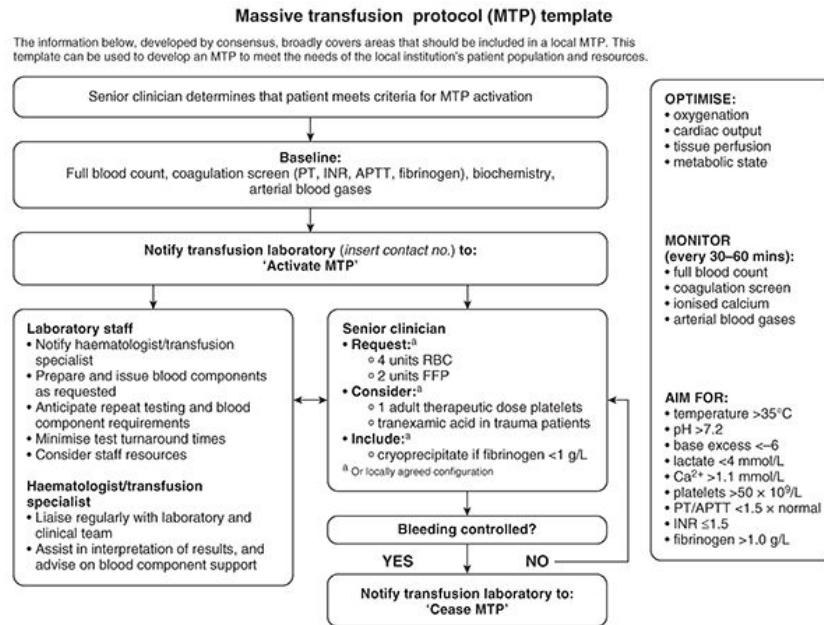

FIGURE 31.1 Massive transfusion protocol template. Abbreviations: APTT, activated partial thromboplastin time; FFP, fresh frozen plasma; INR, international normalized ratio; PT, prothrombin time; RBC, red blood cell. Plasma/Fresh Frozen Plasma

Overall, developing massive transfusion protocols has been an important therapeutic tool for effectively managing life-threatening hemorrhage after trauma, as previously reviewed.¹⁴ Plasma/FFP contains multiple factors for hemostasis and has increasingly been considered an important component. Based on current data and recommendations previously described, current plasma/FFP transfusion:RBC ratios of 1:1 following trauma is recommended and used in most centers for massive transfusion coagulopathy.³

The optimal ratio of plasma/FFP:RBCs was evaluated prospectively in a randomized clinical trial of 680 severely injured patients in North America.¹⁵ Blood product ratios of 1:1:1 (338 patients) versus 1:1:2 (342 patients) during active resuscitation in addition to all local standard-of-care interventions. Primary outcomes were 24-hour and 30-day all-cause mortality. There were no significant differences in mortality at 24 hours (12.7% in 1:1:1 group vs 17.0% in 1:1:2 group) or at 30 days (22.4% vs 26.1%, respectively).

Exsanguination, which was the predominant cause of death within the first 24 hours, was decreased in the 1:1:1 group (9.2% vs 14.6% in 1:1:2 group), and more patients in the 1:1:1 group achieved hemostasis than in the 1:1:2 group (86% vs 78%). Despite the 1:1:1 group receiving more plasma (median of 7 U vs 5 U, $P < .001$) and platelets (12 U vs 6 U, $P < .001$) and similar amounts of RBCs (9 U) over the first 24 hours, no differences between the two groups were found for complications acute lung injury, organ failure, or other prespecified adverse events.¹⁵

There are major differences in the management of severe hemorrhage between the United States and Europe. Based on currently published European guidelines, clinicians are now using factor concentrates

based on ROTEM guidance, with prothrombin complex concentrates, fibrinogen, and factor XIII. Fibrinogen and other factor concentrates have been used for many years in Europe, as cryoprecipitate is not available in all countries. However, therapy is multimodal and requires hemodynamic and hemostatic support as well as efforts to address the underlying bleeding source. An example of a massive transfusion protocol is shown in [Figure 31.1](#).⁶

Platelet Administration

Following traumatic injury or significant postoperative bleeding, the critical platelet count for transfusion is often based on consensus therapy rather than true objective data. Although a count of 50,000 or more is recommended, the threshold for the administration of platelets, especially in cases of dilutional coagulopathy, remains unclear as do the ideal ratio of platelets to other blood components. Most protocols attempt to develop a strategy that mimics whole blood replacement with RBC:plasma/FFP:platelets at a 1:1:1 ratio with massive bleeding.

However, assessing platelet function in the bleeding patient is not possible; therefore, empiric platelet administration is often undertaken. If patients have received antiplatelet agents recently, then even the existing platelets and platelet counts may not be helpful. Therefore, if patients have received antiplatelet agents or are bleeding after separation from cardiopulmonary bypass, then platelet dysfunction should be suspected, and platelet concentrates considered. However, there are significant potential adverse events associated with platelet administration.

Antifibrinolytic Agents

Because of the critical role of fibrinolysis with severe bleeding and trauma, the antifibrinolytic agent tranexamic acid is increasingly used as a therapeutic strategy. Inhibiting fibrinolysis during acute bleeding has many beneficial effects, including preserving initial clot formation at a bleeding site that may otherwise be broken down, similar to the clot destruction seen in hemophilia.⁴

The Clinical Randomisation of an Antifibrinolytic in Significant Hemorrhage 2 study focused on tranexamic acid as a therapeutic agent in traumatic injury in a prospective randomized placebo-controlled trial of 1-g loading followed by 1 g over 8 hours in 20,211 trauma patients.¹⁶ Overall mortality was reduced from 14.5% to 16.0% (relative risk, 0.91; $P = .0035$), as were deaths due to bleeding (4.9% vs 5.7%; relative risk, 0.85; $P = .0077$). Tranexamic acid is also approved in the United States for excessive menstrual bleeding at a dose of 1.3 g 3 times a day (~4 g total dose), without significant reported safety issues. Despite the efficacy and safety of tranexamic acid, clinicians often substitute epsilon-aminocaproic acid, another lysine analog, although this agent has not been studied as well as tranexamic acid and is not available in some European countries.

Procoagulants

Multiple other agents have been used or studied in trauma, and massive transfusion coagulopathy, including prothrombin complex concentrates. The off-label use of many of these agents to increase clot formation following major surgery and/or traumatic injury previously was an empiric approach for treating life-threatening bleeding and often used as a “last-ditch effort” in patients with ongoing bleeding and at risk for death or other adverse events. However, based on recommendations to use viscoelastic monitoring in massive transfusion coagulopathy and following traumatic coagulopathy, many algorithms suggest the use of prothrombin complex concentrates when clot time on EXTEM is abnormal, or there’s a prolonged PT/international normalized ratio value with life-threatening hemorrhage.^{4,12}

Goal-Directed Management

In the future, we may treat our severely injured trauma patients based on their phenotype. We suggest that specific treatment strategies for TIC, like tranexamic acid administration, should be individualized based on shock end points such as base deficit, as shock and/or tissue injury are potential factors that influence either a thrombotic or a bleeding phenotype. Clinicians should consider early goal-directed therapy based on diagnostic testing including viscoelastic assays. They should also be aware of potential that may alter trauma

phenotypes over time, including antiplatelet or anticoagulant therapy, gender, injury pattern, and hemostatic resuscitation.

Postpartum Hemorrhage

Postpartum hemorrhage is an important cause of life-threatening hemorrhage and continues to be a major cause of maternal mortality.¹⁷ A recent published report from an international expert panel in obstetrics, gynecology, anesthesiology, hematology, and transfusion medicine performed a comprehensive literature review to identify patients at high risk for adverse outcomes.¹⁷ They defined severe persistent postpartum hemorrhage as “active bleeding greater than 1,000 mL within the 24 hours following birth that continues despite the use of initial measures, including first-line uterotonic agents and uterine massage.” As in all life-threatening bleeding, a treatment algorithm that includes a massive transfusion protocol is important. The group suggested coagulation testing should be performed to guide therapy. If initial therapy fails to stop bleeding and uterine atony persists, second- and third-line interventions, including mechanical or surgical maneuvers, that is, intrauterine balloon tamponade or hemostatic brace sutures with hysterectomy, are the final surgical option for uncontrollable bleeding.¹⁷ Pharmacologic options include hemostatic agents, including tranexamic acid along with a massive transfusion protocol for blood product administration are also critical to minimize blood loss and optimize clinical outcomes in management of women with severe, persistent postpartum hemorrhage.¹⁷

Multimodal Resuscitation: Damage Control Resuscitation

Managing life-threatening and uncontrolled bleeding is a clinical problem that can occur following traumatic injury, during major surgical procedures, and following delivery. From information learned from combat and battlefield casualties, a multimodal and multispecialty approach has evolved that includes perspectives from surgeons, anesthesiologists, emergency medicine physicians, and transfusion medicine specialists for the optimal resuscitative approach to hemorrhagic shock.¹⁻³ Clinicians and investigators from multiple specialties have coined the term **damage control resuscitation**, a multimodal strategy.³ This concept is a strategy for resuscitating patients to rapidly restore homeostasis. As described by Cap et al,³ the multimodal approaches focus on transfusions with whole blood or component therapy to reconstitute whole blood administration, limited crystalloid to avoid dilutional coagulopathy, hypotensive resuscitation until bleeding control is achieved, empiric use of tranexamic acid, prevention of acidosis and hypothermia, and rapid definitive surgical control of bleeding.

Summary

Coagulopathy associated with massive transfusion is a complex, multifactorial clinical problem. When evaluating the causes of coagulopathy in this setting, preexisting pharmacotherapy, including prior use of anticoagulants, must be considered. The role of hypothermia, dilutional coagulopathy, platelet dysfunction, and fibrinolysis should also be considered. Evaluating fibrinogen levels represents a critical aspect of all transfusion algorithms, especially for patients with massive transfusion and life-threatening hemorrhage. Transfusion algorithms are a critical and relatively new aspect of perioperative management; they attempt to provide adequate factor and hemostatic replacement, although the ideal ratio of various blood components and factor concentrates are still being determined. Significant changes in management have become important in resuscitation strategies, and crystalloids are no longer a primary means of resuscitation; the primary strategy now is replacing acute blood loss with plasma and platelet-containing products instead of early and large amounts of crystalloids and RBCs. Templates for a massive transfusion protocol and activation of a massive transfusion protocol are included in [Figures 31.1](#) and [31.2](#). Several excellent reviews are available for additional reading on this subject.^{1,3,5,18}

PART VI Gastrointestinal System and Metabolism

Gastrointestinal Physiology

Michael J. Murray

Liver

In humans, the liver is the largest organ, and because of the multitude of metabolic functions that occur within its cells, it is also the most exothermic organ, thereby contributing significantly to the maintenance of core temperature. The liver lies in the right upper quadrant (although a small portion extends across the midline, just below the xiphoid process, into the left upper quadrant) just below the diaphragm where it is protected by the ribcage.¹ Hepatocytes comprise 60% of the total number of cells in the liver but, because of their size in comparison to other hepatic cells,² represent approximately 80% of the cytoplasmic mass within the liver. These cells perform diverse and complex functions ([Table 32.1](#)).

TABLE 32.1

Functions of hepatocytes

Absorb nutrients from portal venous blood
Store and release carbohydrates, proteins, and lipids
Excrete bile salts
Synthesize glucose, plasma proteins, coagulation factors, lipoproteins, cholesterol, and fatty acids
Metabolize and detoxify drugs and toxins
Bilirubin uptake, conjugation, and secretion

Hepatocytes have been derived from stem cells for several years, but more recently, those derived from extended pluripotent stem cells are reported to have considerable differentiation potential.³ They are being grown in culture systems to produce organoids that are being studied in bioartificial livers and liver fabrication.⁴

Anatomy

The right and left lobes of the liver are separated by the falciform ligament on the cephalad (diaphragmatic) surface and by the venous and round ligaments on the caudal (visceral) surface. The gallbladder, inferior vena cava, and hilum delineate a quadrate and a caudate lobe in the right lobe of the liver. These anatomic landmarks were not particularly helpful when surgeons began operating on the liver, so a model based on the vascular and biliary systems within the liver was developed.⁵ Newer technologies are being used to gain additional insights into the architecture of the liver,^{2,6} but the concepts developed by Couinaud and Nogueira⁵ remain a widely accepted model described in textbooks. Couinaud divided the liver into “surgical” segments that have independent biliary drainage and vascular supply.⁷ This functional approach to the liver, using these segments as guides, facilitated liver resections with minimal blood loss.

The hepatic artery perfuses the liver with oxygenated blood, whereas the portal vein perfuses the liver with blood flowing from the small intestine that has high concentrations of nutrients. The blood flows through liver sinusoids, which are terminal blood vessels lined with endothelial and Kupffer cells and surrounded by hepatocytes ([Figure 32.1](#)).^{1,2}

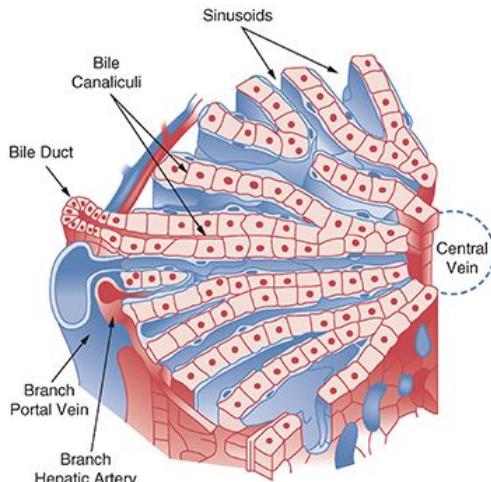

FIGURE 32.1 Schematic depiction of a hepatic lobule with a central vein and plates of hepatocytes extending radially. Blood from peripherally located branches of the hepatic artery and vein perfuses the sinusoids. Bile ducts drain the bile canaliculi that pass between the hepatocytes.

There is usually only one layer of hepatocytes between sinusoids, so the total area of contact with plasma is great. Blood flowing through the sinusoids exits these structures into branches of hepatic veins, the smallest of which are called central veins or terminal hepatic veins. Central veins join to form hepatic veins, which coalesce into two to three large hepatic veins that drain directly into the inferior vena cava.

Each hepatocyte is also located adjacent to bile canaliculi, which coalesce to form the common hepatic duct. This duct and the cystic duct from the gallbladder join to form the common bile duct, which enters the duodenum at a site surrounded by the sphincter of Oddi (Figure 32.2). The main pancreatic duct unites with the common bile duct just before it enters the duodenum.

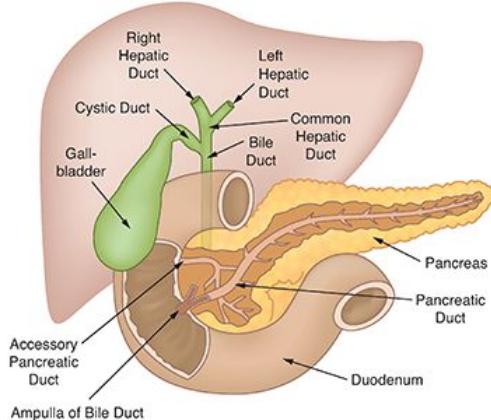

FIGURE 32.2 Connections of the ducts of the gallbladder, liver, and pancreas.

Kupffer cells mentioned earlier are macrophages that are derived from circulating monocytes. They phagocytize 99% or more of bacteria in the portal venous blood. This is crucial because the portal venous blood drains the gastrointestinal tract and usually contains bacteria.

Hepatic stellate cells are located between the endothelium of the sinusoids and the hepatocytes. These cells are normally quiescent, but in response to liver injury secrete collagen, and if the injury is prolonged, the result is fibrosis and ultimately cirrhosis.

Sinusoids are well adapted for the function they serve. They are fenestrated vascular structures without a basement membrane permitting easy diffusion of macromolecules transported via the portal vein from the gastrointestinal tract including plasma lipoproteins, into extravascular spaces of the liver that connect with terminal lymphatics. The extreme permeability of the endothelium results in the formation of large quantities

of lymph, which contains protein concentrations that are only slightly less than the protein concentration of plasma. Approximately one-third to one-half of all lymph are formed in the liver.

Hepatic Blood Flow

The liver receives a dual afferent blood supply from the hepatic artery and the portal vein ([Figure 32.3](#)). Total hepatic blood flow is approximately 1,972 mL per minute or approximately 30% to 40% of the cardiac output.⁸ Of this amount, the portal vein provides ~80% of the total flow but only 50% to 55% of the hepatic oxygen supply because this blood is partially deoxygenated in the organs and tissues (gastrointestinal tract, spleen, pancreas) drained by the portal vein.⁸ The hepatic artery provides only 20% of total hepatic blood flow but provides 45% to 50% of the hepatic oxygen requirements. Hepatic artery blood flow maintains the viability of connective tissues and walls of bile ducts. For this reason, loss of hepatic artery blood flow can be fatal because of ensuing necrosis of vital liver structures. An increase in hepatic oxygen requirements is met by an increase in oxygen extraction rather than a further increase in the already high hepatic blood flow.

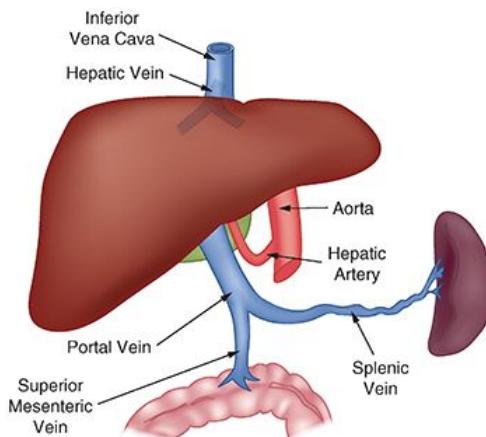

FIGURE 32.3 Schematic depiction of the dual afferent blood supply to the liver provided by the portal vein and hepatic artery.

Control of Hepatic Blood Flow

The control of the afferent blood supply to the liver, coming from both the hepatic artery and portal vein, is complicated. The portal vein has no valves but otherwise is similar to other veins in that the venous flow is through a low-resistance, low-pressure venous system in the liver, terminating in the hepatic sinusoids. Blood flow through the portal vein is a function of the constriction or relaxation of splanchnic arterioles and the resistance within the intrahepatic venous system, which determines portal venous pressure (normally 7-10 mm Hg) (see the “[Portal Venous Pressure](#)” section).

The hepatic artery on the other hand is a high-resistance, high-pressure system in which flow is very much determined by cardiac output and the autonomic nervous system.⁹ Activation of the sympathetic nervous system not only constricts hepatic arterioles but also decreases the permeability of hepatic sinusoids, the net effect of which is a decrease in total hepatic blood flow. Release of norepinephrine by efferent sympathetic nerve terminals induces contraction of hepatic arterioles and hepatic sinusoids. Efferent parasympathetic nerve terminal release of acetylcholine and vasoactive intestinal peptide stimulates relaxation of hepatic arterioles and sinusoids. Thus, the sinusoids have a critical role in reducing hepatic blood flow during hemorrhage and ultimately contribute to the maintenance of circulating blood volume. Similarly, sympathetic innervation of hepatic venules is principally responsible for resistance and compliance of hepatic venules.⁹ Constriction of hepatic venules shifts blood from the liver into the systemic circulation, accounting for the reservoir function of the liver (see the “[Reservoir Function](#)” section).

Fibrotic constriction characteristic of hepatic cirrhosis (most often due to chronic alcohol abuse and hepatitis C) can increase resistance to portal vein blood flow, as evidenced by portal venous pressures of 20 to

30 mm Hg (portal hypertension). The resulting increased resistance to portal vein blood flow may result in development of shunts (varices) to allow blood flow to bypass the hepatic sinusoids. Hepatic artery blood flow is influenced by arteriolar tone that reflects local and intrinsic mechanisms (autoregulation). For example, a decrease in portal vein blood flow is accompanied by an increase in hepatic artery blood flow by as much as 100%. Presumably, a vasodilating substance such as adenosine accumulates in the liver when portal vein blood flow decreases, leading to subsequent hepatic arteriolar vasodilation and washout of the vasodilating material.

Congestive hepatopathy develops when right-sided cardiac failure leads to hepatic venous outflow obstruction secondary to increased right atrial pressure.¹⁰

Cirrhotic cardiomyopathy is a clinical entity in which cirrhosis impairs ventricular function in response to stress in the absence of other potential causes of cardiac disease. “Stress” may include reaction to drugs, intravascular volume shifts and exercise, and surgical interventions, for example, transjugular intrahepatic portosystemic shunts and liver transplant.¹¹

Isoflurane, desflurane, and sevoflurane when administered in equal potent doses decrease hepatic blood flow to a similar degree.^{12–14} In contrast to these inhalation anesthetics, halothane decreased hepatic blood flow to a greater extent but preserved autoregulation of hepatic blood flow, although only to a limited extent and only when used in doses that did not decrease systemic blood pressure >20%.¹⁵ Surgical stimulation may further decrease hepatic blood flow, independent of the anesthetic drug administered. The greatest decreases in hepatic blood flow occur during intra-abdominal operations, presumably due to mechanical interference of blood flow produced by retraction in the operative area as well as the release of vasoconstricting substances such as catecholamines.

Reservoir Function

The liver normally contains approximately 500 mL of blood or approximately 10% of the total blood volume. An increase in central venous pressure causes back pressure, and the liver, being a distensible organ, may accommodate as much as 1 L of extra blood. As such, the liver acts as a storage site when blood volume is excessive, as in congestive heart failure, and is capable of supplying extra blood when hypovolemia occurs. Indeed, the hepatic sinusoids and large hepatic veins, when constricted by stimulation from the sympathetic nervous system, discharge up to 350 mL of blood into the circulation. Therefore, the liver is the single most important source of additional blood during strenuous exercise or acute hemorrhage.

Bile Secretion

Hepatocytes continually form bile (500 mL daily) and then secrete it into bile canaliculi, which empty into progressively larger ducts, ultimately reaching the common bile duct (see [Figure 32.2](#)).¹⁶ Between meals, the tone of the sphincter of Oddi, which guards the entrance of the common bile duct into the duodenum, is high.¹⁷ As a result, bile flow is diverted into the gallbladder, which has a capacity of 35 to 50 mL. The most potent stimulus for emptying the gallbladder is the presence of fat in the duodenum, which evokes the release of the hormone cholecystokinin by the duodenal mucosa. This hormone enters the circulation and passes to the gallbladder, where it causes selective contraction of the gallbladder smooth muscle. As a result, bile is forced from the gallbladder into the duodenum. When adequate amounts of fat are present, the gallbladder empties in approximately 1 hour. The principal components of bile are bile salts, bilirubin, and cholesterol.

Bile Salts

Bile salts combine with lipids in the duodenum to form water-soluble complexes (micelles) that facilitate gastrointestinal absorption of fats (triglycerides) and fat-soluble vitamins. Once absorbed, bile salts return to the liver via the portal vein, where they enter hepatocytes (enterohepatic circulation).¹⁸ In the absence of bile secretion, steatorrhea and a deficiency of vitamin K develop in a few days. Vitamin K is necessary for activation of several of the clotting factors that contain glutamic acid residues.

Bilirubin

After approximately 120 days, the cell membranes of erythrocytes rupture, and the released hemoglobin is converted to bilirubin in reticuloendothelial cells. Bilirubin is then released into the circulation and transported in combination with albumin to the liver. Bilirubin is a hydrophobic tetrapyrrole that is conjugated in the liver to glucuronic acid, and the resulting compound is then excreted in urine and bile. The importance of this process is significant for 200 to 300 mg of bilirubin is produced daily in adults from the degradation of hemoglobin and cellular cytochromes ([Figure 32.4](#)).¹⁹ Unlike conjugated bilirubin, unconjugated bilirubin may be neurotoxic and may even cause a rapidly fatal encephalopathy. In the gastrointestinal tract, bilirubin is converted by bacterial action mainly into urobilinogen.

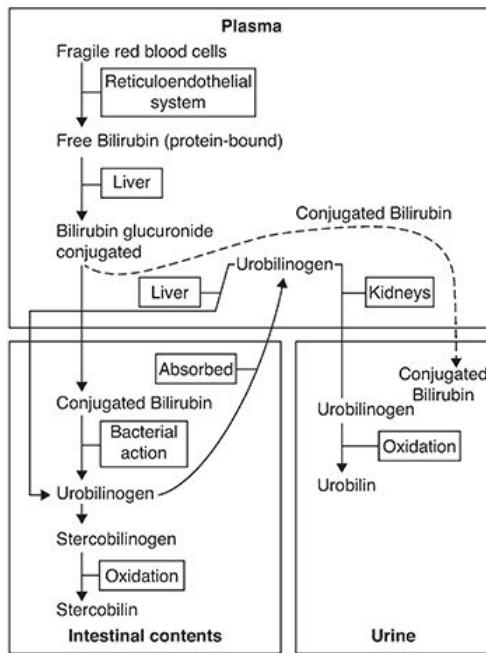

FIGURE 32.4 Schematic depiction of bilirubin formation and excretion. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Jaundice

Jaundice is the yellowish tint of body tissues that accompanies accumulation of bilirubin in extracellular fluid. Skin color usually begins to change when the plasma concentration of bilirubin increases to approximately 3 times normal. The most common types of jaundice are hemolytic jaundice, due to increased destruction of erythrocytes, and obstructive jaundice, due to obstruction of bile ducts.²⁰

Cholesterol

Almost every cell in the body can synthesize all the cholesterol they need for it is an important component of cell walls (synthesized in tissues from acetate in a reaction catalyzed by β -hydroxy β -methylglutaryl coenzyme A), but only the liver can eliminate cholesterol. It is transported from the periphery to the liver as high-density lipoproteins and once there can be excreted in the bile in its unesterified form or in association with bile acids.²¹ Cholesterol in the bile may precipitate as gallstones if there is excess absorption of water in the gallbladder or the diet contains too much cholesterol. Gallstones occur in 10% to 20% of individuals; 85% are cholesterol stones.

Metabolic Functions

Metabolism of carbohydrates, lipids, and proteins depends on normal hepatic function (see [Chapter 33](#)). Furthermore, the liver is an important storage site for vitamins and iron. Degradation of certain hormones

(catecholamines and corticosteroids), as well as drugs, is an important function of the liver. Hepatocytes are the principal site for synthesis of all the coagulation factors, with the exception of von Willebrand factor and factor VIIIC. Because the half-life of clotting factors produced in the liver is short, coagulation is particularly sensitive to acute hepatocellular damage.

Carbohydrates

Regulation of blood glucose concentration is another important metabolic function of the liver. When hyperglycemia is present, glycogen is deposited in the liver, and when hypoglycemia occurs, glycogenolysis provides glucose. Amino acids can be converted to glucose in hepatocytes by gluconeogenesis when the blood glucose concentration is decreased.

Lipids

The liver is responsible for β -oxidation of fatty acids and formation of acetoacetic acid. Triglycerides are formed from the esterification of glycerol with three molecules of fatty acid. Pancreatic lipases and esterases are important in facilitating the absorption of dietary fats. After absorption, fat may be stored as triglycerides (reserve energy) or metabolized to energy. Lipoproteins, cholesterol, and phospholipids, such as lecithin, are formed in the liver. Synthesis of fats from carbohydrates and proteins also occurs in the liver.²¹

Proteins

The most important hepatic functions in protein metabolism are oxidative deamination of amino acids, formation of urea for removal of ammonia, formation of plasma proteins and coagulation factors, and interconversions (transfer of one amino group to another amino acid) among different amino acids. Albumin formed in the liver is critically important for maintaining plasma oncotic pressure as well as providing an essential transport role. The half-life for albumin is about 21 days; therefore, plasma albumin concentrations are unlikely to be significantly altered in acute hepatic failure. Deamination of amino acids is required before these substances can be used for energy or converted into carbohydrates or fats. Decreases in portal vein blood flow, as may occur with the surgical creation of a portacaval shunt to treat esophageal varices, can result in fatal hepatic coma because of accumulation of ammonia.

Gastrointestinal Tract

The primary function of the gastrointestinal tract is to provide the body with a continual supply of water, electrolytes, and nutrients. To achieve this goal, the contents of the gastrointestinal tract must move through the entire system at an appropriate rate for digestive and absorptive functions to occur. Each part of the gastrointestinal tract is adapted for specific functions such as (1) passage of food in the esophagus, (2) storage of food in the stomach or fecal matter in the colon, (3) digestion of food in the stomach and small intestine, and (4) absorption of the digestive end products and fluids in the small intestine and proximal parts of the colon. Overall, approximately 9 L of fluid and secretions enter the gastrointestinal tract daily, and all but approximately 100 mL is absorbed by the small intestine and colon ([Figure 32.5](#)). The pH of gastrointestinal secretions varies widely ([Table 32.2](#)).

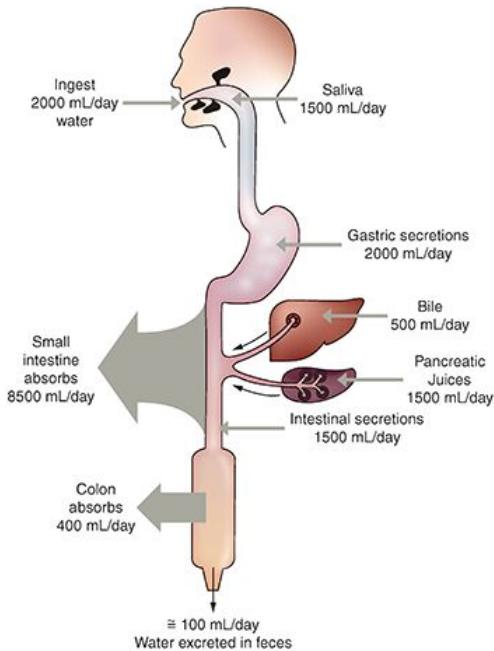

FIGURE 32.5 Overall fluid balance in the human gastrointestinal tract. Approximately 2 L of water are ingested each day, and approximately 7 L of various secretions enter the gastrointestinal tract. Of this 9 L, about 8.5 L are absorbed from the small intestine. Approximately 0.5 L passes to the colon, which normally absorbs 80% to 90% of the water presented to it. *From Berne RM, Levy MN, Koeppen BM, et al. Physiology. 5th ed. St Louis, MO: Mosby; 2004. Colon	7.5-8.0

Anatomy

The smooth muscle of the gastrointestinal tract is a syncytium such that electrical signals originating in one smooth muscle fiber are easily propagated from fiber to fiber. Mechanical activity of the gastrointestinal tract is enhanced by stretch and parasympathetic nervous system stimulation, whereas sympathetic nervous system stimulation decreases mechanical activity to almost zero.

Tonic contraction of gastrointestinal smooth muscle at the pylorus, ileocecal valve, and anal sphincter helps regulate the rate at which materials move through the gastrointestinal tract. In these parts of the gastrointestinal tract, rhythmic movements (peristalsis) occur 3 to 12 times per minute to facilitate mixing and movement of food.²²

Blood Flow

Most of the blood flow to the gastrointestinal tract comes from the celiac and superior mesenteric and inferior mesenteric arteries to supply oxygen needed to produce energy for intestinal digestion and absorption of

digested materials. Blood flow parallels digestive activity of the gastrointestinal tract. Approximately 80% of portal vein blood flow originates from the stomach and gastrointestinal tract, with the remainder coming from the spleen and pancreas.

Parasympathetic efferent fibers traveling through the vagus nerve effect normal gastrointestinal function, dilating arterioles, promoting smooth muscle contraction, and stimulating glandular secretions for digestion. Activation of sympathetic fibers promotes just the opposite, constricting arterioles and inhibiting motility, digestion, and absorption.²³ The decrease in blood flow, however, is transient because local metabolic vasodilator mechanisms elicited by the relatively ischemic mucosa return blood flow toward normal. The importance of this transient sympathetic nervous system–induced vasoconstriction is that it permits shunting of blood from the gastrointestinal tract for brief periods during exercise or when increased blood flow is needed by skeletal muscles or the heart.

Portal Venous Pressure

The liver offers modest resistance to blood flow from the portal venous system. As a result, the pressure in the portal vein averages 7 to 10 mm Hg, which is considerably higher than the almost zero pressure in the inferior vena cava. Cirrhosis of the liver is characterized by increased resistance to portal vein blood flow due to replacement of hepatic cells with fibrous tissue that constricts the hepatic sinusoids. The gradual increase in resistance to portal vein blood flow produced by cirrhosis of the liver causes large collateral vessels to develop between the portal veins and the systemic veins. The most important of these collaterals are from the splenic veins to the esophageal veins. These collaterals may become so large that they protrude into the lumen of the esophagus, producing esophageal varicosities. The esophageal mucosa overlying these varicosities may become eroded, leading to life-threatening hemorrhage.²⁴

Another consequence of cirrhosis is the development of ascites, which is due to inability to compensate for the increased splanchnic arterial vasodilation secondary to portal hypertension. To maintain arterial blood volume, vasoconstrictor and antinatriuretic biochemicals are released, which increase systemic sodium and fluid retention. As portal hypertension worsens, in the face of increased intravascular volume, there is an increase in the capillary pressure on the intestinal surface, with the transudation of protein-poor fluid into the abdominal cavity. Ascitic fluid can also translocate across the diaphragm into the right chest creating a hepatic hydrothorax. Patient with ascites can develop spontaneous bacterial peritonitis, which associated with high mortality.²⁵

Splenic Circulation

The splenic capsule in humans, in contrast to that in many lower animals, is nonmuscular, which limits the ability of the spleen to release large amounts of stored blood in response to sympathetic nervous system stimulation. However, a small amount (150-200 mL) of blood stored in the splenic venous sinuses and can be released by sympathetic nervous system–induced vasoconstriction of the splenic vessels. Release of this amount of blood into the systemic circulation is sufficient to increase the hematocrit 1% to 2%. There is evidence that this neural modulation of the spleen contributes to the development of “idiopathic” or “essential” hypertension.²⁶

The spleen functions to remove erythrocytes from the circulation. This occurs when erythrocytes reenter the venous sinuses from the splenic pulp by passing through pores that may be smaller than the erythrocyte. Fragile cells do not withstand this trauma, and the released hemoglobin that results from their rupture is ingested by the reticuloendothelial cells of the spleen. These same reticuloendothelial cells also function, much like lymph nodes, to remove bacteria and parasites from the circulation. Indeed, asplenic patients are more prone to developing bacterial infections.

During fetal life, the splenic pulp produces erythrocytes in the same manner as does the bone marrow in the adult. As the fetus reaches maturity, however, this function of the spleen is lost. The spleen is the largest lymphoid organ with a multitude of immunologic functions in addition to its role in erythrocyte clearance. The anatomic structure of the spleen facilitates clearance of abnormal cells and pathogens and promotes interaction of lymphocytes with antigen-bearing cells. These antigen-bearing cells in essence regulate B and T cell response to the antigens they transport to the spleen.²⁷

Innervation

The gastrointestinal tract receives innervation from both divisions of the autonomic nervous system as well as from an intrinsic nervous system consisting of the myenteric plexus, or Auerbach plexus, and the submucous plexus, or Meissner plexus. In the absence of sympathetic nervous system or parasympathetic nervous system stimulation, the motor and secretory activities of the gastrointestinal tract continue, reflecting the function of the intrinsic nervous system. Signals from the autonomic nervous system can and do influence the activity of the intrinsic nervous system. For example, impulses from the parasympathetic nervous system increase intrinsic activity, whereas signals from the sympathetic nervous system decrease intrinsic activity. A large number of neuromodulatory substances act in the gastrointestinal tract.²³

The cranial component of parasympathetic nervous system innervation to the gastrointestinal tract (esophagus, stomach, pancreas, small intestine, colon to the level of the transverse colon) is by way of the vagus nerves. The distal portion of the colon is richly supplied by the sacral parasympathetics via the pelvic nerves from the hypogastric plexus. Fibers of the sympathetic nervous system destined for the gastrointestinal tract pass through ganglia such as the celiac ganglia.

Motility

The two types of gastrointestinal motility are mixing contractions and propulsive movements characterized as **peristalsis**. The usual stimulus for peristalsis is distension. Peristalsis occurs only weakly in portions of the gastrointestinal tract that have congenital absence of the myenteric plexus. Peristalsis is also decreased by increased parasympathetic nervous system activity and anticholinergic drugs.

Ileus

Trauma to the intestine or irritation of the peritoneum as follows abdominal operations causes adynamic (paralytic) ileus. Peristalsis returns to the small intestine in 6 to 8 hours, but colonic activity may take 2 to 3 days. Adynamic ileus can be relieved by a tube placed into the small intestine and aspiration of fluid and gas until the time when peristalsis returns.

Salivary Glands

The principal salivary glands (parotid and submaxillary) produce 0.5 to 1.0 mL per minute of saliva (pH 6-7), largely in response to parasympathetic nervous system stimulation. Saliva washes away pathogenic bacteria in the oral cavity as well as food particles that provide nutrition for bacteria. In the absence of saliva, oral tissues are likely to become ulcerated and infected. The bicarbonate ion concentration in saliva is 2 to 4 times that in plasma, and the high potassium content of saliva can result in hypokalemia and skeletal muscle weakness if excess salivation persists.

Esophagus

The esophagus serves as a conduit for passage of food from the pharynx to the stomach. The swallowing or deglutition center located in the medulla and lower pons inhibits the medullary ventilatory center, halting breathing at any point to allow swallowing to proceed. The upper and lower ends of the esophagus function as sphincters to prevent entry of air and acidic gastric contents, respectively, into the esophagus. The sphincters are known as the **upper esophageal (pharyngoesophageal) sphincter** and **lower esophageal (gastroesophageal) sphincter**.

Lower Esophageal Sphincter

The lower esophageal sphincter regulates the flow of food between the esophagus and the stomach. The sphincter mechanism at the lower end of the esophagus consists of the intrinsic smooth muscle of the distal esophagus and the skeletal muscle of the crural diaphragm. Under normal circumstances, the lower esophageal sphincter is approximately 4 cm long. The crural diaphragm, which forms the esophageal hiatus, encircles the proximal 2 cm of the sphincter. The intraluminal pressure of the esophagogastric junction is a measure of the strength of the antireflux barrier and is typically quantified with reference to the intragastric pressure (normal <7 mm Hg). Both the lower esophageal sphincter and the crural diaphragm contribute to the

intragastric pressure. Muscle tone in the lower esophageal sphincter is the result of neurogenic and myogenic mechanisms. A substantial part of the neurogenic tone in humans is due to cholinergic innervation via the vagus nerves. The presynaptic neurotransmitter is acetylcholine, and the postsynaptic neurotransmitter is nitric oxide.

The normal lower esophageal sphincter pressure is 10 to 30 mm Hg at end exhalation. Transient relaxation of the lower esophageal sphincter is a neural reflex mediated through the brainstem. Gastric barrier pressure is calculated as lower esophageal sphincter pressure minus intragastric pressure. This barrier pressure is considered the major mechanism in preventing reflux of gastric contents into the esophagus. Gastric distension, meals high in fat, and pharyngeal stimulation are possible mechanisms by which the afferent stimulus that initiates transient relaxation of the lower esophageal sphincter may originate. Cricoid pressure decreases lower esophageal sphincter pressure, presumably reflecting stimulation of mechanoreceptors in the pharynx created by the external pressure on the cricoid cartilage ([Figure 32.6](#)). General anesthesia decreases lower esophageal sphincter pressure 7 to 14 mm Hg, depending on the degree of skeletal muscle relaxation. Normally, upper esophageal sphincter pressure prevents regurgitation into the pharynx in the awake state. The administration of anesthetic drugs may decrease upper esophageal sphincter pressure even before the loss of consciousness.

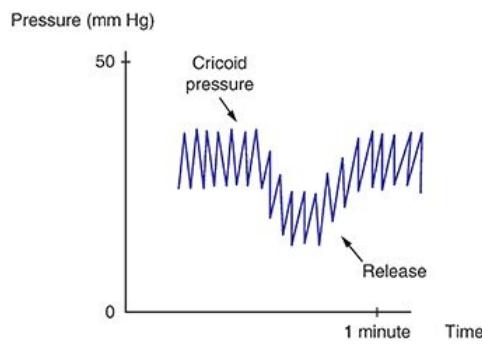

FIGURE 32.6 Application of cricoid pressure causes the lower esophageal sphincter pressure to decrease.

Despite decreases in lower esophageal sphincter pressure associated with anesthesia, the incidence of gastroesophageal reflux is rare in patients undergoing elective operations.[28](#)

Gastroesophageal Reflux Disease

Transient relaxation of the lower esophageal sphincter, rather than decreased lower esophageal sphincter pressure, is the major mechanism of gastroesophageal reflux disease (GERD). Transient relaxation of the lower esophageal sphincter is associated with simultaneous inhibition of the sphincter and crural diaphragm. Some patients with gastroesophageal reflux have a weak lower esophageal sphincter, some have a weak crural diaphragm, and some have both. In GERD, the reflux of gastric fluid into the esophagus or oropharynx causes symptoms (esophagitis characterized as “heartburn”) and/or tissue damage, leading over time to the development of Barrett esophagus. It is estimated that approximately 20% of adults in the United States experience symptoms of GERD at least weekly, and many patients with severe GERD have a hiatal hernia.

Opioids decrease the frequency of transient relaxation of the lower esophageal sphincter in normal patients through an unknown mechanism.[29](#) Antisecretory drugs such as histamine receptor antagonists or proton pump inhibitors may be useful in treating gastroesophageal reflux. Therapy with a prokinetic drug such as metoclopramide may be effective. Patients with severe gastroesophageal reflux may benefit from surgical fundoplication of the esophagus via a laparoscopic technique.

Hiatal Hernia

The majority of patients with moderate to severe gastroesophageal reflux have a hiatal hernia in which a portion of the stomach herniates into the chest. Hiatal hernia may promote gastroesophageal reflux by trapping gastric acid in the hernia sac, which may then flow backward into the esophagus when the lower esophageal sphincter relaxes during swallowing. Hiatal hernia can also cause gastroesophageal reflux when contraction of the crural diaphragm during inspiration and other physical maneuvers lead to a compartmentalization of the stomach between the lower esophageal sphincter and the diaphragm. The presence of acid in the esophagus causes esophagitis, which decreases the lower esophageal sphincter pressure and impairs esophageal contractility.

Achalasia

Achalasia is the best characterized of all esophageal motility disorders reflecting degeneration of neurons in the wall of the esophagus, especially the nitric oxide-producing inhibitory neurons that affect the relaxation of esophageal smooth muscle necessary for opening the lower esophageal sphincter. The loss of inhibitory innervation in the lower esophageal sphincter causes basal sphincter pressure to increase and interferes with sphincter relaxation. In the body of the esophagus, the loss of intramural neurons manifests as aperistalsis. Dysphagia for both solid foods and liquids is the primary symptom of achalasia. A substantial number of patients complaining of heartburn may have achalasia, which may therefore be confused with GERD.

Achalasia can be confirmed with radiographic (barium swallow shows dilatation of the esophagus with a beaklike narrowing of esophagogastric junction), manometric, and endoscopic evaluation (often performed utilizing drugs to produce sedation). The diagnosis may be suggested by a routine radiograph of the chest that shows widening of the mediastinum from the dilated esophagus and the absence of the normal gastric air bubble because lower esophageal sphincter contraction prevents swallowed air from entering the stomach.

Nitrates and calcium channel blockers relax the smooth muscle of the lower esophageal sphincter and may produce limited success in treating patients with achalasia. Pneumatic dilation therapy for achalasia (a large deflated balloon is passed through the mouth to the lower esophageal sphincter and then rapidly inflated) may be helpful. Esophageal perforation is a risk of this treatment. Surgical myotomy of the lower esophageal sphincter performed laparoscopically often results in excellent relief but may be followed by GERD. For this reason, the myotomy may be combined with an antireflux procedure (fundoplication). Endoscopic injection of botulinum toxin into the area of the lower esophageal sphincter blocks the excitatory (acetylcholine-releasing) neurons that contribute to lower esophageal sphincter tone. Unfortunately, the effect is usually short lived (less than 6 months).³⁰ A patient with achalasia presenting for surgery unrelated to the underlying esophageal motility disorder represents a potential risk for pulmonary aspiration during the perioperative period.

Stomach

The stomach is a specialized organ of the digestive tract that stores and processes food for digestion ([Figure 32.7](#)). The ability to secrete hydrogen ions in the form of hydrochloric acid is a hallmark of gastric function. The secretory unit of gastric mucosa is the oxyntic glandular mucosa. The stomach is richly innervated by the parasympathetic fibers from the vagus nerves and sympathetic fibers from the celiac plexus.

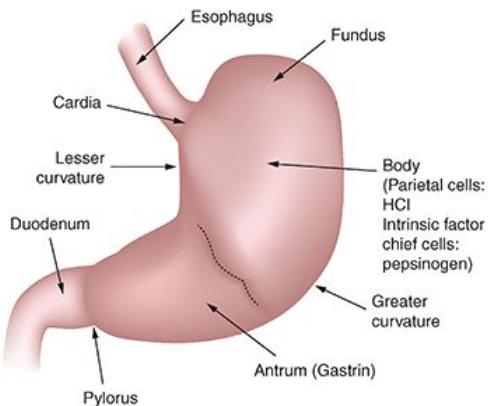

FIGURE 32.7 Anatomy of the stomach indicating the site of production of secretions. Mucus is secreted in all parts of the stomach.

Gastric Secretions

Total daily gastric secretion is approximately 2 L with a pH of 1.0 to 3.5. The stomach secretes only a few milliliters of gastric fluid each hour during the periods between digestion. Strong emotional stimulation, such as occurs preoperatively, can increase secretion of highly acidic gastric fluid to >50 mL per hour. The major secretions are hydrochloric acid, pepsinogen, intrinsic factor, and mucus. Mucous secretion protects the gastric mucosa from mechanical and chemical destruction. Substances that disrupt the mucosal barrier and cause gastric irritation include ethanol and drugs that inhibit prostaglandin synthesis (aspirin, nonsteroidal antiinflammatory drugs).

Parietal Cells

Parietal cells secrete a hydrogen ion-containing solution with a pH of approximately 0.8. At this pH, the hydrogen ion concentration is approximately 3 million times that present in the arterial blood. Hydrochloric acid kills bacteria, aids protein digestion, provides the necessary pH for pepsin to start protein digestion, and stimulates the flow of bile and pancreatic juice.

Secretion of hydrochloric acid depends on stimulation of receptors in the membrane of parietal cells by histamine, acetylcholine (vagal stimulation), and gastrin. All of these receptors increase the transport of hydrogen ions into the gastric lumen by the hydrogen-potassium-adenosine triphosphatase enzyme system ([Figure 32.8](#)). Activation of one receptor type potentiates the response of the other receptors to stimulation. Blockade of receptors with specific antagonist drugs produces effective decreases in acid transport responses by removing the potentiating effect of stimulation of these receptors on the responses to other stimuli. Blockade of muscarinic receptors is produced by atropine or the more specific anticholinergic pirenzepine. Gastrin receptors can be inhibited by proglumide. Alternatively, the hydrogen-potassium-adenosine triphosphatase enzyme system can be inhibited by omeprazole. Pharmacologic manipulation of gastric fluid pH has special implications in the management of patients considered to be at risk for pulmonary aspiration during the perioperative period.

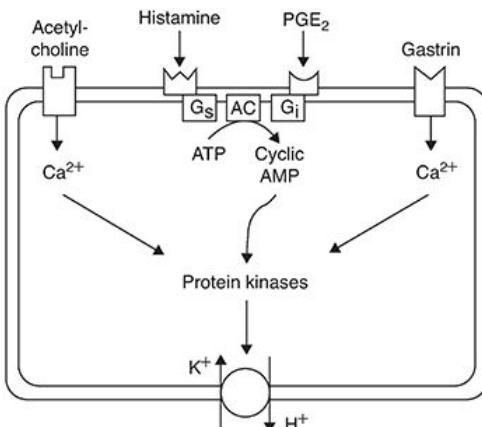

FIGURE 32.8 Gastric hydrogen ion secretion by parietal cells is increased by acetylcholine and gastrin acting on responsive receptors to increase intracellular calcium. Histamine activates receptors to activate stimulatory guanine proteins (G_s) to increase adenylate cyclase (AC) activity, whereas prostaglandins (PGE_2) activate inhibitory guanine proteins (G_i) to decrease AC activity. Cyclic adenosine monophosphate (cyclic AMP) and calcium act via protein kinases to increase transport of hydrogen ions into the gastric lumen.

Intrinsic factor, which is essential for absorption of vitamin B_{12} from the ileum, is secreted by parietal cells. For this reason, destruction of parietal cells, as is associated with chronic gastritis, produces achlorhydria and often pernicious anemia.

Chief Cells

Pepsinogens secreted by chief cells undergo cleavage to pepsins in the presence of hydrochloric acid. Pepsins are proteolytic enzymes important for the digestion of proteins.

G Cells

Gastrin is secreted by gastric antral cells (G cells) into the circulation, which carries this hormone to responsive receptors in parietal cells to stimulate gastric hydrogen ion secretion. Gastrin also increases the tone of the lower esophageal sphincter and relaxes the pylorus.

Gastric Fluid Volume and Rate of Gastric Emptying

Neural and humoral mechanisms greatly influence gastric fluid volume and gastric-emptying time. As discussed previously, parasympathetic nervous system stimulation enhances gastric fluid secretion and motility, whereas sympathetic nervous system stimulation has an opposite effect. The elimination of nonnutritive liquids is an exponential process (volume of liquid emptied per unit of time is directly proportional to the volume present in the stomach), whereas the emptying of solids is a linear process (Figure 32.9). In this regard, emptying of liquids from the stomach begins within 1 minute of ingestion, whereas emptying of solids typically begins after a lag time of 15 to 137 minutes (median 49 min). Gastric emptying in healthy, term, nonobese parturients is not delayed compared to nonpregnant women.³¹ It is generally thought that the delay in gastric emptying of solids is caused by the time necessary for antral contractions to break solids down into small enough particles to exit through the pylorus. Clinical manifestations of delayed gastric emptying include anorexia, persistent fullness after meals, abdominal pain, and nausea and vomiting.

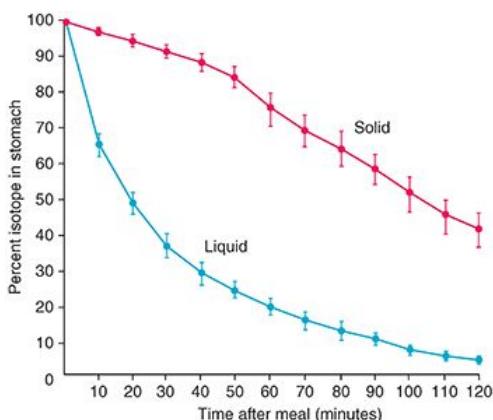

FIGURE 32.9 Gastric emptying of liquids is exponential, whereas emptying of solids is a linear process.

Several factors affect the rate of gastric emptying.³² The primary determinant of the emptying of liquids from the stomach is volume. In addition to volume, another factor that influences the rate of gastric emptying is the composition of the liquids. Emptying of neutral, iso-osmolar, and calorically inert solutions is rapid (250 of 500 mL of normal saline is emptied in 12 min). A small amount of water (up to 150 mL) to facilitate administration of oral medications shortly before the induction of anesthesia does not produce sustained increases in gastric fluid volume and could even contribute to gastric emptying. Solutions that are hypertonic or contain acid, fat, or certain amino acids all retard gastric emptying. High lipid and/or caloric content slows the emptying of solids from the stomach.^{18,23}

Hyperglycemia, impaired neural control, and neuromuscular inflammatory processes are all thought to play a role in the development of diabetic gastroparesis.³³ As many as 50% of patients with moderately controlled diabetes mellitus type I and II exhibit delayed gastric emptying, which can be demonstrated with carbon 13 breath tests, scintigraphy or a wireless motility capsule. Delayed gastric emptying of solids is the most consistent abnormality in diabetics with gastroparesis, but this parallels normal physiology whereby liquids pass through the pylorus exponentially depending on the volume and composition of the liquid, whereas solids pass through much more slowly in a biphasic manner. There is an initial lag period in which solids are digested to particles ≤ 2 mm in size and then a more rapid linear phase mimicking that of liquids.³³ As diabetes progresses, it is possible that gastric retention of liquids will also occur.

Patients with GERD and documented slowing of gastric emptying of solids have been shown to have normal gastric emptying rates for liquids. Most patients with slowed gastric emptying of solids in association with GERD do not demonstrate symptoms such as nausea and vomiting, which are usually associated with gastric stasis. The existence of delayed gastric emptying in gastric ulcer disease is controversial. Some data suggest a slowing of gastric emptying of solids but not liquids in the presence of gastric ulcers. Although obesity and pregnancy are often assumed to slow gastric emptying, there are also data that fail to confirm this slowing, whereas other data suggest accelerated gastric emptying in obese individuals. Contraction of the gastric fundus is responsible for facilitating the emptying of liquids, whereas antral contractions control the emptying of solids, after they have been digested into smaller particles.

Gastrointestinal transit time has been shown to vary during the menstrual cycle, with prolongation occurring during the luteal phase when progesterone levels are increased. Acute viral gastroenteritis has been associated with delayed gastric emptying.

Certain drugs, including opioids, β -adrenergic agonists, and tricyclic antidepressants, may slow gastric emptying. Aluminum hydroxide antacid may slow gastric emptying. Alcohol, at least in concentrations present in wine, does not significantly affect gastric emptying of liquids or solids. Higher concentrations of alcohol, such as present in whiskey, do cause slowing of gastric emptying. The mechanism of this slowing is not clear but may be due to hyperosmolarity, changes in gastric acid secretion, or damage to gastric mucosa.

Total parenteral nutrition may cause gastric stasis. Elemental diets, probably due to their high concentration of amino acids and hyperosmolarity, take longer to empty from the stomach than does blenderized food of comparable caloric composition. Cigarette smoking has been shown to delay emptying of solids, although it may accelerate emptying of liquids. Gastric prokinetic drugs such as metoclopramide may speed the emptying of solids and liquids. New therapeutic regimens demonstrating potential to treat delayed gastric emptying include ghrelin receptor agonists and selective 5-hydroxytryptamine receptor agonists.³³

Gastric Emptying Prior to Elective Surgery

Clear liquids can be administered to adult patients scheduled for elective operations until 2 hours before induction of anesthesia without increasing gastric fluid volume. It takes 3 to 4 hours for the stomach to empty following a light breakfast (one slice of white bread with butter and jam, 150 mL of coffee without milk or sugar, 150 mL of pulp-free orange juice). These data are consistent with the most recent recommendations from the most recent American Society of Anesthesiologists that a 6-hour fast should be enforced after a light breakfast.³⁴ However, there are a number of Enhanced Recovery after Surgery protocols that are somewhat more lenient. Because of the heterogeneity of these protocols, it is not possible to recommend that oral nutrition support improves the condition of patients undergoing colorectal surgery, the group of patients for whom Enhanced Recovery after Surgery was initially developed,³⁵ and therefore, the issue of preoperative fasting remains somewhat controversial.³⁶

Opioid-Induced Slowing of Gastric Emptying

Opioids receptors are found throughout the gastrointestinal system with particularly high concentrations in the gastric antrum and proximal duodenum. Central and peripheral μ -opioid receptors can regulate gastric emptying, and opioid-induced delay in gastric emptying can be reversed with naloxone, which acts simultaneously at both central and peripheral sites. The demonstration that methylnaltrexone, a selective peripheral-acting opioid antagonist, attenuates morphine-induced changes in the rate of gastric emptying indicates that peripheral opioid receptors modulate this response in humans (see [Chapter 7](#)).³⁷

Measurement of the Rate of Gastric Emptying

As mentioned earlier, the rate of gastric emptying can be evaluated by carbon 13 breath tests, scintigraphy, or by use of a wireless motility capsule.³³ Potentially of more interest to anesthesiologists is the use of ultrasonography both to measure gastric volume preoperatively³⁸ and, from a research perspective, to measure the rate of gastric emptying.³⁹ This technology is increasingly being used throughout the United States and at least for certain procedures is considered a standard of care.

Vomiting

Vomiting is coordinated by the vomiting center in the medulla. This center receives input from multiple sites including the chemoreceptor trigger zone in the floor of the fourth ventricle, from the vestibular apparatus, from cortical centers, and from the gastrointestinal tract. The blood–brain barrier is poorly developed around the chemoreceptor trigger zone, and emetic substances present in the circulation are readily accessible to this site. Serotonin acting at 5-hydroxytryptamine receptors ($5-HT_3$) is an important emetic signal via neural pathways from the gastrointestinal tract ending at the chemoreceptor trigger zone. Likewise, dopamine and acetylcholine may provide emetic signals to the chemoreceptor trigger zone. Pharmacologic antagonism of these emetic signals results in antiemetic effects. The role of specific opioid receptors in emetic responses is unresolved. Following stimulation of the vomiting center (directly or indirectly via neural pathways), vomiting is mediated by efferent pathways including the vagus and phrenic nerves, and innervation of the abdominal musculature. The initial manifestation of vomiting often involves nausea in which gastric peristalsis is reduced or absent and the tone of the upper small intestine is increased and gastric reflux occurs. The next steps involve the closure of the glottis with simultaneous contraction of the diaphragm, which creates significantly negative intrathoracic pressure. The pylorus and abdominal muscles contract greatly increasing intragastric pressure. The final step is coordinated relaxation of the upper stomach and lower and

upper esophageal sphincters, which leads to explosive expulsion of gastric contents. Risk factors for postoperative nausea and vomiting include female sex, young age (children), history of motion sickness, abstinence from tobacco, and obesity (perhaps reflecting emetic anesthetic drugs stored in adipose tissue).

Small Intestine

The small intestine consists of the duodenum (from the pylorus to the ligament of Treitz), the jejunum, and the ileum (ending at the ileocecal valve). There is no distinct anatomic boundary between the jejunum and ileum, but the first 40% of small intestine after the ligament of Treitz is often considered the jejunum. The small intestine is presented with approximately 9 L of fluid daily (2 L from the diet and the rest representing gastrointestinal secretions), but only 1 to 2 L of chyme enters the colon. The small intestine is the site of most of the digestion and absorption of proteins, fats, and carbohydrates ([Table 32.3](#)).

TABLE 32.3

Site of absorption

	Duodenum	Jejunum	Ileum	Colon
Glucose	++	+++	++	0
Amino acids	++	+++	++	0
Fatty acids	+++	++	+	0
Bile salts	0	+	+++	0
Water-soluble vitamins	+++	++	0	0
Vitamin B ₁₂	0	+	+++	0
Sodium	+++	++	+++	+++
Potassium	0	0	+	++
Hydrogen	0	+	++	++
Chloride	+++	++	+	0
Calcium	+++	++	+	?

Chyme moves through the 5 meters of small intestine at an average rate of 1 cm per minute. As a result, it takes 3 to 5 hours for chyme to pass from the pylorus to the ileocecal valve. On reaching the ileocecal valve, chyme may remain in place for several hours until the person eats another meal. An inflamed appendix can increase the tone of the ileocecal valve to the extent that emptying of the ileum ceases. Conversely, gastrin causes relaxation of the ileocecal valve. When more than 50% of the small intestine is resected, the absorption of nutrients and vitamins is so compromised that development of malnutrition is likely.

Secretions of the Small Intestine

Mucous glands (Brunner glands) present in the first few centimeters of the duodenum secrete mucus to protect the duodenal wall from damage by acidic gastric fluid. Stimulation of the sympathetic nervous system inhibits the protective mucus-producing function of these glands, which may be one of the factors that cause this area of the gastrointestinal tract to be the most frequent site of peptic ulcer disease.

The crypts of Lieberkühn contain epithelial cells that produce up to 2 L daily of secretions that lack digestive enzymes and mimic extracellular fluid, having a pH of 6.5 to 7.5. This fluid provides a watery vehicle for absorption of substances from chyme as it passes through the small intestine. The most important mechanism for regulation of small intestine secretions is local neural reflexes, especially those initiated by distension produced by the presence of chyme.

The epithelial cells in the crypts of Lieberkühn continually undergo mitosis, with an average life cycle of approximately 5 days. This rapid growth of new cells allows prompt repair of any excoriation that occurs in the mucosa. This rapid turnover of cells also explains the vulnerability of the gastrointestinal epithelium to chemotherapeutic drugs (see [Chapter 42](#)).

The epithelial cells in the mucosa of the small intestine contain digestive enzymes that most likely are responsible for digestion of food substances because they are absorbed across the gastrointestinal epithelium. These enzymes include peptidases for splitting peptides into amino acids, enzymes for splitting disaccharides into monosaccharides, and intestinal lipases.

Absorption From the Small Intestine

Mucosal folds (valvulae conniventes), microvilli (brush border), and epithelial cells provide an absorptive area of approximately 250 m^2 in the small intestine for nearly all the nutrients and electrolytes as well as approximately 95% of all the water. Daily absorption of sodium is 25 to 35 g, emphasizing the rapidity with which total body sodium depletion can occur if excessive intestinal secretions are lost as occurs with extreme diarrhea. Active transport of sodium ions in the small intestine is important for the absorption of glucose, which is the physiologic basis for treating diarrhea by oral administration of saline solutions containing glucose. Bacterial toxins, for example, from *Clostridium difficile* or from *Escherichia coli*, can stimulate the chloride-bicarbonate ion exchange mechanism, resulting in life-threatening diarrhea consisting of loss of sodium, bicarbonate, and an isosmotic equivalent of water.

Colon

The functions of the colon are absorption of water and electrolytes from the chyme and storage of feces. A test meal reaches the cecum in approximately 4 hours and then passes slowly through the colon during the next 6 to 12 hours, during which time 1 to 2 L of chyme are converted to 200 to 250 g of feces ([Figure 32.10](#)). The circular muscle of the colon constricts and, at the same time, strips of longitudinal muscle (tinea coli) contract, causing the unstimulated portion of the colon to bulge outward into baglike sacs, or haustra. Vagal stimulation causes segmental contractions of the proximal part of the colon and stimulation of the pelvic nerves causes explosive movements. Activation of the sympathetic nervous system inhibits colonic activity. Bacteria are predictably present in the colon.

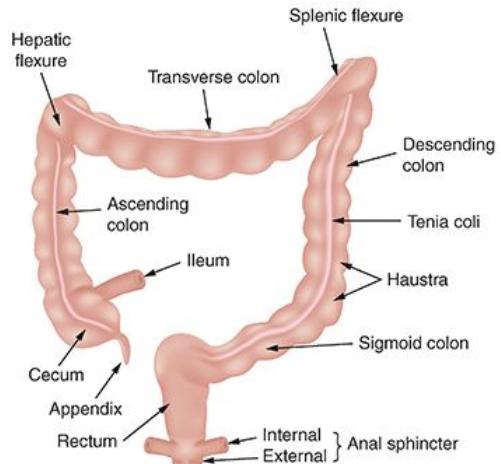

FIGURE 32.10 Anatomy of the colon.

Secretions of the Colon

Epithelial cells lining the colon secrete almost exclusively mucus, which protects the intestinal mucosa against trauma. The alkalinity of the mucus due to the presence of large amounts of bicarbonate ions provides a barrier to keep acids that are formed in the feces from attacking the intestinal wall. Irritation of a segment of colon as occurs with bacterial infection causes the mucosa to secrete large quantities of water and electrolytes in addition to mucus, diluting the irritating factors and causing rapid movement of feces toward the anus. The resulting diarrhea may result in dehydration and cardiovascular collapse.

Pancreas

The pancreas lies parallel to and beneath the stomach, serving as both an endocrine (insulin or glucagon) and exocrine gland. Exocrine secretions (approximately 1.5 L daily) are rich in bicarbonate ions to neutralize duodenal contents and digestive enzymes to initiate breakdown of carbohydrates, proteins, and fats.

Regulation of Pancreatic Secretions

Pancreatic secretions are regulated more by hormonal than neural mechanisms. For example, secretin is released by duodenal mucosa in response to hydrochloric acid. This hormone enters the circulation and causes the pancreas to produce large amounts of alkaline fluid necessary to neutralize the acidic pH of gastric fluid. In addition to the release of secretions, the presence of food in the duodenum causes the release of a second polypeptide hormone, cholecystokinin. Cholecystokinin also enters the circulation and causes the pancreas to secrete digestive enzymes (trypsin, amylase, lipases). Trypsins are activated in the gastrointestinal tract by the enzyme enterokinase, which is secreted by the gastrointestinal mucosa when chyme is exposed to the mucosa. Damage to the pancreas or blockade of a pancreatic duct may cause pooling of proteolytic enzymes, resulting in acute pancreatitis due to autodigestion by these enzymes. In general, pancreatic secretions are stimulated by the parasympathetic nervous system and inhibited by the sympathetic nervous system.

Metabolism

Michael J. Murray

One of the most important functions of the gastrointestinal tract is the ingestion of nutrients—carbohydrate, protein, lipid, minerals, vitamins, and water—used for production of energy, creation of complex proteins and lipid moieties, and maintenance of electrolytes and total body water stores. The production of energy involves the oxidation of nutrients (carbohydrates, fats, and proteins) that results in creation of high-energy phosphate compounds in which energy is stored for life processes, with carbon dioxide and water produced as side products. The most important high-energy phosphate molecule is adenosine triphosphate (ATP) ([Figure 33.1](#)). This ubiquitous molecule is the energy storehouse for the body, providing the energy necessary for essentially all physiologic processes and chemical reactions. Probably the most important intracellular process that requires energy from hydrolysis of ATP is formation of peptide linkages between amino acids during protein synthesis. Likewise, efficient skeletal muscle contraction cannot occur without energy derived from ATP hydrolysis. Metabolism of nutrients is necessary for creation of ATP that, when hydrolyzed provides energy for transport of ions across cell membranes. Active transport is required to maintain the distribution of ions necessary for multiple cellular processes, including the propagation of nerve impulses. In renal tubules, as much as 80% of ATP is used for membrane transport of ions. In addition to its function in energy transfer, ATP is also the precursor of cyclic adenosine monophosphate, an important signaling molecule.

For adults, total energy expenditure averages 39 kcal/kg in men and 34 kcal/kg in women. Approximately 20 kcal/kg is expended as basal metabolism necessary to maintain integrity of the cell membrane and other energy-requiring tasks essential for life. In the resting state, the basal expenditure of calories is equivalent to approximately 1.1 kcal per minute, which requires approximately 200 to 250 mL per minute of oxygen in a 70-kg person for oxidation of nutrients. As the level of activities increase above the basal state, the caloric (and oxygen) requirements increase in proportion to the energy expenditure required ([Table 33.1](#)). The caloric values of carbohydrates, fats, and proteins are approximately 3.75, 9.3, and 4.1 kcal/g, respectively. Fat is the major energy storage depot because of its greater mass and high caloric value ([Figure 33.2](#)).¹ As a consequence, the primary form in which potential chemical energy is stored in the body is in adipose tissue as triglycerides. The high caloric density and hydrophobic nature of triglycerides permit efficient energy storage without adverse osmotic consequences.

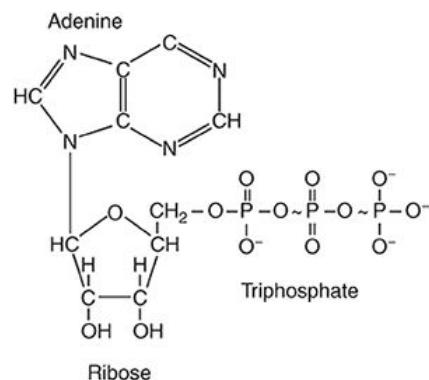

FIGURE 33.1 Metabolism of nutrients in cells is directed toward the ultimate synthesis of adenosine triphosphate. Energy necessary for physiologic processes and chemical reactions is derived from the high-energy phosphate bonds of adenosine triphosphate.

TABLE 33.1

Estimates of energy expenditure in adults

Activity	Calorie expenditure (kcal per minute)
Basal	1.1
Sitting	1.8
Walking (2.5 miles per hour)	4.3
Walking (4 miles per hour)	8.2
Climbing stairs	9.0
Swimming	10.9
Bicycling (13 miles per hour)	11.1

Carbohydrate Metabolism

Carbohydrates comprise a group of organic compounds that include sugars and starches and, in addition to carbon, contain hydrogen and oxygen in the same ratio as in water (2:1). Three disaccharides are important in human biology—sucrose: glucose and fructose; lactose: glucose and galactose; and maltose: glucose and glucose. Starch, found in grains such as wheat, rice, barley, and other plants, including potatoes and corn, consists of many units of glucose joined by glycosidic bonds. The monosaccharide glucose is an important energy source for the body and the sole source of energy for the brain.

Glucose levels are tightly controlled in the body by the enzyme glucose kinase. This enzyme is produced in the pancreas where it is involved in the rate-limiting step for the release of insulin and in the liver where it is involved in glycogenesis when intrahepatic concentration of glucose is high, for example, after a meal when glucose concentration in the portal vein is increased.¹

Ingested sugars and starches are digested in the small intestine to the monosaccharides glucose, fructose, and galactose. The latter two molecules can be converted to glucose in the liver; at least 99% of all the energy derived from glucose is used by mitochondria to form ATP in cells ([Figure 33.3](#)).

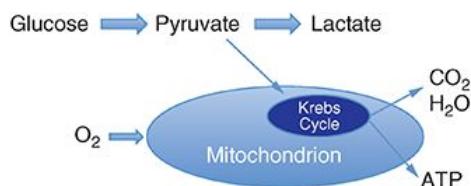

FIGURE 33.3 Formation of adenosine triphosphate (ATP) from glucose.

After absorption into the portal venous system, and when they reach the liver, monosaccharides form reversible complexes with membrane bound carrier proteins. The latter are coupled cotransporters; that is, the transport of these monosaccharides into cells is coupled to the transport of Na^+ .² Once inside hepatocytes, they are phosphorylated. For example, glucose is converted to glucose-6-phosphate under the influence of the enzyme hexose kinase. Phosphorylated glucose is ionized at a pH of 7, and because plasma membranes are not permeable to the ions, the phosphorylated glucose cannot pass back through the membrane and is effectively trapped within the cell.

In the liver, glucose can be stored as glycogen (see the following text) or released into the systemic circulation depending on blood glucose concentrations. Fructose, 2.5 times sweeter than glucose, has a much slower rate of absorption from the gastrointestinal tract and therefore has a glycemic index (measure of the increase in blood glucose of a carbohydrate, with glucose having a glycemic index of 100) of 23.³ The glycemic index of sucrose is 65; of lactose (glucose and galactose) is 46, the latter reflecting the fact that ingested galactose has very little effect on blood glucose levels.³

The fetus derives almost all its energy from glucose obtained from the maternal circulation. Immediately after birth, the infant stores of glycogen are sufficient to supply glucose for only a few hours. Furthermore, gluconeogenesis is limited in the neonate. As a result, the neonate is vulnerable to hypoglycemia if feeding is not initiated.

Glycogen

After entering cells, glucose can be used immediately for release of energy to cells or it can serve as a substrate for glycogen synthase, primarily in hepatocytes and myocytes. Glycogen synthase is activated when dephosphorylated by a protein phosphatase 1 (in the liver hepatic protein phosphatase 1 regulatory subunit 3B is the responsible phosphatase⁴), which in turn is regulated by insulin and glucagon. Activated glycogen synthase combines molecules of glucose into a long polymer, similar to the way plants store carbohydrate as starch. Glycogen synthase is deactivated when it is phosphorylated—by glycogen synthase kinase-3,5'-adenosine monophosphate-activated protein kinase, and protein kinase A. The liver and skeletal muscles are particularly capable of storing large amounts of glycogen, but all cells can store at least some glucose as glycogen, and the glycogen in these cells is increasingly recognized as having important roles in both health and disease. In hepatocytes, for example, if glycogen stores are high, fructose, for example, does not further increase glycogen stores but, especially if an individual is sedentary, is converted to very-low-density lipoprotein and released into the systemic circulation,⁵ hence, the current controversy over consumption of soft drinks and juices containing sucrose; 12 oz of some soft drinks have 35 g. However, during glycogen-depleting exercise, fructose-containing foods/drinks may optimize performance and recovery.⁵

The liver stores glycogen for release of glucose during fasting, and muscle, which can store as much as 90% of the glucose contained in a meal, catabolizes glycogen during strenuous exercise.⁶ The ability to form glycogen makes it possible to store substantial quantities of glucose without significantly altering the osmotic pressure of intracellular fluids. Glucose is cleaved from glycogen between meals, during fasting, and during exercise by glycogen phosphorylase and by a debranching enzyme.

Gluconeogenesis

Gluconeogenesis is the formation of glucose from amino acids and the glycerol portion of fat. Amino acids are first deaminated before entering the citric acid (Krebs) cycle (see [Figure 33.3](#)). This process occurs when body stores of glycogen decrease below normal levels. An estimated 60% of the amino acids in the body's proteins can be converted easily to pyruvate and glucose, whereas the remaining 40% have chemical configurations that make this conversion difficult.

Gluconeogenesis is stimulated by hypoglycemia. Particularly in the liver, simultaneous release of cortisol mobilizes proteins, making them available for breakdown to amino acids used in gluconeogenesis. Thyroxine is also capable of increasing the rate of gluconeogenesis.

[Energy Release From Glucose](#)

Glucose is progressively broken down into two molecules of pyruvate, both of which can enter the citric acid cycle ([Figure 33.4](#)), and the resulting energy is used to form ATP. For each mole of glucose that is completely degraded to carbon dioxide and water, a total of 38 moles of ATP is ultimately formed. The most important means by which energy is released from the glucose molecule is by glycolysis and the subsequent oxidation of the end products of glycolysis. Glycolysis is the splitting of the glucose molecule into two molecules of pyruvate, which enter the mitochondria where the pyruvate is converted to acetyl-coenzyme A (acetyl-CoA), which enters the citric acid cycle and is converted to carbon dioxide and hydrogen ions with the formation of ATP (oxidative phosphorylation). Oxidative phosphorylation occurs only in mitochondria, in the presence of adequate amounts of oxygen, and in the presence of a high ratio of ionized nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide and hydrogen.¹

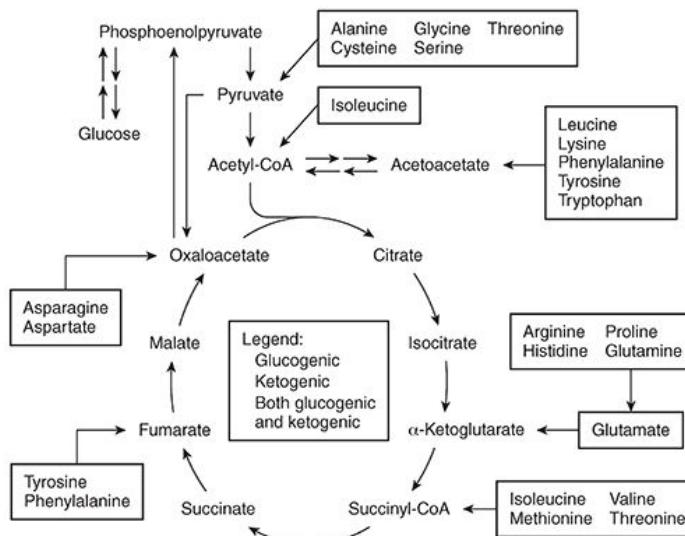

FIGURE 33.4 The citric acid cycle. Abbreviation: CoA, coenzyme A. *From Mikael Häggström, MD, Wikimedia Commons.*

Anaerobic Glycolysis

In the absence of adequate amounts of oxygen, a small amount of energy can be released by anaerobic glycolysis, also known as fermentation in plants, fungi, and bacteria because conversion of glucose to pyruvate does not require oxygen. Indeed, glucose is the only nutrient that can serve as a substrate for the formation of ATP without oxygen. This release of energy to cells can be lifesaving for a few minutes should oxygen become unavailable.

During anaerobic glycolysis, most pyruvic acid is converted to lactic acid, which diffuses rapidly out of cells into extracellular fluid. When oxygen is again available, lactic acid can be reconverted to glucose, predominantly in the liver. Severe liver disease may interfere with the ability of the liver to convert lactic acid to glucose, leading to metabolic acidosis.

Lipid Metabolism

Lipids are hydrophobic organic molecules that include waxes, sterols, fat-soluble vitamins, triglycerides (fats), phospholipids, and other substances. Lipids contain a high amount of potential energy but are also important as structural components of cell membranes, in signaling pathways, and as precursors to a number of cytokines. Fatty acids and their derivatives as well as molecules that contain sterols such as cholesterol are also considered lipids. Although there are biosynthetic pathways to synthesize and degrade lipids, some fatty acids are essential and must be ingested in the diet. Fatty acids are carboxylic acids consisting of a long hydrocarbon chain ending in a carboxyl group; the hydrocarbon chain can be saturated or unsaturated ([Figure 33.5](#)). Humans can desaturate carbon atoms no closer than the ninth carbon from the tail of the aliphatic

chain. However, humans require fatty acids (that are therefore essential) that are desaturated as close as the sixth and as close as the third carbon to the terminus of the aliphatic chain— ω 6 and ω 3 fatty acids, respectively. Twenty carbon chain fatty acids are stored in the second position of phospholipids (see the following text) and, when released, serve as substrates for a group of very important cytokines, the eicosanoids—prostaglandins, thromboxanes, and leukotrienes. Arachidonic acid (see [Figure 33.5](#)), a 20-carbon chain v6 fatty acid (C20:4 ω 6), is a precursor for prostaglandins and thromboxanes of the two series and leukotrienes of the four series, whereas eicosapentaenoic acid, C20:5 ω 3, is a precursor for prostaglandins and thromboxanes of the three series and leukotrienes of the five series.

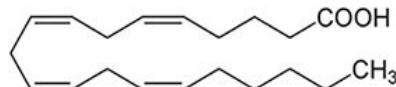

FIGURE 33.5 A long chain fatty acid, arachidonic acid. *From Yikrazuul via Wikimedia Commons.*

A glycerol stem to which three fatty acid molecules are bound is known as a triglyceride ([Figure 33.6](#)). A triglyceride molecule to which one of the terminal fatty acids is replaced with a phosphate ion is known as a phospholipid ([Figure 33.7](#)). Phospholipids are the building blocks of cell membranes ([Figure 33.8](#)), form myelin, and, because of their unique structure and functions, are being used in other scientific applications.

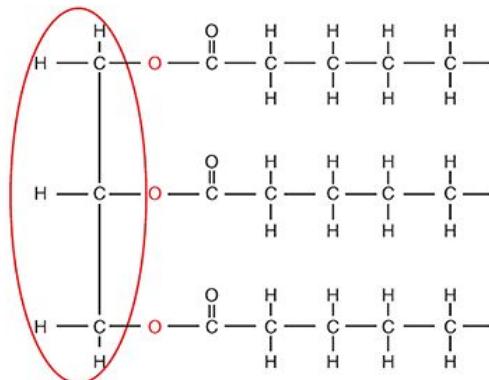

FIGURE 33.6 Triglyceride made up of a molecule of glycerol (circled in red) and three fatty acids.

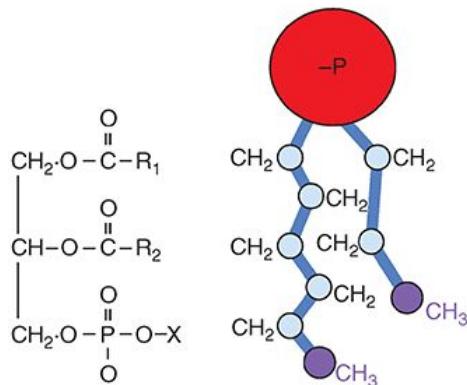

FIGURE 33.7 Substitution of one of the terminal fatty acids with a phosphate ion creates a phospholipid. Chemical structure on left; cartoon on right shows the hydrophilic phosphate group in red, with the hydrophobic hydrocarbon chains in blue. *From Wikimedia Commons.*

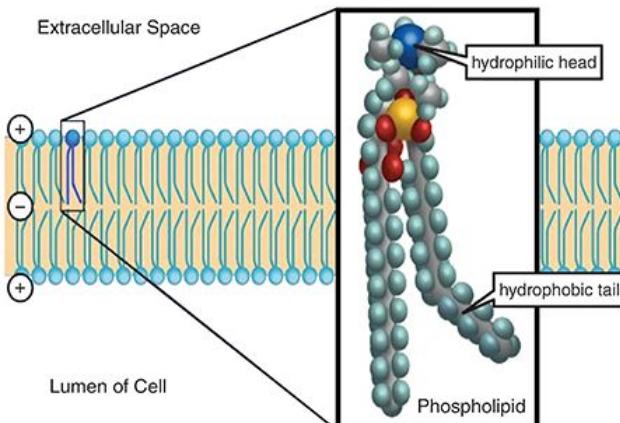

FIGURE 33.8 Cell membrane is a bilipid layer—made up of two opposing layers of phospholipids. The phosphate terminus is hydrophilic, whereas the two fatty acids, which are hydrophobic, orient to the interior of the membrane. *From Ties van Brusse, Wikimedia Commons.*

Triglycerides, after absorption from the gastrointestinal tract, are transported in the lymph and then, by way of the thoracic duct, into the circulation in droplets known as **chylomicrons**. Chylomicrons are rapidly removed from the circulation and stored as they pass through capillaries of adipose tissue and skeletal muscles. Triglycerides are used in the body mainly to provide energy for metabolic processes similar to those fueled by carbohydrates.

Cholesterol does not contain fatty acids, but it is a lipid because it is composed of carbon and hydrogen, not as aliphatic chains of carbon but with four rings made up of carbon ([Figure 33.9](#)). Seventy-five percent of cholesterol is produced in the liver in a synthetic process that involves 37 steps; the other 25% of cholesterol is ingested in the diet.

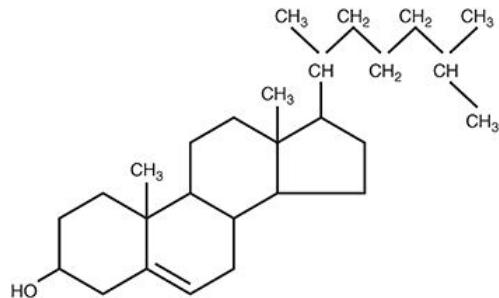

FIGURE 33.9 The chemical structure of a cholesterol molecule.

Molecules that are part lipid and part protein, lipoproteins, are also synthesized primarily in the liver ([Table 33.2](#)). The presumed function of lipoproteins is to provide a mechanism of transport for lipids throughout the body. Lipoproteins are classified according to their density, which is inversely proportional to their lipid content. All the cholesterol in plasma is found in lipoprotein complexes, with low-density lipoproteins (LDLs) representing the major cholesterol component in plasma. These LDLs provide cholesterol to tissues, where it is an essential component of cell membranes and is used in the synthesis of corticosteroids and sex hormones. In the liver, LDLs are taken up by receptor-mediated endocytosis. An intrinsic feedback control system increases the endogenous production of cholesterol when exogenous intake is decreased, explaining the relatively modest lowering effect on plasma cholesterol concentrations produced by low-cholesterol diets. If this endogenous increase in cholesterol synthesis is blocked by drugs that inhibit hydroxymethylglutaryl CoA reductase, then there is an appreciable decrease in the plasma cholesterol concentration.

TABLE 33.2

Types of proteins		
Globular	Fibrous	Conjugated
Albumin	Collagen	Mucoprotein
Globulin	Elastin fibers	Structural components of cells
Fibrinogen	Keratin	
Hemoglobin	Actin	
Enzymes	Myosin	
Nucleoproteins		

Drugs that selectively inhibit hydroxymethylglutaryl CoA are known as statins. Statins effectively lower plasma LDL cholesterol concentrations and may provide protection against acute cardiac events, perhaps reflecting antiinflammatory effects. In addition, statins lower plasma triglyceride concentrations and modestly increase high-density lipoprotein cholesterol concentrations. Drugs that bind bile salts (cholestyramine, colestipol) prevent cholesterol from reentering the circulation as part of the enterohepatic circulation. A disadvantage of using drugs that bind bile salts to lower plasma cholesterol concentrations is an associated increase in plasma triglyceride concentrations.

The first step in the use of triglycerides for energy is hydrolysis into fatty acids and glycerol and subsequent transport of these products to tissues, where they are oxidized. Almost all cells, except for brain cells, can use fatty acids interchangeably with glucose for energy. Degradation and oxidation of fatty acids occur only in mitochondria, resulting in progressive release of two carbon fragments (β -oxidation) in the form of acetyl-CoA (Figure 33.10). These acetyl-CoA molecules enter the citric acid cycle in the same manner as acetyl-CoA formed from pyruvate during the metabolism of glucose, ultimately leading to formation of ATP. In the liver, two molecules of acetyl-CoA formed from the degradation of fatty acids can combine to form acetoacetic acid (see Figure 33.10). A substantial amount of acetoacetic acid is converted to β -hydroxybutyric acid and small amounts of acetone. In the absence of adequate carbohydrate metabolism (starvation or uncontrolled diabetes mellitus), large quantities of acetoacetic acid, β -hydroxybutyric acid, and acetone accumulate in the blood to produce ketosis because almost all the energy of the body must come from metabolism of lipids. Whereas β -hydroxybutyric acid may be elevated in diabetic ketoacidosis in type 1 diabetes mellitus, an elevated level of α -hydroxybutyric acid is highly correlated with impaired glucose tolerance and may serve as a biomarker for type 2 diabetes mellitus.⁸

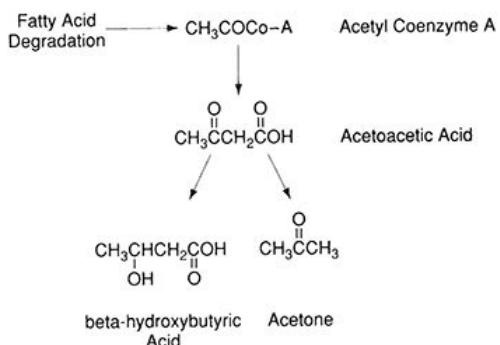

FIGURE 33.10 Fatty acid degradation in the liver leads to the formation of acetyl-coenzyme A (acetyl-CoA). Two molecules of acetyl-CoA combine to form acetoacetic acid, which, in large part, is converted to β -hydroxybutyric acid and, in lesser amounts, to acetone.

In contrast to glycogen, large amounts of lipids can be stored in adipose tissue and in the liver. A major function of adipose tissue is to store triglycerides until they are needed for energy. Epinephrine and norepinephrine activate triglyceride lipase in cells, leading to mobilization of fatty acids.

Protein Metabolism

Approximately 75% of the solid constituents of the body are proteins ([Table 33.3](#)). All proteins are composed of the same 20 amino acids, and several of these must be supplied in the diet because they cannot be formed endogenously (essential amino acids) ([Table 33.4](#)). Dietary proteins must be cleaved into amino acids and di- and tripeptides before they can be absorbed. The process begins in the stomach where pepsinogen is converted to pepsin in the acidic pH. The process continues in small intestine into which the pancreas secretes trypsin and chymotrypsin and carboxypeptidases. These gastric and pancreatic proteases hydrolyze proteins into medium- and small-chain peptides. Peptidases in the brush border of the small intestine hydrolyze these medium- and small-chain peptides into free amino acids and di- and tripeptides. These end products of digestion, formed on the surface of the enterocyte, are ready for absorption by sodium-dependent amino acid transporters.

TABLE 33.3

Composition of lipids in the plasma

	Phospholipid (%)	Triglyceride (%)	Free cholesterol (%)	Cholesterol esters	Protein (%)	Density
Chylomicrons	3	90	2	3	2	0.94
LDL	21	6	7	46	20	1.019-1.063
HDL	25	5	4	16	50	1.063-1.21
IDL	20	40	5	25	10	1.006-1.019
VLDL	17	55	4	18	8	0.94-1.006

Abbreviations: HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

TABLE 33.4

Amino acids

Essential	Nonessential
Arginine	Alanine
Histidine	Asparagine
Isoleucine	Aspartic acid
Leucine	Cysteine
Lysine	Glutamic acid
Methionine	Glutamine
Phenylalanine	Glycine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

Nonessential amino acids can be synthesized from the appropriate α -keto acid. For example, pyruvate formed during the glycolytic breakdown of glucose is the keto acid precursor of alanine. Each amino acid has an acidic carboxyl group (COOH) and an amino group (NH_3^+) ([Figure 33.11](#)). Proteins are formed by amino acids connected one to another by an amide bond, a covalent chemical bond between the carboxyl group of one amino acid with the amino group of another amino acid. The resulting $\text{C}(\text{O})\text{NH}$ bond is called a peptide bond, and the resulting molecule is an amide. The four-atom functional group $-\text{C}(=\text{O})\text{NH}-$ is called a peptide link ([Figure 33.12](#)). Even the smallest proteins characteristically contain more than 20 amino acids connected by peptide linkages, whereas complex proteins have as many as 100,000 amino acids. In addition, more than

one amino acid chain in a protein may be bound to another amino acid chain by hydrogen bonds, hydrophobic bonds, or electrostatic forces.

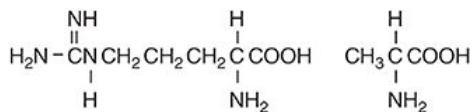

FIGURE 33.11 Examples of amino acids containing an acidic group (COOH) or an amino group (NH_2)

FIGURE 33.12 Formation of amides from carboxylic acid and primary amine

Amino acids are relatively strong acids and exist in the blood principally in the ionized form. After a meal, the blood amino acid concentration increases only a few milligrams, reflecting rapid tissue uptake, especially by the liver. Passage of amino acids into cells requires active transport mechanisms because these substances are too large to pass by diffusion or through channels in cell membranes. In proximal renal tubules, amino acids that have entered the glomerular filtrate are actively transported back into the blood. These transport mechanisms have maximums above which amino acids appear in the urine. In the normal person, however, loss of amino acids in the urine each day is negligible. Failure to transport amino acids into the blood is indicative of renal disease.

Storage of Amino Acids

Immediately after entry into cells, amino acids are conjugated under the influence of intracellular enzymes into cellular proteins. The concentration of amino acids within cells is low as the cell uses them as substrate to create proteins within the liver, kidneys, and gastrointestinal mucosa. Nevertheless, these proteins can be rapidly decomposed again into amino acids under the influence of intracellular lysosomal digestive enzymes. The resulting amino acids can then be transported out of cells into blood to maintain optimal plasma amino acid concentrations. Tissues can synthesize new proteins from amino acids in blood. This response is especially apparent in relation to protein synthesis in cancer cells. Cancer cells are prolific users of amino acids, and, simultaneously, the proteins of other tissues become markedly depleted, contributing to cachexia.

Plasma Proteins

Plasma proteins are represented by (1) albumin, which provides colloid osmotic pressure; (2) globulins necessary for innate and acquired immunity; and (3) fibrinogen, which polymerizes into long fibrin threads during coagulation of blood. Essentially, all plasma albumin and fibrinogen and 60% to 80% of the globulins are formed in the liver. Additional globulins are formed in lymphoid tissues and other cells of the reticuloendothelial system. The rate of plasma protein formation by the liver can be greatly increased in situations, such as severe burns, in which there is loss of large amounts of fluid and protein.

The hepatic synthetic rate of proteins depends on the concentration of amino acids in the portal vein and in the hepatic artery. Even during starvation or severe debilitating diseases, the ratio of total tissue proteins to total plasma proteins in the body remains relatively constant at approximately 33:1. Because of the reversible equilibrium between plasma proteins and other proteins of the body, one of the most effective of all therapies for acute protein deficiency is the intravenous administration of plasma proteins. Within hours, amino acids of the administered protein become distributed throughout cells of the body to form proteins where they are needed.

Albumin

Albumin is the most abundant plasma protein and is principally responsible for maintaining plasma osmotic pressure and as a transporter of plasma-bound substances, often including exogenously administered drugs. Normal daily synthesis of albumin is about 10 g, and the half-life for this protein may be as long as 22 days. Therefore, serum albumin concentrations may not be noticeably decreased in early states of acute hepatic failure. However, within hours of the onset of a critical illness or injury, albumin levels decrease by as much as 33% due to changes in the distribution between intravascular and extravascular compartments and rates of synthesis and degradation of protein. Despite the fact that low serum albumin is a poor prognostic factor in critical illness, supplementation has not been shown to improve prognosis.

Coagulation Factors

Hepatocytes synthesize all coagulation factors with the exception of von Willebrand factor and factor VIIIC. Coagulation may be rapidly impaired by acute liver failure, reflecting the short plasma half-life for many critical components (factor VII: 100-300 minutes). Vitamin K (uptake dependent on bile salts) is necessary for modification of several of the clotting factors (prothrombin, antithrombin, protein S, and protein C) and may be deficient in malabsorptive states and malnutrition.

Use of Proteins for Energy

Once cells contain a maximum amount of amino acids, any additional amino acids are deaminated (oxidative deamination) to keto acids that can enter the citric acid cycle to become ATP or the keto acids are released into the bloodstream, taken up by adipocytes, and converted to and stored as triglycerides. Ammonia resulting from deamination is converted to urea in the liver for excretion by the kidneys. Acute hepatic failure manifests by accumulation of toxic concentrations of ammonia. Certain deaminated amino acids are similar to the breakdown products that result from glucose and fatty acid metabolism. For example, deaminated alanine is pyruvic acid, which can be converted to glucose or glycogen, or it can be converted to acetyl-CoA, which is polymerized to fatty acids. The conversion of amino acids to glucose or glycogen is **gluconeogenesis**, and the conversion of amino acids into fatty acids is **ketogenesis**. In the absence of protein intake, approximately 20 to 30 g of endogenous protein are degraded into amino acids daily. In severe starvation, cellular functions deteriorate because of protein depletion. Carbohydrates and lipids spare protein stores to a certain extent because they are used in preference but not exclusively to proteins for energy.

Growth hormone and insulin promote the synthetic rate of cellular proteins, possibly by facilitating the transfer of amino acids into cells. Glucocorticoids increase the breakdown rate of extrahepatic proteins, thereby making increased amino acids available to the liver. This allows the liver to synthesize increased amounts of cellular proteins and plasma proteins. Testosterone increases protein deposition in tissues, particularly the contractile proteins of skeletal muscles.

Effects of Stress on Metabolism

Carbohydrate, lipid, and protein metabolism are significantly altered by stress. In response to stress, the body increases secretion of cortisol, catecholamines, and glucagon, resulting in increased endogenous glucose production (hepatic gluconeogenesis) and hyperglycemia (to provide glucose to cells for ATP production in those cells involved in the fight or flight response). Stress-induced β -adrenergic stimulation increases the breakdown of triglycerides (lipolysis). The products of lipolysis can be used for gluconeogenesis or directly by cells to produce ATP. Likewise, a predictable response to stress is catabolism of proteins in skeletal muscles, releasing keto acids that can be used for ATP production or for gluconeogenesis.

Exogenous glucose administered to injured or septic patients has a minimal effect on gluconeogenesis and lipolysis. Conversely, administration of glucose in the presence of starvation decreases gluconeogenesis and lipolysis.

Obesity

Given the importance of energy stores to individual survival and reproductive capacity, the ability to conserve energy in the form of adipose tissue at one time may have conferred a survival advantage; however, an increase in adiposity would have been a disadvantage in that it increased the risk of predation.⁹ Independent

of the teleologic rationale, the combination of easy access to calorically dense foods and a sedentary lifestyle¹⁰ has made the metabolic consequences maladaptive. In addition, certain medications are commonly associated with weight gain ([Table 33.5](#)).

TABLE 33.5

Drugs commonly associated with weight gain

Classification	Drug	Alternative drug
Antidepressants	Tricyclic antidepressants Monoamine oxidase inhibitors	Selective serotonin reuptake inhibitors
Antidiabetics	Insulin Sulfonylureas Thiazolidinediones	Metformin Acarbose
Antiepileptics	Gabapentin Valproic acid	Lamotrigine Topiramate
Antipsychotics	Clozapine	Haloperidol
Steroids	Glucocorticoids	

Obesity is the most common and costly nutritional problem in the United States. Based on body mass index (BMI) (weight in kilograms divided by the square of the height in meters), 67% of adult males and 62% of adult females are overweight (BMI ≥ 25) and 27.5% of adult males and 34% of adult females (BMI ≥ 30 to <40) are obese; individuals with BMI ≥ 40 have extreme obesity. The prevalence of obesity peaks between 60 and 69 years of age, but greater numbers of children are increasingly found to be obese for their age.¹¹

For every 5-unit increase in BMI above 25 kg/m^2 , mortality increases by ~29%, mortality from vascular disease by ~40%, and diabetes-related mortality by >200%. Central adiposity, that is, increased waist circumference, correlates with cardiometabolic risk, independent of the BMI.¹² In this regard, an overweight person with a predominant abdominal fat distribution (common in elderly males with impaired glucose tolerance) may be at high risk for these diseases even if not considered obese by BMI criteria. The increased risk for morbidity and mortality extend beyond measurements of BMI and fat distribution, as reflected by the diagnosis of **metabolic syndrome**, which is present if a patient has three of the following five risk factors: increased waist circumference (as described previously), low levels of high-density lipoprotein cholesterol, increased triglycerides, hypertension, and glucose intolerance ([Table 33.6](#)). The risk of anesthesia may be increased in obese patients, reflecting mechanical difficulties (airway, positioning, and ventilation) and increased incidence of comorbid conditions (diabetes mellitus, systemic hypertension).

TABLE 33.6

Criteria for diagnosis of metabolic syndrome (any three of the following characteristics)

Characteristic	Specific finding
Waist circumference	Males $>102 \text{ cm}$ (40 inches) Females $>88 \text{ cm}$ (35 inches)
Blood glucose concentration (fasting)	$>110 \text{ mg/dL}$
Increased systemic blood pressure	Systolic $>130 \text{ mm Hg}$ Diastolic $>85 \text{ mm Hg}$
Serum triglyceride concentration	$>150 \text{ mg/dL}$
High-density lipoprotein cholesterol concentration	Males $<40 \text{ mg/dL}$ Females $<50 \text{ mg/dL}$

Treatment of obesity by decreasing caloric intake and increasing metabolic rate (exercise) directed toward a long-term decrease in body weight is largely ineffective, unless coupled with an intensive

counseling program.¹³ Proteins and carbohydrates can be metabolically converted to fat, and there is no evidence that changing the relative proportions of protein, carbohydrate, and fat in the diet without decreasing caloric intake will promote weight loss. However, fat has a higher caloric density than protein and carbohydrate, and its contribution to the palatability of foods promotes its ingestion and increases the intake of calories.

Pharmacologic Treatment

A number of U.S. Food and Drug Administration–approved drugs are available for treating obesity, all with varying efficacy and side effects. Phentermine, a sympathomimetic amine, is an appetite suppressant that is used for short-term (a few weeks) therapy intended to induce weight loss. Only a fraction of a pound per week is lost, and its use is associated with an increase in systemic blood pressure, heart rate, and anxiety.¹⁴ It is the most commonly prescribed weight loss drug in the United States. In the past, this drug was frequently used in combination with fenfluramine (the latter induces the development of valvular heart disease, similar to that seen with carcinoid syndrome and has been removed from the market.). It has been replaced by another combination drug, phentermine and topiramate, which is also somewhat effective. Along with the side effects associated with phentermine, the addition of topiramate may induce dry mouth, paresthesia, constipation, dysgeusia, insomnia, and impaired cognition.¹⁴

Orlistat inhibits lipases in the gastrointestinal lumen, thus antagonizing triglyceride hydrolysis and decreasing fat absorption by about 30%. Because orlistat is not absorbed, its ability to cause weight loss likely reflects the resulting low-fat diet and lower caloric intake. Weight loss with orlistat is modest, a mean of 2.5 to 3.4 kg. Gastrointestinal side effects (abdominal discomfort, flatus, fecal urgency) reflecting the increased fat content in stool are dose limiting and occur in the majority of patients treated with orlistat. Orlistat should not be prescribed for patients with known malabsorptive conditions, and daily multivitamin supplementation is recommended.¹⁴

Lorcaserin is a third drug currently used in the United States, associated with a mean weight loss of 3.1 kg over 1 year compared to a placebo. Lorcaserin is a selective 5-HT_{2C} agonist, which activates proopiomelanocortin production and promotes weight loss through satiety.¹⁴

Antiemetics*

Updated by: Christopher M. Lam • Michael J. Murray

Postoperative nausea and vomiting (PONV) is defined as nausea and/or vomiting occurring within 24 to 48 hours of surgery. Along with pain, PONV is the most important complaint patients report following surgery under anesthesia and is the leading cause of unanticipated hospital admission following outpatient surgery.^{1,2} It is a very common complication; without prophylaxis, nausea occurs in up to 40% of patients who undergo general anesthesia but can be as high as 80% in high-risk patients.¹ There have been hundreds of studies examining ways to prevent PONV and to effectively treat it when it does develop. Anesthesia societies and organizations continue to develop guidelines on how to best address the problem, the most recent by the Society for Ambulatory Surgery in 2016.³ There have been a number of nonpharmacologic methods used to prevent and/or attenuate this disorder,^{4,5} but this chapter focuses on the pharmacologic therapies used as prophylaxis and treatment of PONV.

Definition

Postoperative nausea and vomiting (PONV), recognized by the National Library of Medicine as a single medical subject heading term, actually refers to two distinct entities. Although nausea and emesis are intimately related, a person can have one without the other. Some drugs are more effective in treating one than the other. A patient who experiences nausea or has emesis within 24 to 48 hours of a surgical procedure that required anesthesia meets the criteria for the diagnosis of PONV. The classification is further divided into early PONV (within 24 hours of emergence from anesthesia) or late PONV (24-48 hours, sometimes even up to 72 hours after the procedure), also called postdischarge nausea and vomiting.⁶

Incidence

As mentioned previously, PONV occurs in 30% to 40% of all patients who undergo general anesthesia, but among patients with identified risk factors for developing PONV, it can occur in 70% to 80%. From a patient satisfaction point of view, PONV is a major issue. The Perception of Quality in Anesthesia questionnaire was developed by addressing concerns from 120 patients and community members. Seven hundred and fourteen patients were surveyed, revealing PONV, postoperative pain, and communication with the anesthesia provider being the most important aspect of the patient experience.⁷ Independent of patient perception, PONV has been associated with physical morbidity, including dehydration, electrolyte abnormalities, wound dehiscence, bleeding, esophageal rupture, and airway compromise.⁸

Pathophysiology

Patients with nausea have a subjective feeling of the need to vomit; the sensation is very, very unpleasant. Emesis is not always preceded by nausea. Vomiting typically begins with contractions of the ileum and jejunum, moving their contents back toward the stomach. The glottis is then closed, protecting the airway, and the diaphragm contracts, creating negative intrathoracic pressure as the pharyngeal sphincters relax. At the same time, the abdominal muscles contract, creating increased intra-abdominal pressure that compresses the stomach. Under pressure and with open upper sphincters, emesis occurs. When the stomach is empty, retching or dry heaves occur, which involves the same process happens, but no stomach contents are expelled. Emesis is different from regurgitation in which the sphincters are not completely closed and the stomach contents can pass into the esophagus in the setting of elevated abdominal pressure such as might occur during excessive mask ventilation.

The highly choreographed sequence that occurs during vomiting and retching is controlled by the vomiting center. It consists of the nucleus of the tractus solitarius and parts of the reticular formation in the

medulla oblongata.⁹ A number of neurotransmitters activate and inhibit activity of the vomiting center, including acetylcholine, dopamine, histamine, substance P, and serotonin ([Figure 34.1](#)). Drugs that are used to control nausea and vomiting modulate the activity of these receptors. The chemoreceptor trigger zone (CRTZ) located in the area postrema on the floor of the fourth ventricle is outside the blood–brain barrier. As such, a natural hormone or potentially dangerous substance does not need to cross the blood–brain barrier to be detected by the CRTZ.

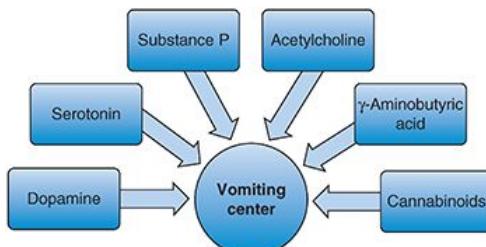

FIGURE 34.1 Pharmacologic systems that interact with the vomiting center.

The vomiting center can be activated by the vestibular apparatus, the thalamus and cerebral cortex, and neurons within the gastrointestinal tract itself. The interaction with the vestibular apparatus could create the common interaction between vertigo and vomiting whereas the cerebral cortex could induce psychogenic vomiting.

Upon activation, the vomiting center sends efferent signals via the cranial nerves V, VII, IX, X, and XII through the vagal parasympathetic fibers and sympathetic chain and to skeletal muscle through α motor neurons.¹⁰ Signals from the vomiting center via these nerves trigger the complex motor process resulting in emesis.

Prophylaxis

Preventing PONV is easier than treating it,¹¹ but the side effects of the antiemetic drugs are such that the American Society of Anesthesiologists has recommended that antiemetic agents should be used for the prevention and treatment of nausea and vomiting when indicated but not routinely. To determine whether prophylaxis is indicated, it is important to assess a patient's propensity to develop PONV according to risk factors that increase or decrease a patient's chances of experiencing PONV. First validated by Apfel et al¹² in 1999, these risk factors are traditionally divided into patient, surgical, and anesthetic risk factors.

Patient Factors

Women, nonsmokers, and those with a history of motion sickness¹³ or of previous episodes of PONV are at an increased risk for experiencing PONV if they undergo a surgical procedure under anesthesia. Women most likely are at increased risk for PONV because of the effects of progesterone and/or estrogen on the CRTZ or on the vomiting center itself, as evidenced by the fact that the incidence of PONV varies within the menstrual cycle and is reduced after menopause.¹⁴ Obese patients, because of exposure to greater amount of emetogenic lipophilic drugs such as the inhalational anesthetic agents stored in their adipose tissue, were once thought to have a higher incidence of PONV, but a subsequent investigation did not show this to be true.³ Other patient factors that have been disproven or hold limited clinical relevance for PONV risk include history of anxiety, history of migraine, perioperative fasting, presence of nasogastric tube, and use of supplemental oxygen.³ Generally, the incidence of PONV decreases per decade in adults, whereas the incidence increases with age in children, with relatively low incidence reported in children younger than 3 years of age.¹⁵

Surgical Factors

The longer the surgical procedure, the greater the risk for a patient to develop PONV, potentially due to prolonged exposure to emetogenic lipophilic drugs.¹⁶ Independent of duration, certain surgical procedures have been associated with an increased incidence of PONV, including laparotomies; gynecologic operations;

laparoscopic procedures; as well as ear, nose, throat, breast, plastic, and orthopedic surgical procedures.¹⁶ In pediatric patients having surgery under general anesthesia, the greatest association is with the surgical procedure itself. Herniorrhaphy, tonsillectomy and adenoidectomy, strabismus procedures, and surgical procedures on male genitalia have the highest risk.¹⁷

Anesthetic Factors

There have been a number of anesthetic-related factors that investigators have assessed for their relationship to the development of PONV. The inhalation anesthetic agents, nitrous oxide, neostigmine, and opioids have all been implicated in the genesis of PONV.¹⁵ However, correlation is limited, and most scoring systems used to identify patients at risk for PONV do not incorporate anesthetic factors, although the duration of anesthetic exposure is associated with the development of PONV.³ Furthermore, although the use of intraoperative opioids does not appear to increase the risk of PONV, postoperative opioids do.¹⁸

Pharmacologic Interventions

A multimodal approach for prophylaxis in patients at high risk for developing PONV and for rescue therapy in patients who develop PONV in the postanesthetic care unit works well because of the complexity of systems involved in the pathogenesis of PONV. The drugs that modulate activity in the vomiting center and CRTZ are listed in **Table 34.1** and discussed in the following sections. Traditionally, there are six categories of medications used to treat PONV (serotonergic antagonists, anticholinergics, antihistamines, corticosteroids, dopamine antagonists, and neurokinin-1 antagonists); however, other medications have been successful in comanagement of this condition, including benzodiazepines and cannabinoids.

TABLE 34.1
Pharmacologic therapies for treatment of nausea and vomiting

5-HT ₃ antagonists	Dolasetron Granisetron Ondansetron Palonosetron Ramosetron Tropisetron
Anticholinergics	Atropine Hyoscine Scopolamine
Antihistamines	Dimenhydrinate Diphenhydramine Meclizine Promethazine
Benzodiazepines	Midazolam
Cannabinoids	Dronabinol Nabilone
Corticosteroids	Dexamethasone
Dopamine (D ₂) antagonists	Amisulpride Chlorpromazine Droperidol Haloperidol Metoclopramide Prochlorperazine
Neurokinin-1 antagonists	Aprepitant Fosaprepitant

5-HT₃ Receptor Antagonists

The 5-HT₃ receptors are excitatory ligand-gated nonselective cation channels. The ion channel is a pentamer consisting of five subunits, each with four transmembrane segments that form a central pore, which can be readily permeated by small cations.¹⁹ The 5-HT₃ receptors are extensively distributed on neurons in the gastrointestinal tract and in the brain. Serotonin is released from the enterochromaffin cells of the small intestine, stimulates the vagal afferents through 5-HT₃ receptors, and initiates the vomiting reflex. The highest density of 5-HT₃ receptors in the brain is found in the area postrema, the site of the CRTZ.¹⁹ Antagonists of these receptors have antiemetic effects. Clinically used 5-HT₃ receptor antagonists are selective for these receptors with almost no significant binding with other 5-HT receptor subtypes.

Clinical Uses

The 5-HT₃ receptor antagonists (ondansetron, tropisetron, granisetron, dolasetron) represent a significant advance in the prophylaxis and treatment of nausea and vomiting are useful antiemetics in the prophylaxis and treatment of chemotherapy (CINV) and radiation therapy-induced nausea and vomiting²⁰ and are equally effective in the prevention and treatment of PONV. The 5-HT₃ receptor antagonists, however, are not effective in the treatment of nausea and vomiting caused by vestibular stimulation (see the following text). The convenience of use, efficacy, and safety profile account for the popularity of 5-HT₃ receptor antagonists for management of PONV.

Comparison With Other Antiemetics

Ondansetron (4 mg), dexamethasone (4 mg), or droperidol (1.25 mg) administered intravenously (IV) as prophylactic therapy before induction of general anesthesia are equally effective in decreasing the incidence of PONV by about 26%.¹⁸ However, a cost–benefit analysis did not support the use of 5-HT₃ receptor antagonists for routine antiemetic prophylaxis when studied in the early 2000s,²¹ but now that some 5-HT₃ antagonists are available as lower-cost generic preparations, they are deemed the “gold standard” for antiemetics.³

Pharmacokinetics

The 5-HT₃ receptor antagonists are readily absorbed after oral administration and readily cross the blood–brain barrier. Following IV administration, the maximum brain concentration is achieved quickly. These antagonists are moderately bound to protein (60%–75%). Metabolism is by different subtypes of cytochrome P450 enzymes, and the metabolites undergo principally renal excretion. The bioavailability of ondansetron, granisetron, and dolasetron range from 56% to 77% with the t_{1/2} between 3.5 and 7.3 hours. Given the similar safety and therapeutic profiles of these drugs, their pharmacokinetics do not play a role in the selection of 5-HT₃ antagonists when not combined with other antiemetics.²²

Ondansetron

Ondansetron is a carbazalone derivative that is structurally related to serotonin and possesses specific 5-HT₃ subtype receptor antagonist properties without altering dopamine, histamine, adrenergic, or cholinergic receptor activity.²³ As a result, ondansetron is free of neurologic side effects common to droperidol and metoclopramide.²³ Ondansetron is effective when administered orally or IV and has an oral bioavailability of about 60% with therapeutic blood concentrations appearing 30 to 60 minutes after administration. Like other 5-HT₃ antagonists described in the following text, metabolism to inactive metabolites occurs predominantly in the liver, and the elimination half-time is 3 to 4 hours. The most commonly reported side effects from treatment with ondansetron are headache and diarrhea. Transient increases in the plasma concentrations of liver transaminase enzymes have been observed only in patients receiving chemotherapy and may be due to these drugs rather than ondansetron. Cardiac arrhythmias and conduction disturbances (atrioventricular block) have been reported after the IV coadministration of ondansetron and metoclopramide.²⁴ Ondansetron

and other 5-HT₃ receptor antagonists can cause slight prolongation of the QTc interval on the electrocardiogram of treated patients, but this has not created the same level of concern as that ascribed to droperidol for unclear reasons.

It is estimated that for every 100 patients who receive ondansetron for the prevention of PONV, 20 patients will not vomit who would have vomited without treatment (“number needed to treat”), and 3 of those 100 patients will develop a headache who would have not had this adverse effect without the drug (“number needed to harm”).²⁵ Ondansetron, 4 to 8 mg IV (administered over 2-5 minutes immediately before the induction of anesthesia), is highly effective in decreasing the incidence of PONV in a susceptible patient population (ambulatory gynecologic surgery, middle ear surgery). Oral (0.15 mg/kg) or IV (0.05-0.15 mg/kg) administration of ondansetron is effective in decreasing the incidence of postoperative vomiting in preadolescent children undergoing ambulatory surgery, including tonsillectomy and strabismus surgery.

Ondansetron, although highly effective in decreasing the incidence and intensity of PONV, does not totally eliminate this complication. The most significant feature of ondansetron prophylaxis and treatment is the relative freedom from side effects as compared with other described classes of antiemetic drugs. Use of propofol for induction and maintenance of anesthesia is almost as effective as ondansetron in preventing PONV (19% vs 26%, respectively), and ondansetron continues to have antiemetic effects when used in a propofol-based anesthetic.¹⁸

Tropisetron

Tropisetron is an indoleacetic acid ester of tropine that possesses highly selective 5-HT₃ receptor blocking effects. Compared with ondansetron, tropisetron has the benefit of a longer elimination half-time (7.3 vs 3.5 hours). Overall, the beneficial effects and side effects of tropisetron resemble those of ondansetron.²⁰ This drug is also effective in the treatment of symptoms related to carcinoid syndrome and may also possess gastrokinetic properties. As an antiemetic, tropisetron is effective in prevention of chemotherapy- and radiotherapy-induced emesis and in the prevention of PONV when administered (2-5 mg IV) before the induction of general anesthesia.²⁰ Rescue treatment using a single dose of tropisetron is often effective in decreasing further nausea and vomiting. Tropisetron did not prevent PONV associated with epidural morphine, whereas dexamethasone (5 mg IV) was effective.²⁰ However, tropisetron is not approved for use in the United States.³

Granisetron

Granisetron is a more selective 5-HT₃ receptor antagonist than ondansetron. Like ondansetron, granisetron is effective when administered orally and IV. Doses as low as 0.02 to 0.04 mg/kg IV have been described as effective in prevention of emesis and prevention of PONV.²⁶ Concomitant administration of dexamethasone significantly improved the acute antiemetic efficacy of granisetron.²⁷ Metabolism to inactive metabolites occurs in the liver with only about 10% of the drug excreted unchanged by the kidneys. The elimination half-time of granisetron (9 hours) is 2.5 times longer than that of ondansetron and thus may require less frequent dosing. For example, a single dose of granisetron may be effective for 24 hours. The longer duration of action is particularly beneficial in outpatient surgery where nausea and vomiting commonly occur on the way home. Side effects are mild and include headache, sedation, and diarrhea.

Dolasetron

Dolasetron is a highly potent and selective 5-HT₃ receptor antagonist that is effective in the prevention of CINV and PONV following either oral or IV administration. Dolasetron is a prodrug. After its administration, dolasetron is rapidly metabolized to hydrodolasetron, which is responsible for the antiemetic effect.²⁸ Hydrodolasetron has an elimination half-time of approximately 8 hours and is approximately 100 times more potent as a serotonin antagonist than the parent compound.

A single IV dose of dolasetron, 1.8 mg, is equivalent to ondansetron, 32 mg IV, and granisetron, 3 mg IV, in preventing CINV. Established PONV is effectively blunted by treatment with dolasetron, 12.5 mg IV.²⁶ Oral dolasetron, 25 to 50 mg, is effective as prophylaxis for decreasing PONV. Although serotonergic

pathways are involved in the development of postoperative shivering, dolasetron was not effective in preventing this complication.²⁹ Common side effects include headache, dizziness, and increased appetite. It is unclear if an increased heart rate attributed to dolasetron is different from the incidence observed in placebo-treated patients.²⁶ In 2010, the U.S. Food and Drug Administration (FDA) advised against use of IV dolasetron for CINV due to concerns for QT prolongation and torsades de pointes; however, it can still be used for PONV treatment due to lower doses used.³⁰

Anticholinergics

Muscarinic acetylcholine receptors are found in the vestibular system near the CRTZ. Activation of this receptor results in activation of the CRTZ resulting in nausea. Anticholinergics prevent this pathway resulting in its antiemetic effects.³¹ One of the most commonly used perioperative anticholinergic antiemetic is scopolamine.

Scopolamine

Prevention of Motion-Induced Nausea and of PONV

Transdermal absorption of scopolamine provides sustained therapeutic plasma concentrations, which protect against motion-induced nausea usually without introducing prohibitive side effects such as sedation, cycloplegia, or drying of secretions. For example, a postauricular application of scopolamine delivers the drug at about 5 µg per hour for 72 hours (total absorbed dose is <0.5 mg). Once the patch is removed, the half-life is 9 hours.²⁶ Protection against motion-induced nausea is greatest if the transdermal application of scopolamine is initiated at least 4 hours before the noxious stimulus. Administration of transdermal scopolamine (TDS) after the onset of symptoms is less effective than prophylactic administration. Similar protection against motion-induced nausea by oral or IV administration of scopolamine would require large doses, resulting in undesirable side effects and subsequent poor patient acceptance.

Application of a TDS patch has been shown to exert significant antiemetic effects in patients experiencing motion sickness and in those treated with patient-controlled analgesia or epidural morphine for the management of postoperative pain.³² It is well known that motion sickness is caused by stimulation of the vestibular apparatus. It has also been shown that morphine and synthetic opioids increase vestibular sensitivity to motion.³³ It is presumed that scopolamine blocks transmission to the medulla of impulses arising from overstimulation of the vestibular apparatus of the inner ear. Indeed, application of a TDS patch before the induction of anesthesia protects against nausea and vomiting after middle ear surgery, which is likely due to altered function of the vestibular apparatus.³² Furthermore, prophylactic TDS applied the evening before surgery decreases but does not abolish the occurrence of nausea and vomiting after outpatient laparoscopy using general anesthesia.³² Conversely, not all reports describe an antiemetic effect in patients treated with TDS who are undergoing general anesthesia.³⁴ Apfel et al³² performed a meta-analysis of 25 studies of TDS used to treat PONV and found that TDS was associated with significant reductions in PONV with both early and late application during the first 24 hours after the start of anesthesia. The TDS was associated with a higher prevalence of visual disturbances at 24 to 48 hours after surgery, but no other adverse events were noted.³² Some of the visual disturbances may be due to anisocoria, which has been attributed to contamination of the eye after digital manipulation of the TDS patch.²⁶ More than 90% of unilateral dilated pupils occur on the same side as the patch. This diagnosis is confirmed by history and failure of the mydriasis to respond to topical installation of pilocarpine.

Central Anticholinergic Syndrome

Scopolamine and atropine can enter the central nervous system (CNS) and produce symptoms characterized as the central anticholinergic syndrome. Symptoms range from restlessness and hallucinations to somnolence and unconsciousness. Presumably, these responses reflect blockade of muscarinic cholinergic receptors and competitive inhibition of the effects of acetylcholine in the CNS.³⁵ Glycopyrrolate does not easily cross the blood-brain barrier and thus is not likely to cause central anticholinergic syndrome.

Central anticholinergic syndrome has been attributed to the IV administration of anticholinergic drugs before the induction of anesthesia.³⁵ Physostigmine, a lipid-soluble tertiary amine anticholinesterase drug administered in doses of 15 to 60 µg/kg IV, is a specific treatment for the central anticholinergic syndrome. Treatment may need to be repeated every 1 to 2 hours. Edrophonium, neostigmine, and pyridostigmine are not effective antidotes because their quaternary ammonium structure prevents these drugs from easily entering the CNS. The central anticholinergic syndrome is often mistaken for delayed recovery from anesthesia. Ventilation may be depressed. Differentiation of this syndrome from other causes of perioperative confusion is possible with slow IV administration of physostigmine, 0.4 mg/kg.³⁶

Overdose

Deliberate or accidental overdose with an anticholinergic drug produces a rapid onset of symptoms characteristic of muscarinic cholinergic receptor blockade. The mouth becomes dry, swallowing and talking are difficult, vision is blurred, photophobia is present, and tachycardia is prominent. The skin is dry and flushed, and a rash may appear, especially over the face, neck, and upper chest (blush area).³⁷ Even therapeutic doses of anticholinergic drugs sometimes may selectively dilate cutaneous vessels in the blush area. Body temperature is likely to be increased by anticholinergic drugs, especially when the environmental temperature is also increased. This increase in body temperature largely reflects inhibition of sweating by anticholinergic drugs, emphasizing that innervation of sweat glands is by sympathetic nervous system nerves that release acetylcholine as the neurotransmitter.³⁷ Small children are particularly vulnerable to drug-induced increases in body temperature, with “atropine fever” occurring occasionally in this age group after administration of even a therapeutic dose of anticholinergic drug. Minute ventilation may be slightly increased due to CNS stimulation and the impact of an increased physiologic dead space due to bronchodilation. Arterial blood gases are usually unchanged. Fatal events due to an overdose of an anticholinergic drug include seizures, coma, and medullary ventilatory center paralysis.

Small children and infants seem particularly vulnerable to developing life-threatening symptoms after an overdose with an anticholinergic drug. Physostigmine, administered in doses of 15 to 60 µg/kg IV, is the specific treatment for reversal of symptoms.³⁸ Because physostigmine is metabolized rapidly, repeated doses of this anticholinesterase drug may be necessary to prevent the recurrence of symptoms.

Decreased Barrier Pressure

Barrier pressure is the difference between gastric pressure and lower esophageal sphincter pressure. Administration of atropine, 0.6 mg IV, or glycopyrrolate, 0.2 to 0.3 mg IV, decreases lower esophageal sphincter pressure and thus decreases barrier pressure and the inherent resistance to reflux of acidic fluid into the esophagus.³⁹ This effect may persist longer with glycopyrrolate (60 minutes) than after administration of atropine (40 minutes).

Histamine Receptor Antagonists

The effects of histamine are mediated via histaminergic receptors, and at least three histamine receptors subtypes have been identified and classified as H₁, H₂, and H₃.⁴⁰ Histamine acting through H₁ receptors and inositol phospholipid hydrolysis evokes smooth muscle contraction in the gastrointestinal tract. In the CNS, histamine receptors are present in the area postrema and vomiting center of the vestibular nucleus along with the nucleus tractus solitarius.^{26,41} As such, antihistamines have long been used for treatment and prevention of motion sickness.⁴² Nonspecific antihistamines, likely acting on H₁ receptors including diphenhydramine, dimenhydrinate, cyclizine, and promethazine, are used as antiemetics. It is important to note that many H₁ receptor antagonists have anticholinergic effects as well, concomitantly blocking muscarinic receptors in the vestibular system.^{26,41} The antiemetic properties may partially be attributed to this mechanism. Some H₂ receptor antagonists have been used for antiemetic effects with mixed results.²⁶

Dimenhydrinate has been used to treat PONV as well as motion sickness. It is speculated that the efficacy of dimenhydrinate in motion sickness and inner ear diseases may be due to inhibition of the integrative functioning of the vestibular nuclei by decreasing vestibular and visual input. Manipulation of the

extraocular muscles as in strabismus surgery may trigger an “oculo-emetic” reflex similar to the well-described oculocardiac reflex. If the afferent arc of this reflex is also dependent on the integrity of the vestibular nuclei apparatus, then dimenhydrinate may attenuate or block this reflex and decrease the incidence of PONV. Administration of dimenhydrinate, 1 mg/kg IV, in adults decreases vomiting after outpatient surgery.³ In children, antihistamines significantly decreases the incidence of vomiting after ophthalmologic surgery but not adenotonsillectomy.⁴³

Diphenhydramine is another commonly used antihistamine for PONV management. It is available in PO and IV administration (25–50 mg per dose via either route). Most antihistamines are extensively metabolized by the hepatic CYP system.²⁶ Patients with increased levels of hepatic CYP3A4 and CYP2D6 may have alterations in metabolic activity resulting in variances in therapeutic effect in patients when given antihistamines.²⁶ The most common side effects from antihistamines are associated to their anticholinergic effects including dry mouth and somnolence.

Corticosteroids

Dexamethasone has been shown to be useful in the management of PONV, but the mechanism of antiemetic activity is unclear. Corticosteroids are proposed to centrally inhibit prostaglandin synthesis and control endorphin release. It has also been theorized that the antiinflammatory effect of steroids along with the resultant decrease in arachidonic acid release plays a role.⁴⁴ As discussed already, dexamethasone has efficacy similar to ondansetron and droperidol¹⁸ and with a minimal side effect profile associated with one-time use. Obese and diabetic patients are at increased risk for perioperative hyperglycemia when they receive a single dose of dexamethasone.

Dopamine Receptor Antagonists

Along with serotonin and histamine, dopamine has a role in modulating the sensation of nausea in the CRTZ.⁴⁵ In total, there are five subtypes of the dopamine receptor, and the D₂ subtype is found in the CRTZ.⁴⁶ Among one of the four categories of antiemetics first used, dopamine D₂ antagonists were found from derivatives of phenothiazines. Domperidone was first identified in 1974 as a D₂ antagonist with inability to cross the blood–brain barrier with less chance to evoke extrapyramidal side effects, allowing for safer utilization as an antiemetic. Later, other commonly utilized antiemetics such as benzamides and butyrophenones were found to have D₂ antagonistic properties as well.⁴⁵ Here, we discuss these medications as they relate to their antidopaminergic properties.

Benzamides

Metoclopramide

The benzamides, aside from their antidopaminergic effects, stimulate the gastrointestinal tract via cholinergic mechanism, which results in (1) contraction of the lower esophageal sphincter and gastric fundus, (2) increased gastric and small intestinal motility, and (3) decreased muscle activity in the pylorus and duodenum when the stomach contracts. Metoclopramide and domperidone are the two benzamides currently in use, but domperidone is not available in the United States because the FDA was concerned about its use in lactating women (increases milk production), although the risk for prolonged QTc intervals risk was low for domperidone.^{47,48}

This review therefore focuses on metoclopramide, which presumably has either a peripheral effect as just described or because it readily crosses the blood–brain barrier may have direct effects on the CRTZ and/or vomiting center because of its antidopaminergic effect.

A meta-analysis of 30 trials evaluating 10 mg of systemic metoclopramide on PONV outcomes concluded that, compared to placebo, the incidence of 24-hour PONV was reduced with metoclopramide with an odds ratio of 0.58 and a 95% confidence interval of 0.43 to 0.78. The number needed to treat was 7.8.⁴⁹

Because of its antidopaminergic activity, metoclopramide should be used with caution if at all in patients with Parkinson disease, with restless legs syndrome, or who have movement disorders related to dopamine

inhibition or depletion.⁵⁰ In patients with no known movement disorders, dystonic extrapyramidal reactions (oculogyric crisis, opisthotonus, trismus, torticollis) occur in less than 1% of patients treated chronically with metoclopramide. Although usually a problem if large oral doses (40-80 mg daily) are administered chronically, there are reports of neurologic dysfunction related to the preoperative administration of metoclopramide.⁵¹ These extrapyramidal reactions are identical to the parkinsonism evoked by antipsychotic drugs that antagonize the CNS actions of dopamine.⁵² Akathisia, a feeling of unease and restlessness may follow the IV administration of metoclopramide, sometimes so severe that it can result in cancellation of surgery⁵³ or which may manifest in the postanesthesia care unit.⁵⁴

Butyrophенones

Butyrophenones are members of the first-generation antipsychotics that exercise their activity via antagonism of the dopamine receptor.⁵⁵ Aside from antidopaminergic effects, these medications also have antinoradrenergic, anticholinergic, and antihistaminergic activity.

Droperidol and Haloperidol

After the FDA placed boxed warnings on droperidol due to its association with prolonged QT syndromes, many physicians stopped using droperidol.⁵⁶ However, the FDA's warning on droperidol was based on case reports in which higher doses were used, higher than are necessary for the treatment of PONV. Because of its efficacy at low dose, the use of droperidol has increased over the last several years for prophylaxis and as rescue therapy as an antiemetic.⁵⁷ Prophylactic doses of droperidol of 0.625 to 1.25 mg IV are effective for the prevention and treatment of PONV. For patients in whom dopamine antagonism is not a concern, droperidol is as effective as dexamethasone or ondansetron in preventing and treating PONV.¹⁸

Haloperidol also has antiemetic properties when used in low doses, 0.5 to 2 mg IV. At these doses, sedation does not occur.

Phenothiazines

Phenothiazines are another group of medications with antidopaminergic activity used for their antiemetic effects. It is also another member of first-generation antipsychotics similar to the butyrophenones with antidopaminergic, antiadrenergic, and antihistaminergic activity.^{45,58} The most commonly used medication in this class is chlorpromazine with typical therapeutic dosing at 10 to 25 mg orally or 25 to 50 mg intramuscularly/IV.⁵⁹ Similar to the butyrophenones, side effects from phenothiazines include dry mouth, sedation, QTc prolongation, and extrapyramidal symptoms. However, phenothiazines may also cause agranulocytosis and orthostatic hypotension; thus, care should be exercised when providing this medication to patients as an antiemetic.⁵⁸

Amisulpride

Amisulpride is a selective D₂ and D₃ dopaminergic antagonist originally used as a second-generation antipsychotic for the management of schizophrenia.⁶⁰ Because of its antidopaminergic activity and safety profile, it was investigated for use as an antiemetic. A double-blind randomized control trial comparing amisulpride to placebo found that it was superior to placebo for management of PONV with no increased risk of QTc prolongation or extrapyramidal side effects.⁶¹ Zhang et al⁶² performed a meta-analysis resulting in five identified studies evaluating amisulpride's ability to prevent and treat PONV. The findings showed that low-dose amisulpride was safe and efficacious for prevention and treatment of PONV compared to placebo.⁶² Amisulpride was approved by the FDA in February 2020 for use in PONV management with the potential adverse effects of QTc prolongation, increased prolactin levels, hypokalemia, hypotension, abdominal distention, and infusion site pain.⁶³ The recommended dosage for prevention of PONV is 5 mg IV over 1 to 2 minutes at the time of induction of anesthesia, whereas the treatment dosage for PONV was 10 mg over 1 to 2 minutes.⁶⁴

Neurokinin-1 Antagonists

Neurokinin-1 is a centrally and peripherally expressed G-protein–coupled receptor whose primary ligand is substance P. The expression of neurokinin-1 in the brainstem is theorized to have a role in the vomiting reflex through the nucleus tractus solitarius and area postrema.⁶⁵ Neurokinin-1 antagonists are increasingly used for CINV as chemotherapeutic drugs induce substance P release resulting in acute and delayed nausea, which are both attenuated by these medications.⁶⁶ Their effectiveness in CINV patients led to their use in the perioperative management of PONV. Aprepitant and its prodrug fosaprepitant are the only FDA-approved neurokinin-1 antagonists.⁶⁵ Aprepitant is available only as an oral capsule with dosing of 40 mg within 3 hours of induction of anesthesia for prevention of PONV.⁶⁵ The expense of aprepitant has resulted in recommendations that it only be given to patients at high risk for PONV or in patients for whom vomiting would compromise the surgical repair.³ Common side effects of aprepitant include headache, fatigue, and constipation, with less common side effects including mucous inflammation, neutropenia, and fever. It is generally well tolerated at doses 40 mg or less. Because of aprepitant's effect on the P450 CYP3A4 enzyme, one should be cautious when administering this medication to patients who are concomitantly taking medications metabolized by this enzyme.⁶⁵

Midazolam

The activity of the benzodiazepines is relatively well known, but with respect to a possible mechanism of action in PONV, benzodiazepines may decrease synthesis and release of dopamine within the CRTZ.⁶⁷ Perioperative administration of midazolam may reduce PONV by 38% to 55%; administration of 2 mg of midazolam IV 30 minutes prior to the end of surgery may be as effective as 4 mg of ondansetron for the treatment of PONV.⁶⁸ A meta-analysis by Ahn et al⁶⁹ of 16 studies confirmed the effectiveness of midazolam for management of PONV.

Cannabinoids

Much like the neurokinin antagonists, cannabinoids have been found to be a useful adjunct in treating CINV.⁷⁰ The mechanism of their action is thought to be mediated by the binding of cannabinoid receptor type 1 peripherally (suppressing intestinal motility) and centrally in the nucleus of the solitary tract.²⁶ Currently, the orally available cannabinoids are nabilone (a synthetic analogue of Δ-9-tetrahydrocannabinol) and dronabinol (synthetic Δ-9-tetrahydrocannabinol).²⁶ Despite their success in treating CINV, cannabinoids are ineffective for managing PONV.³

Summary

PONV presents a significant and prevalent condition for patients in the perioperative setting. Because of the physiologic consequences and increased risks of comorbidities with burden to the health care system of PONV, measures to mitigate and treat this condition should be initiated when possible. Currently, six classifications of medications are used to treat this condition. Weighing patient comorbidities and factors, will allow for careful selection of an appropriate agents.

Antacids and Gastrointestinal Motility Drugs*

Updated by: Michael J. Murray

Aspiration is the inhalation of gastric or oropharyngeal contents into the lungs. Aspiration during general anesthesia occurs in approximately 1 in 8,500 adults and 1 in 4,400 children younger than 16 years of age.¹ A study of 102,425 pediatric cases published in 2016 identified 22 patients who had an anesthetic and who aspirated, an incidence of 0.02% (1 in 4,655), similar to what had been reported 10 years earlier.² Most of the patients were American Society of Anesthesiologists (ASA) 1 and 2 with no history of previous aspiration, which makes identifying patients at risk difficult. As in previous studies, aspiration was unexpected and occurred more commonly in ASA 1E and 2E patients during induction of anesthesia. A systematic review of 35 articles reporting on aspiration during sedation (conscious or monitored anesthesia care) for procedures found few cases except during gastrointestinal endoscopy, with full recovery typical. Of those that occurred outside of gastrointestinal endoscopy suites, most were benign.³ However, there were eight deaths in the 292 patients who aspirated during gastrointestinal endoscopy, a mortality rate of 2.7%. An examination of the records of 60,770 patients who underwent upper gastrointestinal endoscopies identified 28 cases (1 in 2,170) who aspirated. Those who aspirated were more likely to be admitted to an intensive care unit, had longer hospital lengths of stay, and had a higher mortality rate (0% vs 7%; $P = .004$).⁴

Factors associated with pulmonary complications of aspiration include the volume and acidity of the aspirated gastric contents. Drugs that increase the pH of gastric contents (antacids) and that decrease the volume of gastric contents (prokinetic drugs) have a role in decreasing the severity of the sequelae of aspirating gastric contents. Enforcement of the recently updated ASA Task Force fasting recommendations may also reduce the risk of pulmonary aspiration.⁵

Oral Antacids

Antacids are drugs that neutralize hydrogen ions from gastric contents or decrease the secretion of hydrogen chloride into the stomach. Oral antacids have been used for centuries. In current practice, the oral antacids used most often are salts of magnesium, calcium, and aluminum; the hydrogen ions in stomach acid react with the base, forming a stable compound. As hydrogen ions are consumed, the pH of the stomach contents increases. The best known example would be sodium bicarbonate, which, in the stomach, combines with hydrochloric acid (HCl) to produce sodium chloride (NaCl), water (H₂O), and carbon dioxide (CO₂).

Increasing gastric pH relieves the symptoms of gastritis, but if the pH of the stomach is too high, digestion of food is inhibited as an acidic pH is necessary for the breakdown of many foods. In addition, increases in gastric fluid pH to >5 result in inactivation of pepsin and produce bile-chelating effects. Neutralization of gastric fluid pH increases gastric motility via the action of gastrin (aluminum hydroxide is an exception) and increases lower esophageal sphincter tone by a mechanism that is independent of gastrin.

Sodium bicarbonate results in a prompt and rapid antacid action, so much so that the pH is raised to the point that the stomach's pH is neutral, which can lead to acid rebound. Recently published data show that reducing hydrogen ion concentration in the stomach affects acid-base balance in such a way that it increases the performance of trained cyclists⁶ and enhances the recovery of elite boxers after a strenuous workout.⁷ Patients with hypertension or heart disease, though, may not tolerate the increased sodium load associated with chronic use of this antacid.

Magnesium hydroxide (or magnesium oxide, which in an aqueous medium as found in the stomach promptly forms magnesium oxide) also produces prompt neutralization of gastric acid but is not associated with significant acid rebound. A prominent laxative effect (osmotic diarrhea) is characteristic of magnesium hydroxide. Approximately, 15% of the magnesium is absorbed,⁸ enough that some clinicians prescribe it to

treat hypomagnesemia, but also enough, depending on the oral dose, to cause neurologic, neuromuscular, and cardiovascular impairment in patients with renal dysfunction. Long-term use of magnesium-containing antacids is associated with hip fractures in older patients.⁹

Calcium carbonate, CaCO₃, is also used as an antacid.

The plasma concentration of calcium is increased transiently. Symptomatic hypercalcemia may occur in patients with renal disease. The administration of calcium carbonate-containing antacids may result in hypophosphatemia. Even small amounts of calcium carbonate-containing antacids evoke hypersecretion of hydrogen ions (acid rebound). The chalky taste of calcium carbonate is an additional disadvantage. The release of CO₂ in the stomach may cause eructation and flatulence. Constipation is minimized by including magnesium oxide with calcium carbonate.

Aluminum hydroxide [Al(OH)₃] in the stomach dissociates into aluminum (Al₃) and OH⁻, which then binds to hydrogen (H⁺) to produce H₂O, and the Al³⁺ binds to anions, primarily Cl⁻, to form insoluble salts. Less than 1% of the available aluminum is absorbed and then excreted by the kidneys; in patients with renal disease, the plasma and tissue concentrations of Al³⁺ may become excessive. Side effects of Al(OH)₃ include hypomagnesemia, hypophosphatemia, anemia, and constipation.¹⁰ Seizures and encephalopathy in patients undergoing hemodialysis have been attributed to intoxication with aluminum. A number of neurodegenerative diseases are associated with the administration of Al(OH)₃.¹¹ Aluminum compounds, in contrast to other antacids, cause slowing of gastric emptying and marked constipation and, therefore, are occasionally prescribed for patients with chronic diarrhea for its constipating effect; however, hypophosphatemia may result.

Occasional failure of particulate antacids to increase gastric fluid pH may reflect inadequate mixing with stomach contents or an unusually large volume of gastric fluid such that the standard dose of antacid is inadequate to neutralize gastric H⁺ ions. Layering is also common with particulate antacids.

Sodium citrate (Na₃C₆H₅O₇) is a nonparticulate antacid.

There are no prospective studies that demonstrate that oral antacids decrease the risk of aspiration pneumonitis in patients having an anesthetic, but it is common practice to administer sodium citrate to pregnant patients and to nonpregnant patients who are at risk for aspirating and are undergoing an anesthetic.¹² Sodium citrate is preferred over other oral antacids because it is less likely to cause a foreign body reaction if aspirated and its mixing with gastric fluid is more complete and more rapid than is that of particulate antacids. Sodium citrate, 15 to 30 mL of a 0.3-mol/L solution administered 15 to 30 minutes before the induction of anesthesia, is effective in reliably increasing gastric fluid pH in pregnant¹³ and nonpregnant patients.

Complications of Antacid Therapy

The increase in gastric volume and in pH resulting from antacid use has been associated with adverse events. Chronic alkalinization of gastric fluid has been associated with bacterial overgrowth in the duodenum and small intestine.¹⁴ The use of antacids also can result in metabolic alkalosis,¹⁵ which in turn can lead to alkalinization of the urine, predisposing patients to urinary tract infections; if it is chronic, urolithiasis is possible. Increased urine pH may persist >24 hours after administration of an antacid, leading to changes in the renal elimination of drugs.

Acid rebound is a side effect that is unique to calcium-containing antacids. This response is characterized by a marked increase in gastric acid secretion that takes place several hours after neutralization of gastric acid. It is unclear if acid rebound persists with chronic calcium carbonate treatment.

The milk-alkali syndrome is characterized by hypercalcemia, increased blood urea nitrogen and plasma creatinine concentrations, and systemic alkalosis, as reflected by an above-normal plasma pH. The plasma calcium-phosphate concentration is usually increased and renal function, with calcification of the parenchyma, may be markedly decreased.¹⁶ This syndrome is most commonly associated with ingestion of large amounts of calcium carbonate along with >1 L of milk every day.¹⁵

Phosphorus depletion can occur in patients who ingest large doses of aluminum salts because, although chloride is the anion most commonly bound by Al³⁺, the aluminum cation will also bind phosphate or any other anion, depending on the concentration of the various anions in the stomach. This effect may actually be beneficial in patients with renal disease because it can decrease the plasma phosphate concentration, but, unfortunately, patients with chronic renal failure are at risk for developing toxicity from the aluminum. Individuals with hypophosphatemia may experience anorexia, skeletal muscle weakness, and malaise. Osteomalacia, osteoporosis, and fractures may occur. If it is necessary to administer aluminum-containing antacids on a chronic basis to patients with osteomalacia or osteoporosis, phosphate supplements should be considered.

Drug Interactions

Gastric alkalinization increases gastric emptying, resulting in a faster delivery of drugs into the small intestine. This may facilitate absorption of drugs that are poorly absorbed or it may shorten the time available for absorption, depending on where in the gastrointestinal tract absorption occurs. There are many drugs whose absorption is enhanced by antacids. The rate of absorption of salicylates, indomethacin, and naproxen is increased when gastric fluid pH is increased. Conversely, absorption of drugs that are weak bases, for example, ketoconazole, itraconazole, dipyridamole, and enoxacin, is decreased if gastric pH is >5.¹⁷

Aluminum hydroxide accelerates absorption and increases bioavailability of diazepam by an unknown mechanism. Conversely, bioavailability of certain drugs may be decreased because of their capacity to form complexes with antacids. Antacids containing aluminum, and to a lesser extent, calcium or magnesium, interfere with the absorption of tetracyclines and possibly digoxin from the gastrointestinal tract.

Histamine-Receptor Antagonists

Histamine induces contraction of smooth muscles in the airways, increases the secretion of acid in the stomach, and stimulates the release of neurotransmitters in the central nervous system (CNS) through three receptor subtypes: H₁, H₂, H₃. Recently, a fourth histamine receptor, designated as an H₄ receptor, was cloned, which has led to the development of several drugs that inhibit its action.

Depending on what responses to histamine are inhibited, drugs are classified as H₁-, H₂-, H₃-, and H₄-receptor antagonists. Histamine-receptor antagonists bind to receptors on effector cell membranes, to the exclusion of agonist molecules, without themselves activating the receptor. For histamine-receptor antagonists, this is a competitive and reversible interaction. Histamine-receptor antagonists do not inhibit release of histamine but, rather, attach to receptors and prevent responses mediated by histamine.

H₃- and H₄-receptor modulators do not currently play a role in anesthetic practice and as such are not described in detail.

H₁-Receptor Antagonists

H₁-receptor antagonists are characterized as first-generation and second-generation receptor antagonists (**Figure 35.1**). First-generation drugs tend to produce sedation, whereas second-generation drugs are relatively nonsedating (**Table 35.1**). H₁-receptor antagonists are highly selective for H₁ receptors, having little effect on H₂, H₃, or H₄ receptors. First-generation H₁-receptor antagonists may also activate muscarinic, cholinergic, 5-hydroxytryptamine (5-HT serotonin), or α-adrenergic receptors, whereas few of the second-generation antagonists have any of these properties. The selectivity of the second-generation antagonists for H₁ receptors decreases CNS toxicity. An increased understanding of the molecular pharmacologic features of these drugs has resulted in their reclassification as inverse agonists rather than as H₁-receptor antagonists.¹⁸

H_1 -receptor antagonists act as inverse agonists that combine with and stabilize the inactive form of the H_1 receptor, shifting the equilibrium toward the inactive state.

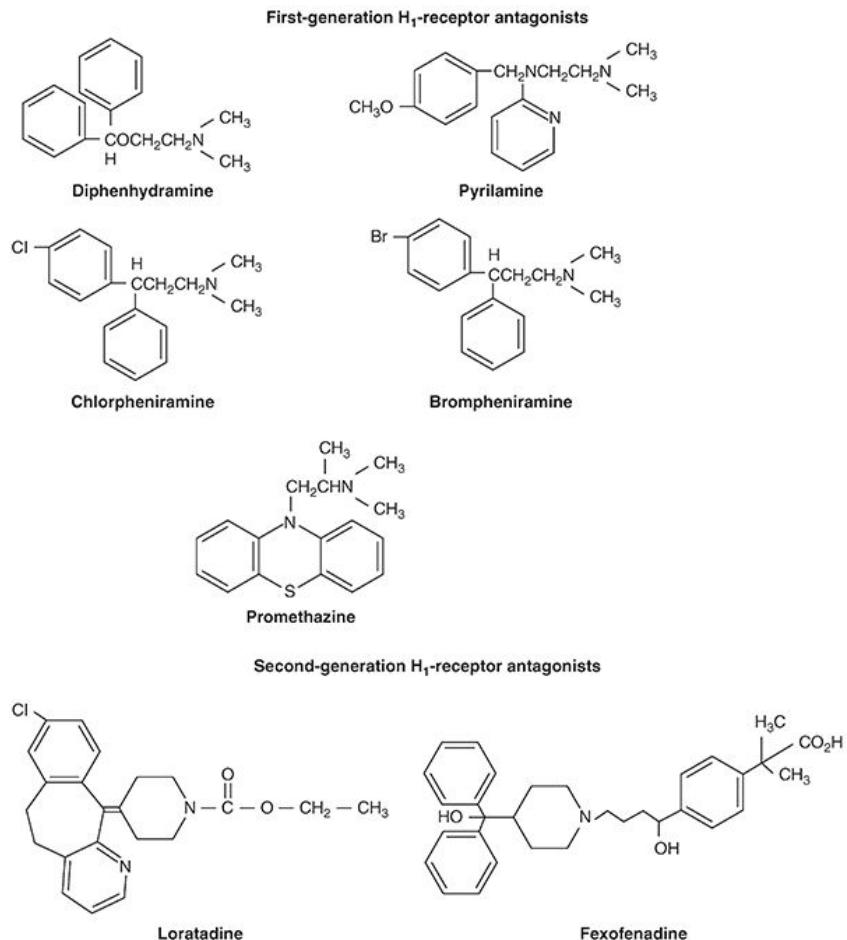

FIGURE 35.1 First- and second-generation H_1 -receptor antagonists.

Azelastine	5.3	22	8.5

^aData from Simons FE, Simons KJ. The pharmacology and use of H_1 -receptor-antagonist drugs. *N Engl J Med.* 1994;330:1663-1670.

Pharmacokinetics

H₁-receptor antagonists are well absorbed after oral administration, often reaching peak plasma concentrations within 2 hours (see [Table 35.1](#)). Many are highly protein bound, with ranges from 78% to 99%. Most of the new H₁-receptor antagonists do not accumulate in tissue to any extent. Interestingly, there is little tachyphylaxis seen with their use.¹⁹ Most H₁-receptor antagonists are metabolized by the hepatic microsomal mixed-function oxidase system. Plasma concentrations are relatively low after a single oral dose, which indicates first-pass hepatic extraction. Values for the elimination half-lives of these drugs are variable. For example, the elimination half-life of chlorpheniramine is >24 hours and that of acrivastine is about 2 hours (see [Table 35.1](#)). Acrivastine is excreted mostly unchanged in urine, as is cetirizine, the active carboxylic metabolite of hydroxyzine.

Clinical Uses

H₁-receptor antagonists are among the most widely used of all medications. H₁-receptor antagonists prevent and relieve the symptoms of allergic rhinoconjunctivitis (sneezing, nasal and ocular itching, rhinorrhea, tearing, and conjunctival erythema),²⁰ but they are less effective for the nasal congestion characteristic of a delayed allergic reaction. In contrast to their role in the treatment of allergic rhinitis, H₁-receptor antagonists provide little benefit in the treatment of upper respiratory tract infections and are of no benefit in the management of otitis media. Depending on the H₁-receptor antagonist selected and its dose, pretreatment may provide some protection against bronchospasm induced by various stimuli (histamine, exercise, cold dry air). Earlier concerns about drying of secretions in patients with asthma have not been substantiated. In patients with chronic urticaria, H₁-receptor antagonists relieve pruritus and decrease the number, size, and duration of urticarial lesions. In some patients with refractory urticaria, concurrent treatment with an H₂-receptor antagonist (cimetidine, ranitidine) may enhance relief of pruritus. In addition to a direct effect on H₂ receptors, which account for 10% to 15% of all histamine receptors in the vasculature, this effect may be due in part to the ability of some H₂-receptor antagonists to inhibit the metabolism of H₁-receptor antagonists by the hepatic cytochrome P450 system, leading to an increased plasma and tissue concentration of H₁-receptor antagonists. The second-generation H₁-receptor antagonists (cetirizine, fexofenadine, loratadine, desloratadine, azelastine) are supplanting first-generation drugs (diphenhydramine, chlorpheniramine, cyproheptadine) in the treatment of allergic rhinoconjunctivitis and chronic urticaria. Their greater cost can be justified because of a more favorable risk-benefit ratio (eg, they have fewer CNS side effects). For example, the first-generation H₁-receptor antagonists have sedating effects that result in delayed reaction times.

Diphenhydramine is prescribed as a sedative, an antipruritic, and an antiemetic. When administered alone, it modestly stimulates ventilation by augmenting the interaction of hypoxic and hypercarbic ventilatory drives. When diphenhydramine is administered in combination with systemic or neuraxial opioids to control nausea and pruritus, there is the conceptual risk of depression of ventilation. However, diphenhydramine counteracts to some extent the opioid-induced decreases in the slope of the ventilatory response to CO₂ and does not exacerbate the opioid-induced depression of the hypoxic ventilatory response during moderate hypercarbia.

The rich distribution of histamine receptors in the myocardium and coronary vasculature predisposes the heart to cardioregulatory changes during massive histamine release that characterizes type 1 immune-mediated hypersensitivity (anaphylactic) reactions. Use of antihistamines in the acute treatment of anaphylactic reactions is directed at blocking further histamine-mediated respiratory sequelae and other systemic complications.

The administration of epinephrine is indicated as first-line therapy for the treatment of anaphylaxis. H₁ and H₂ antihistamines may be helpful in treating cutaneous and upper respiratory signs and symptoms of anaphylaxis and are considered second-line therapies, along with other drugs, including glucocorticoids.¹⁸

Concerns of possible attenuation of H₂-mediated increases in inotropy and chronotropy, thereby limiting potential cardioexcitatory compensatory mechanisms, does not seem to be clinically significant.

Histamine-receptor antagonists may also be administered prophylactically for anaphylactoid reactions to radiocontrast dyes. Second-generation H₁-receptor antagonists such as terfenadine, fexofenadine, and astemizole have low water solubility, and, unlike first-generation drugs, are not available for parenteral use.

Dimenhydrinate is an H₁-receptor antagonist that is the theoclate salt of diphenhydramine.

Dimenhydrinate has been used to treat motion sickness as well as postoperative nausea and vomiting. It is speculated that the efficacy of dimenhydrinate in motion sickness and inner ear diseases may be due to inhibition of the integrative functioning of the vestibular nuclei by decreasing vestibular and visual input. Manipulation of the extraocular muscles as in strabismus surgery may trigger an “oculoemetic” reflex similar to the well-described oculocardiac reflex. If the afferent arc of this reflex is also dependent on the integrity of the vestibular nuclei apparatus, then dimenhydrinate may attenuate or block this reflex and decrease the incidence of postoperative nausea and vomiting. Administration of dimenhydrinate, 20 mg intravenously (IV), to adults decreases vomiting after outpatient surgery. In children, dimenhydrinate, 0.5 mg/kg IV, significantly decreases the incidence of vomiting after strabismus surgery and is not associated with prolonged sedation. Compared with 5-HT antagonists, dimenhydrinate is an inexpensive antiemetic.

Side Effects

First-generation H₁ antagonists often have adverse effects on the CNS, including somnolence, diminished alertness, slowed reaction time, and impairment of cognitive function. Because there is some cross-reactivity with muscarinic receptors, anticholinergic effects such as dry mouth, blurred vision, urinary retention, and impotence may be seen. Tachycardia is common, and prolongation of the QTc interval on the electrocardiogram, heart block, and cardiac arrhythmias have occurred. First-generation H₁-receptor antagonists are still prescribed because they are effective and inexpensive. Administration of these drugs at bedtime is sometimes recommended because drug-related somnolence is of no concern during the night. Indeed, H₁-receptor antagonists may be sold as nonprescription sleeping aids.

Second-generation H₁ antagonists are unlikely to produce CNS side effects such as somnolence unless the recommended doses are exceeded. Enhancement of the effects of diazepam or alcohol is unlikely by second-generation drugs. Fexofenadine, a metabolite of terfenadine, does not prolong the QTc interval on the electrocardiogram, even in large doses. Patients with hepatic dysfunction, cardiac disorders associated with prolongation of the QTc interval, or metabolic disorders such as hypokalemia or hypomagnesemia may be especially prone to adverse cardiovascular effects of H₁-receptor antagonists. Most second-generation H₁-receptor antagonists are not removed by hemodialysis.

Antihistamine intoxication is similar to anticholinergic poisoning and may be associated with seizures and cardiac conduction abnormalities resembling tricyclic antidepressant overdose. Older nonsedating antihistamine drugs (terfenadine, astemizole) were associated with prolongation of the QTc interval and atypical (*torsades de pointes*) ventricular tachycardia, both after overdose and after coadministration with macrolide antibiotics or other drugs that interfere with their elimination. These drugs were removed from the market in 1999.

H₂-Receptor Antagonists

Cimetidine, ranitidine, famotidine, and nizatidine are H₂-receptor antagonists that produce selective and reversible inhibition of H₂ receptor-mediated secretion of hydrogen ions by parietal cells in the stomach ([Figures 35.2](#) and [35.3](#)). The relationship between gastric hypersecretion of fluid containing high concentrations of hydrogen ions and peptic ulcer disease emphasizes the potential value of a drug that selectively blocks this response. Despite the presence of H₂ receptors throughout the body, inhibition of histamine binding to the receptors on gastric parietal cells is the major beneficial effect of H₂-receptor antagonists.

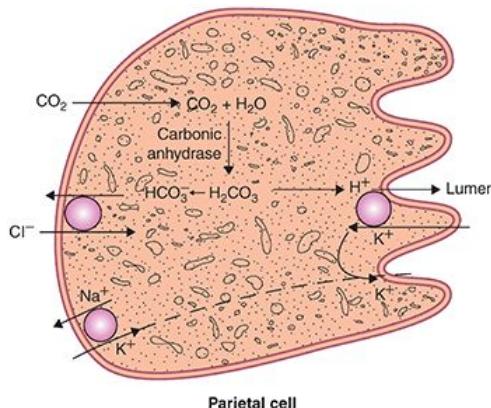

FIGURE 35.2 Ion flux through parietal cell.

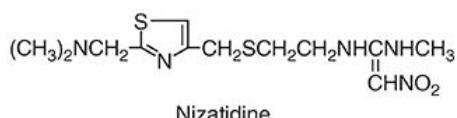

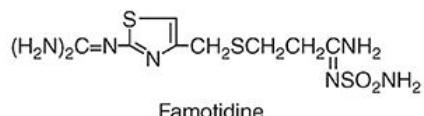

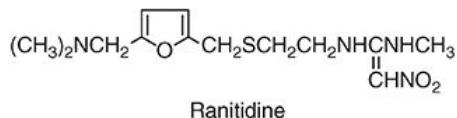

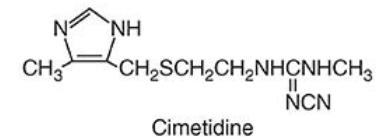

FIGURE 35.3 H₂-receptor antagonists.

Mechanism of Action

The histamine receptors on the basolateral membranes of acid-secreting gastric parietal cells are of the H₂ type and thus are not blocked by conventional H₁ antagonists. The occupation of H₂ receptors by histamine released from mast cells and possibly other cells activates adenylate cyclase, increasing the intracellular concentrations of cyclic adenosine monophosphate (cAMP). The increased concentrations of cAMP activates the proton pump of gastric parietal cells (an enzyme designated as hydrogen-potassium-ATPase) to secrete hydrogen ions against a large concentration gradient in exchange for potassium ions. H₂-receptor antagonists competitively and selectively inhibit the binding of histamine to H₂ receptors, thereby decreasing the intracellular concentrations of cAMP and the subsequent secretion of hydrogen ions by the parietal cells.

The relative potencies of the four H₂-receptor antagonists for inhibition of secretion of gastric hydrogen ions varies from 20- to 50-fold, with cimetidine as the least potent and famotidine the most potent ([Table 35.2](#)). The duration of inhibition ranges from approximately 6 hours for cimetidine to 10 hours for ranitidine, famotidine, and nizatidine. None of the four H₂-receptor antagonists has produced any consistent effects on

lower esophageal sphincter function or the rate of gastric emptying. Discontinuation of chronic H₂-receptor antagonist therapy is followed by rebound hypersecretion of gastric acid.

TABLE 35.2

Pharmacokinetics of H₂-receptor antagonists^a

	Cimetidine	Ranitidine	Famotidine	Nizatidine
Potency	1	4-10	20-50	4-10

^bEC₅₀ denotes the plasma concentration of the drug necessary to inhibit the pentagastrin-stimulated secretion of hydrogen ions by 50%.

Pharmacokinetics

The absorption of cimetidine, ranitidine, and famotidine is rapid after oral administration. Because of extensive first-pass hepatic metabolism, however, the bioavailability of these drugs is approximately 50% (see [Table 35.2](#)). Nizatidine does not undergo significant hepatic first-pass metabolism, and its bioavailability after oral administration approaches 100%. The average time to peak plasma concentrations of the four H₂-receptor antagonists ranges from 1 to 3 hours after oral administration. Because the volume of distribution for all four drugs exceeds the body's total body water content, some binding (13%-35%) to proteins must occur (see [Table 35.2](#)).

Cimetidine is widely distributed in most organs but not fat. Approximately 70% of the total body content of cimetidine is found in skeletal muscles. The volume of distribution is not altered by renal disease but is increased by severe hepatic disease and can be altered by changes in systemic blood pressure and cardiac output. All four drugs are present in breast milk and can cross the placenta and blood-brain barrier. The presence of cimetidine in cerebrospinal fluid is increased in patients with severe hepatic disease. The dose of cimetidine may need to be decreased to avoid mental confusion in patients with severe liver disease. The volume of distribution of cimetidine is also decreased about 40% in elderly patients, presumably reflecting the decrease in skeletal muscle mass associated with aging.

Although there is considerable variation in the clearance and elimination half-lives of H₂-receptor antagonists, their plasma elimination half-lives range from 1.1 to 4 hours (see [Table 35.2](#)).²¹ The elimination of all four drugs occurs by a combination of hepatic metabolism, glomerular filtration, and renal tubular secretion. Hepatic metabolism is the principal mechanism for clearance from the plasma of oral doses of cimetidine, ranitidine, and famotidine, and renal excretion is the principal pathway for clearance from the plasma of an oral dose of nizatidine. The liver may metabolize 25% to 40% of an IV dose of nizatidine. Only nizatidine appears to have an active metabolite (*N*₂-monodesmethyl-nizatidine), possessing about 60% of the activity of the parent drug. Hepatic metabolism of cimetidine occurs primarily by conversion of its side chain to a thioether or sulfoxide, and these inactive products appear in the urine as 5-hydroxymethyl and/or sulfoxide metabolites. The renal clearance of all four H₂-receptor antagonists is typically 2 to 3 times greater than creatinine clearance, reflecting extensive renal tubular secretion. Renal failure increases the elimination half-life of all four drugs, with the greatest effect on nizatidine and famotidine. Decreases in the doses of all four drugs are recommended for patients with renal dysfunction. Doses of H₂-receptor antagonists may also need to be decreased in patients with acute burns. Only 10% to 20% of total body cimetidine or ranitidine is cleared by hemodialysis.

Hepatic dysfunction does not seem to significantly alter the pharmacokinetics of H₂-receptor antagonists. Increasing age must be considered when determining the dose of H₂-receptor antagonists. For example, cimetidine clearance decreases 75% in patients between the ages of 20 and 70 years. There is also a 40% decrease in the volume of distribution of cimetidine in older patients. The elimination half-life of ranitidine and famotidine may be increased up to twofold in older patients.

Clinical Uses

H₂-receptor antagonists are most commonly administered for the treatment of duodenal ulcer disease associated with hypersecretion of gastric hydrogen ions. In the preoperative period, H₂-receptor antagonists have been administered as chemoprophylaxis to increase the pH of gastric fluid before induction of anesthesia. However, the ASA's practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration state that there is evidence that H₂-receptor antagonists increase gastric pH and reduce gastric volume and may be administered preoperatively to patients at increased risk for aspirating. The routine preoperative use of medications that block gastric acid secretion to decrease the risks of pulmonary aspiration in patients who have no apparent increased risk for pulmonary aspiration is not recommended.⁵ When indicated though, H₂-receptor antagonists have been advocated as useful drugs in the preoperative period to decrease the risk of acid pneumonitis if inhalation of acidic gastric fluid were to occur in the perioperative period. One approach is to administer cimetidine, 300 mg orally (3-4 mg/kg), 1.5 to 2 hours before the induction of anesthesia, with or without a similar dose the preceding evening. Famotidine given the evening before and the morning of surgery or on the morning of surgery is equally effective in decreasing gastric fluid pH in outpatients and inpatients; there is no difference between famotidine doses of 20 and 40 mg.

Unfortunately, H₂-receptor antagonists, in contrast to antacids, have no influence on the pH of the gastric fluid that is already present in the stomach. Cimetidine crosses the placenta but does not adversely affect the fetus when administered before cesarean section. The other H₂-receptor antagonists have a profile similar to that of cimetidine with respect to placental transfer.

Preoperative preparation of patients with allergic histories or patients undergoing procedures associated with an increased likelihood of allergic reactions (radiographic contrast dye administration) may include prophylactic oral administration of an H₁-receptor antagonist (diphenhydramine, 0.5-1.0 mg/kg) and an H₂-receptor antagonist (cimetidine, 4 mg/kg) every 6 hours in the 12 to 24 hours preceding the possible triggering event. A corticosteroid administered at least 24 hours earlier is commonly added to this regimen.

The magnitude of the systemic blood pressure decrease that occurs in response to drug-induced (morphine, atracurium, mivacurium, and protamine) histamine release is decreased by prior administration of H₁- and H₂-receptor antagonists, confirming that prior occupation of histamine receptors with a specific

antagonist drug attenuates the cardiovascular effects of subsequently released histamine. Pretreatment with an H₁-receptor antagonist (diphenhydramine) or H₂-receptor antagonist (cimetidine) alone is not effective in preventing the cardiovascular effects of histamine that are released in response to drug administration, emphasizing the role of both H₁- and H₂-receptors in these responses. In fact, drug-induced histamine release may be exaggerated in patients pretreated with only H₂-receptor antagonists.

Side Effects

The frequency of severe side effects is low with all four H₂-receptor antagonists (**Table 35.3**). The risk for experiencing adverse side effects during treatment with an H₂-receptor antagonist is increased by the presence of multiple medical illnesses, hepatic or renal dysfunction, and advanced age. The most common adverse side effects are diarrhea, headache, fatigue, and skeletal muscle pain. Side effects that occur with a prevalence of <1% include mental confusion, dizziness, somnolence, gynecomastia, galactorrhea, thrombocytopenia, increased plasma levels of liver enzymes, drug fever, bradycardia, tachycardia, and cardiac arrhythmias. Cardiac reactions are most likely related to blockade of cardiac H₂ receptors. Mental confusion in patients being treated with cimetidine may be more likely in the presence of hepatic or renal dysfunction. Changes in mental status usually occur in the elderly and tend to be associated with high doses of cimetidine administered IV, often to patients in an intensive care unit. Most patients have an improvement in mental status 24 to 48 hours after discontinuing cimetidine. Ranitidine and famotidine also cross the blood–brain barrier and have been reported to produce mental confusion and to interfere with sleep.²² Mental confusion has rarely been observed in ambulatory patients being treated chronically with H₂-receptor antagonists.

TABLE 35.3

Side effects of H₂-receptor antagonists

Interaction with cerebral H ₂ receptors (headache, somnolence, confusion)
Interaction with cardiac H ₂ receptors (bradycardia, hypotension, heart block)
Hyperprolactinemia
Acute pancreatitis
Increased hepatic transaminase levels
Alcohol dehydrogenase dehydration
Thrombocytopenia
Agranulocytosis
Interstitial nephritis
Interference with drug metabolism by cytochrome P450

Cimetidine and, to a lesser extent, ranitidine increase the plasma concentrations of prolactin, which may result in galactorrhea in females and gynecomastia in males. Famotidine and nizatidine do not appear to increase plasma prolactin levels. Cimetidine, but not the other H₂-receptor antagonists, inhibits the binding of dihydrotestosterone to androgen receptors. Impotence and loss of libido may occur in males receiving chronic high-dose treatment with cimetidine.

The adverse effects of H₂-receptor antagonists on hepatic function are typically reflected by reversible increases in the plasma level of aminotransaminase enzymes, mostly in patients receiving large IV doses of H₂-receptor antagonists. H₂-receptor antagonists probably do not markedly alter hepatic blood flow.

Cardiac arrhythmia (sinus bradycardia, sinus arrest, sinus arrest with idioventricular escape rhythm, complete atrioventricular heart block) have been described after either oral or IV administration of H₂-receptor antagonists. Most of the described arrhythmias have occurred after chronic administration. Prolonged QTc interval and fatal cardiac arrest with famotidine have been reported. Cardiac effects of H₂-

receptor stimulation are similar to β_1 stimulation mediated by cAMP. This would explain why blockade of H_2 receptors might evoke bradycardia. Furthermore, blockade of H_2 receptors could increase H_1 -receptor effects, including negative dromotropy. Bradycardia and hypotension are generally associated with rapid IV administration of these drugs, most often to critically ill or older patients. The mechanism for hypotension appears to be peripheral vasodilation. A prudent approach is to administer these drugs over 15 to 30 minutes when administered IV.

Pulmonary infections from inhaled secretions may be more likely if the acid-killing effect on bacteria in the stomach is altered. Sustained increases of gastric fluid pH may lead to an overgrowth of other organisms such as *Candida albicans*. This may account for the occasional case of *Candida* peritonitis observed after peptic ulcer perforation in patients treated with an H_2 -receptor antagonist.

Drug Interactions

Numerous drug interactions have been described between H_2 -receptor antagonists and other drugs ([Table 35.4](#)). Drug interactions generally occur when a new drug is either started or discontinued. In this regard, measurement of plasma drug concentrations or laboratory measurements of an effect (prothrombin time) may be useful.

TABLE 35.4

Drug interactions with cimetidine^a

Drug	Effect of cimetidine on plasma concentration	Clearance of drug (% decrease)	Mechanism
Ketoconazole	Decreased	No change	Decreased absorption due to increased gastric fluid pH that slows dissolution
Warfarin ^b	Increased	23-36	Decreased hydroxylation of dextrorotatory isomer
Theophylline ^b	Increased	12-34	Decreased methylation
Phenytoin ^b	Increased	21-24	Decreased hydroxylation (?)
Propranolol	Increased	20-27	Decreased hydroxylation
Nifedipine	Increased	38	Unknown
Lidocaine	Increased	14-30	Decreased N-dealkylation
Quinidine	Increased	25-37	Decreased 3-hydroxylation (?)
Imipramine	Increased	40	Decreased N-demethylation
Desipramine	Increased	36	Decreased hydroxylation in rapid metabolizers
Triazolam	Increased	27	Decreased hydroxylation
Meperidine	Increased	22	Decreased oxidation
Procainamide ^b	Increased	28	Competition for renal tubular secretion

^aData from Feldman M, Burton ME. Histamine₂-receptor antagonists. Standard therapy for acid-peptic diseases. 1. *N Engl J Med*. 1990;323:1672-1680.

^bLesser drug interactions also occur with ranitidine.

The principal type of drug interaction reported with cimetidine is impairment of the hepatic metabolism of another drug because of the binding of cimetidine to the heme portion of the cytochrome P450 oxidase system. Cimetidine retards metabolism of drugs such as propranolol and diazepam that normally undergo high hepatic extraction. Slowed metabolism and prolonged elimination half-life with associated exaggerated pharmacologic effects of propranolol and diazepam have been documented with only 24 hours of treatment with cimetidine ([Figures 35.4](#) and [35.5](#)). In contrast, benzodiazepines, such as oxazepam and lorazepam, that are eliminated almost entirely by glucuronidation are not altered by cimetidine-induced effects on P450

enzyme activity. Cimetidine may slow metabolism of lidocaine and thus increase the possibility of systemic toxicity. In contrast, plasma concentrations of bupivacaine after epidural anesthesia for cesarean section are not influenced by a single dose of cimetidine administered before induction of anesthesia ([Figure 35.6](#)).

Ranitidine, although more potent than cimetidine, binds less avidly to the cytochrome P450 enzyme system and has less potential than cimetidine to alter the oxidative metabolism of other drugs. Famotidine and nizatidine do not bind notably to the cytochrome P450 enzyme system and thus have very limited potential for inhibiting the metabolism of other drugs.

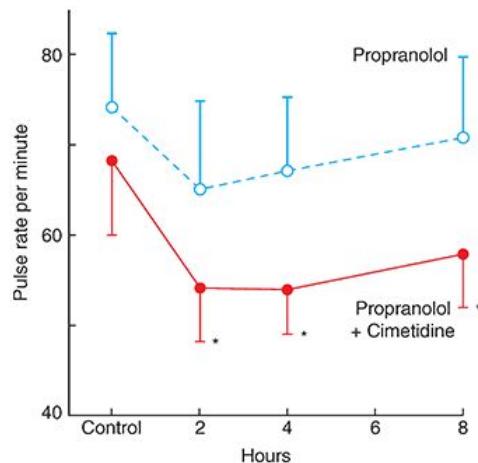

FIGURE 35.4 The effect of propranolol on resting heart rate is accentuated by the concomitant administration of cimetidine (mean \pm SD; $n = 5$; $*P < .05$). From Feely J, Wilkinson GR, Wood AJ. Reduction of liver blood flow and propranolol metabolism by cimetidine. N Engl J Med. 1981;304(12):692-695. Copyright © 1981 Massachusetts Medical Society. H_2 -receptor antagonists compete with cationic compounds for renal tubular secretion. Because of the competition of cimetidine and ranitidine with creatinine for renal tubular secretion, serum creatinine levels are increased about 15%. Cimetidine and ranitidine, but not famotidine, impair renal tubular secretion of procainamide and theophylline. Famotidine, however, has been reported to interfere with phosphate absorption, leading to the development of hypophosphatemia. Impairment of renal theophylline clearance with cimetidine is probably negligible compared with impairment of the hepatic metabolism of theophylline.

Similar to oral antacids, all four H_2 -receptor antagonists have the potential to alter the absorption of some drugs by increasing the gastric fluid pH. Cimetidine has been reported to enhance the absorption of ethanol from the stomach as a result of inhibition of gastric alcohol dehydrogenase.

In addition to drug interactions produced by H_2 -receptor antagonists, several drugs alter the disposition of the antagonists. Magnesium and aluminum hydroxide antacids decrease by 30% to 40%, respectively, the bioavailability of cimetidine, ranitidine, and famotidine. Despite this impaired absorption, therapeutic blood levels of the H_2 antagonist can still be achieved, and rigorous separation of dosage schedules during combined drug therapy is probably unnecessary.

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) (omeprazole, esomeprazole, lansoprazole, pantoprazole, rabeprazole) are the most effective drugs available for controlling gastric acidity and volume (Table 35.5). The final step in gastric acid secretion is the membrane enzyme proton pump (hydrogen-potassium-ATPase) that moves hydrogen ions across the gastric parietal cell membranes in exchange for potassium ions. The secretion of HCl by gastric parietal cells ultimately depends on the function of the proton (hydrogen ion) pump. PPIs are more effective than H_2 -receptor antagonists for healing esophagitis and preventing relapse. PPIs also appear to be more effective than H_2 -receptor antagonists for relieving heartburn, the cardinal feature of “gastroesophageal reflux disease.” However, for patients without esophagitis and infrequent symptoms H_2 -receptor antagonists are more cost-effective.

Choice of PPI

The available PPIs are interchangeable when a decrease in gastric pH following a single dose is the goal.¹⁹ The PPIs, compared to H₂-receptor antagonists, have been associated with an almost one-third increase in the incidence of *C difficile* infection²³ and with an increased incidence of pneumonia in patients who have sustained a cerebrovascular accident,²⁴ presumably because of the loss of a bactericidal acidic environment in the stomach. For these and other reasons, there are those who believe that we should be more selective in patients to whom we administer PPIs.²⁵

TABLE 35.5

Pharmacokinetics of proton pump inhibitors

	Bioavailability	Time to peak plasma concentration (hour)	Protein binding	Elimination half-life (hour)	Hepatic metabolism	Interference with cytochrome P450
Omeprazole	60%	2-4	>90%	0.5-1.0	Yes	Minimal
Esomeprazole	60%	2-4	>90%	0.5-1.0	Yes	Minimal
Lansoprazole	85%	1.5-3.0	97%	1.5	Yes	Minimal
Pantoprazole	77%	2.5	98%	1.9	Yes	No
Rabeprazole	85%	2.9-3.8	96%	1	Yes	No

Omeprazole

Omeprazole is a substituted benzimidazole that acts as a prodrug that becomes a PPI (Figure 35.7). As a weak base, omeprazole is concentrated in the secretory canaliculi of the gastric parietal cells, where it is protonated to its active form. The initial dose of omeprazole will only inhibit those proton pumps present on the luminal surface. As pumps are generated and inserted into the luminal surfaces, additional doses are required to inhibit these new pumps. Therefore, omeprazole takes several days to exert its maximal inhibitory effect on gastric acid secretion. Daily administration results in about 66% inhibition of gastric acid secretion by about 5 days. Likewise, discontinuation of omeprazole is not followed immediately by return of gastric acid secretion.

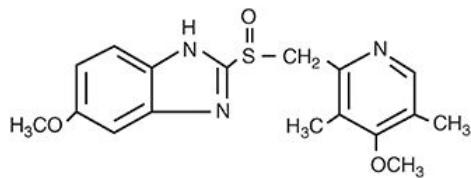

FIGURE 35.7 Omeprazole.

Omeprazole provides prolonged inhibition of gastric acid secretion, regardless of the stimulus, and it inhibits daytime and nocturnal acid secretion and meal-stimulated acid secretion to a significantly greater degree than do the H₂-receptor antagonists. This drug heals duodenal and possibly gastric ulcers more rapidly than do the H₂-receptor antagonists. In patients with bleeding peptic ulcers and signs of recent bleeding, treatment with omeprazole decreases the rate of bleeding and the need for surgery. Omeprazole is superior to H₂-receptor antagonists for the treatment of reflux esophagitis and is the best pharmacologic treatment of Zollinger-Ellison syndrome.

Preoperative Medication

As preoperative medication, omeprazole effectively increases gastric fluid pH and decreases gastric fluid volume in children and adults. In this regard, the onset of the gastric antisecretory effect of omeprazole after a single oral dose (20 mg) occurs within 2 to 6 hours. The duration of action is prolonged (>24 hours) because the drug is concentrated selectively in the acidic environment of gastric parietal cells. Omeprazole, 20 mg,

orally administered the night before surgery increases gastric fluid pH, whereas administration on the day of surgery (up to 3 hours before induction of anesthesia) fails to improve the environment of the gastric fluid. This suggests that oral omeprazole should be administered >3 hours before anticipated induction of anesthesia for chemoprophylaxis. If sufficient time is not available, the administration of bicarbonate with omeprazole has been demonstrated to achieve the desired decrease in gastric pH.²⁶

Side Effects

Omeprazole crosses the blood–brain barrier and may cause headache, agitation, and confusion. Gastrointestinal side effects include abdominal pain, flatulence, nausea, and vomiting. Small bowel bacterial overgrowth may occur owing to acid suppression.¹⁴ The loss of the inhibitory effect of gastric acid results in increased plasma concentrations of gastrin. There is no need to decrease the dose of PPIs in the presence of renal or hepatic dysfunction.²¹

Esomeprazole

Esomeprazole is the levorotatory isomer of omeprazole that is metabolized differently in the liver, resulting in greater plasma concentrations of the drug compared with the racemic drug, omeprazole. The pharmacodynamic properties of esomeprazole are similar to those of omeprazole.

Pantoprazole

Pantoprazole is the most potent and fast acting of the available PPIs and is frequently administered in an intensive care unit as prophylaxis against stress-related mucosal damage. A 2019 study published in *The New England Journal of Medicine* found no difference between intensive care unit patients considered at risk for upper gastrointestinal bleeding who were administered pantoprazole versus placebo in terms of 90-day mortality and clinically important events.²¹

Gastrointestinal Prokinetics

Motility-modulating drugs exert their therapeutic effects by increasing lower esophageal sphincter tone, enhancing peristaltic contractions, and accelerating the rate of gastric emptying.

Dopamine Blockers

Domperidone

Domperidone is a benzimidazole derivative that, like metoclopramide, acts as a specific dopamine antagonist that stimulates peristalsis in the gastrointestinal tract, speeds gastric emptying, and increases lower esophageal sphincter tone ([Figure 35.8](#)). Domperidone is only available on a compassionate-use basis in the US.

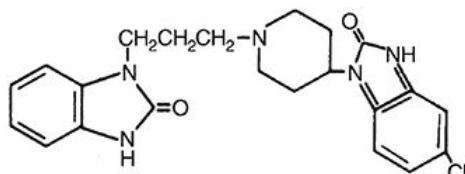

FIGURE 35.8 Domperidone.

Unlike metoclopramide, domperidone does not easily cross the blood–brain barrier and does not appear to have any anticholinergic activity. Its gastrokinetic actions have, therefore, been attributed to its peripheral dopaminergic activity. Because it lacks dopaminergic effects in the CNS, this drug is not associated with extrapyramidal symptoms. However, similar to metoclopramide, it does affect prolactin secretion by the pituitary. The FDA refused to give approval for domperidone's sale in the United States because of concerns about lactating women using domperidone to increase breast milk production because of the cardiac risks associated with its use (eg, cardiac arrhythmias, cardiac arrest, and sudden death). It is possible to obtain permission from the FDA to prescribe domperidone for nonlactating adults with gastrointestinal motility

disorders that are difficult to manage with available therapy, in whom domperidone's potential benefits outweigh its cardiac risks. Even in countries that allow its use, there is increasing concern because of the possibility of cardiac arrhythmias and sudden death²⁸ now thought to be secondary to inhibition of human Ether-a-go-go related gene (hERG) channel activity, which in turn decreases the rapid component of the cardiac delayed rectifier K⁺ current.²⁹

Metoclopramide

Metoclopramide acts as a gastrointestinal prokinetic drug that increases lower esophageal sphincter tone and stimulates motility of the upper gastrointestinal tract. It remains the only drug approved by the U.S. Food and Drug Administration (FDA) for the treatment of diabetic gastroparesis.²⁷ Gastric hydrogen ion secretion is not altered. The net effect is accelerated gastric clearance of liquids and solids (decreased gastric emptying time) and a shortened transit time through the small intestine.

Mechanism of Action

Metoclopramide produces selective cholinergic stimulation of the gastrointestinal tract (gastrokinetic effect) consisting of (1) increased smooth muscle tension in the lower esophageal sphincter and gastric fundus, (2) increased gastric and small intestinal motility, and (3) relaxation of the pylorus and duodenum during contraction of the stomach. The cholinergic stimulating effects of metoclopramide are largely restricted to smooth muscles of the proximal gastrointestinal tract and require some background cholinergic activity. There is evidence that metoclopramide sensitizes gastrointestinal smooth muscles to the effects of acetylcholine, which explains the observation that metoclopramide, unlike conventional cholinergic drugs, requires background cholinergic activity to be effective. Postsynaptic activity results from the ability of metoclopramide to cause the release of acetylcholine from cholinergic nerve endings. Indeed, atropine opposes metoclopramide-induced increases in lower esophageal sphincter tone and gastrointestinal hypermotility, indicating that metoclopramide acts on postganglionic cholinergic nerves intrinsic to the wall of the gastrointestinal tract.

Metoclopramide acts as a dopamine-receptor antagonist, but any effects on dopamine-induced inhibition of gastrointestinal motility are not considered to be clinically significant. However, metoclopramide does cross the blood–brain barrier, and within the CNS, metoclopramide inhibition of dopamine receptors can produce significant extrapyramidal side effects. In 2009, the FDA issued a boxed warning regarding the development of tardive dyskinesia with its use, and, since then, its use has decreased because the number of lawsuits has increased.³⁰ Metoclopramide's dopamine receptor antagonism also stimulates prolactin secretion, but its risk-benefit ratio is considered safer than that of a domperidone. Metoclopramide-induced antagonism of dopamine-agonist effects on the chemoreceptor trigger zone (located outside the blood–brain barrier) contributes to an antiemetic effect.

Pharmacokinetics

Metoclopramide is rapidly absorbed after oral administration, reaching peak plasma concentrations in 40 to 120 minutes. Extensive first-pass hepatic metabolism limits bioavailability to about 75%. Most patients achieve therapeutic plasma concentrations of 40 to 80 ng/mL after 10 mg of orally administered metoclopramide. The elimination half-life is 2 to 4 hours. Metoclopramide readily crosses the blood–brain barrier and the placenta. The concentration of metoclopramide in breast milk may exceed the plasma concentration. Approximately, 85% of an oral dose of metoclopramide appears in the urine, equally divided between unchanged drug and sulfate and glucuronide conjugates. Impairment of renal function prolongs the elimination half-life and necessitates a decrease in metoclopramide dosage.

Clinical Uses

Clinical uses of metoclopramide include (1) preoperative decrease of gastric fluid volume, (2) production of an antiemetic effect, (3) treatment of gastroparesis, (4) symptomatic treatment of gastroesophageal reflux, and (5) intolerance to enteral feedings in patients who are critically ill. Administration of metoclopramide, 10 to 20 mg IV, may be useful to speed gastric emptying before the induction of anesthesia, to facilitate small-

bowel intubation, or to speed gastric emptying to improve radiographic examination of the small intestine. Metoclopramide has been used to improve the effectiveness of oral medication if other drugs or the patient's underlying condition slows gastric emptying.

Preoperative Decrease in Gastric Fluid Volume

Metoclopramide, 10 to 20 mg IV over 3 to 5 minutes administered 15 to 30 minutes before induction of anesthesia, results in increased lower esophageal sphincter tone and decreased gastric fluid volume. More rapid IV administration may produce abdominal cramping. This gastric-emptying effect of metoclopramide may be of potential benefit before the induction of anesthesia in (1) patients who have recently ingested solid food; (2) trauma patients; (3) obese patients; (4) patients with diabetes mellitus and symptoms of gastroparesis; and (5) parturients, especially those with a history of esophagitis ("heartburn"), suggesting lower esophageal sphincter dysfunction and gastric hypomotility. Nevertheless, beneficial effects of metoclopramide on gastric fluid volume may be difficult to document in patients with low gastric fluid volumes who are awaiting elective surgery (**Table 35.6**).

TABLE 35.6

Volume of gastric contents and pH in study groups (mean \pm standard error)^a

	Metoclopramide (n = 30)	Placebo (n = 28)
Gastric volume (range)	24 \pm 2 mL (3-600)	30 \pm 5 mL (4-155)
Volume <25 mL	16 ^b (53%)	15 ^b (54%)
Gastric pH (range)	2.86 \pm 0.27 (1-6)	2.55 \pm 5 mL (1-5.5)
pH <2.5	12 ^b (40%)	16 ^b (57%)

^aData from Cohen SE, Jasson J, Talafre ML, Chauvelot-Moachon L, Barrier G. Does metoclopramide decrease the volume of gastric contents in patients undergoing cesarean section? *Anesthesiology*. 1984;61:604-607, with permission.

^bNumber of patients.

Regardless of the effects of gastric fluid volume, the administration of metoclopramide does not reliably alter gastric fluid pH. Furthermore, it is important to recognize that opioid-induced inhibition of gastric motility may not be reversible with metoclopramide. Likewise, the beneficial cholinergic stimulant effects of metoclopramide on the gastrointestinal tract may be offset by concomitant administration of atropine in the preoperative medication. Metoclopramide and other prophylactic drugs (antacids or H₂ antagonists) do not replace the need for proper airway management, including placement of a cuffed tracheal tube.

Production of an Antiemetic Effect

The antiemetic effect of metoclopramide in preventing postoperative nausea and vomiting has been debated. However, metoclopramide has been shown to decrease chemotherapy-induced nausea and vomiting and nausea and vomiting after cesarean section, although it is less efficacious than 5-HT₃ antagonists. The antiemetic property of metoclopramide probably results from antagonism of dopamine's effects in the chemoreceptor trigger zone. Additional antiemetic effects are provided by metoclopramide-induced increases in lower esophageal sphincter tone and facilitation of gastric emptying into the small intestine. These latter effects reverse the gastric immobility and cephalad peristalsis that accompany the vomiting reflex.

Side Effects

Metoclopramide should not be administered to patients with Parkinson disease or restless legs syndrome or who have movement disorders related to dopamine inhibition or depletion. In patients with no known movement disorders, dystonic extrapyramidal reactions (oculogyric crises, opisthotonus, trismus, torticollis, tardive dyskinesia) have been reported to occur in 1% to 10% of patients treated chronically with metoclopramide. However, a recent meta-analysis concluded that the incidence of tardive dyskinesia associated with metoclopramide is lower than this, ~0.1% per 1,000 patient-years. Patients at increased risk

are those who are older, female, diabetic, who have hepatic or renal failure, and those also taking antipsychotic drugs.³¹ Although extrapyramidal reactions may be a problem if large oral doses (40-80 mg daily) are administered chronically, there are reports of neurologic dysfunction related to the preoperative administration of a single dose of metoclopramide. These extrapyramidal reactions are identical to the parkinsonian syndrome evoked by antipsychotic drugs that antagonize the CNS actions of dopamine. Akathisia, a feeling of unease and restlessness in the lower extremities, may follow the IV administration of metoclopramide, resulting in cancellation of scheduled surgery, or may manifest in the postanesthesia care unit.

Abdominal cramping may follow rapid IV administration (<3 minutes) of metoclopramide. The IV administration of metoclopramide may also be associated with hypotension, tachycardia, bradycardia, and cardiac arrhythmia. Sedation, dysphoria, agitation, dry mouth, glossal or periorbital edema, hirsutism, and urticarial or maculopapular rash are rare side effects that have not been observed after single doses of metoclopramide. Breast enlargement, galactorrhea, or menstrual irregularities that occur rarely are presumed to reflect metoclopramide-induced increases in plasma prolactin concentrations. For this reason, patients with a history of breast cancer probably should not be treated chronically with metoclopramide.

Placental transfer of metoclopramide occurs rapidly, but adverse fetal effects with single doses have not yet been observed. The usual dopamine-induced inhibition of aldosterone secretion is prevented by metoclopramide. As a result, the possibility of sodium retention and hypokalemia should be considered, especially in patients who develop peripheral edema during chronic therapy.

Metoclopramide should probably not be administered in combination with phenothiazine or butyrophenone drugs or to patients with preexisting extrapyramidal symptoms or signs, as mentioned previously, or with seizure disorders. Patients being treated with monoamine oxidase inhibitors or tricyclic antidepressants should likewise probably not receive metoclopramide. Metoclopramide decreases bioavailability of orally administered cimetidine by 25% to 50%. It would seem prudent not to administer metoclopramide to a patient with a suspected or known mechanical obstruction to gastric emptying. Likewise, metoclopramide is not administered after gastrointestinal surgery such as pyloroplasty or intestinal anastomosis because it stimulates gastric motility and may delay healing.

Metoclopramide has an inhibitory effect on plasma cholinesterase activity when tested in vivo, which may explain occasional observations of prolonged responses to succinylcholine and mivacurium in patients receiving these drugs and metoclopramide concomitantly. Parturients may be at increased risk for developing this response, considering the already decreased plasma cholinesterase activity associated with pregnancy. Likewise, the metabolism of ester local anesthetics could be slowed by metoclopramide-induced decreases in plasma cholinesterase activity.

Macrolides

The antibiotic erythromycin, as well as other macrolide antibiotics (ie, azithromycin), increases lower esophageal sphincter tone, enhances intraduodenal coordination, and promotes emptying of gastric liquids and solids in patients with diabetic gastroparesis, in patients awaiting emergency surgery, in patients without comorbidities, and in patients in the intensive care unit with food intolerance ([Figure 35.9](#)). The macrolide antibiotics' prokinetic properties are attributed to their binding to motilin receptors in the stomach and duodenum, although part of their prokinetic action may be secondary to cholinergic stimulatory properties. Side effects of the macrolide compounds are the same as for any antibiotic, and, therefore, because of concerns about tolerance, there are those that believe that erythromycin should only be used if all other prokinetic agents have failed.

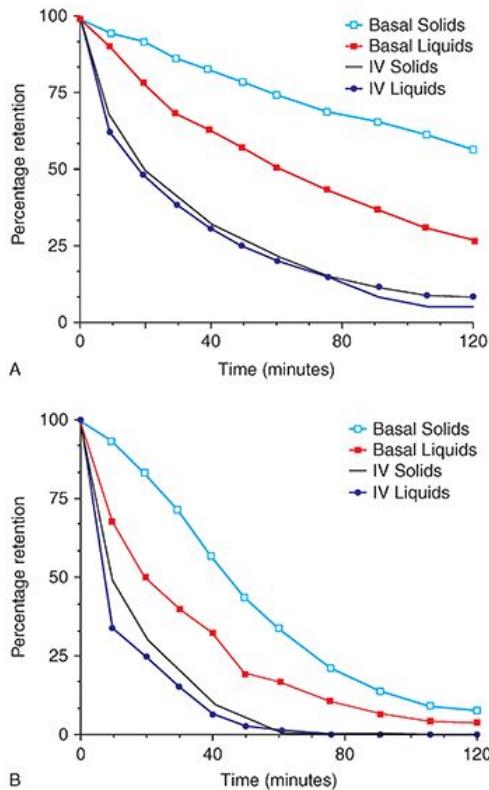

FIGURE 35.9 Erythromycin, 200 mg, administered intravenously over 15 minutes, followed by ingestion of a radioactive-labeled meal (scrambled egg, toast, and water) resulted in more rapid emptying of solids and liquids (intravenous [IV] solids and IV liquids) in patients with diabetic gastroparesis (A) and patients without diabetes (B) compared with gastric emptying times in the absence of erythromycin (basal solids and basal liquids). This research was originally published in *JNM*. Urbain JL, Vantrappen G, Janssens J, Van Cutsem E, Peeters T, De Roo M. Intravenous erythromycin dramatically accelerates gastric emptying in gastroparesis diabeticorum and normals and abolishes the emptying discrimination between solids and liquids. *J Nucl Med*. 1990;31(9):1490-1493. © SNMMI.

5-HT₄-Receptor Agonists

Nonselective 5-HT₄-receptor agonists, such as cisapride and mosapride, decrease acid reflux, increase lower esophageal sphincter tone, improve gastric motility, and increase motility in the small and large intestine by enhancing the release of acetylcholine from nerve endings in the myenteric plexus of the gastrointestinal mucosa. Opioid-induced gastric stasis, which is an important cause of postoperative nausea and vomiting, is reversed by cisapride. Tegaserod, a partial 5-HT₄-receptor agonist, improves small and large intestine transit and reduces constipation. Due to its relative nonselectivity, and because of side effects, cisapride was removed from the market several years ago.

Serotonin Agonists

Serotonin is involved in gastrointestinal motility and secretion, but studies of nonselective drugs that enhance serotonin action have not shown benefit.²⁷

Nutrition

Michael J. Murray

In 1974, Charles Butterworth, MD, Chairman of the Council on Foods and Nutrition of the American Medical Association, published an article “The skeleton in the hospital closet.”¹ He commented that despite the knowledge of the importance of nutrition in recovery from illness and injury, few physicians made an effort to improve the nutritional status of their patients. In fact, just the opposite was true in that many hospitalized patients became malnourished, and some even starved, while in hospitals. More than four decades later, the same observation could be made, and, in fact, the points that Dr Butterworth made are probably as true now^{2,3} as they were then ([Table 36.1](#))

Despite the emphasis on improving outcomes by improving nutritional intake in hospitalized patients, few studies have shown a difference. A retrospective study of 1,223 patients concluded, “Early adequate feeding *may be* [emphasis added] associated with better outcomes.”⁴ Two prospective studies in 2017 and 2018, respectively, designed to ensure that patients received adequate nutrition support either by providing parenteral nutrition to supplement enteral feedings⁵ or by providing parenteral nutrition to patients able to take per os⁶ failed to demonstrate an improvement in mortality, infections, or length of stay (LOS). Because of the paucity of supporting literature, recent United States and European clinical practice guidelines on nutrition support in critically ill and injured patients are based more on expert opinion than on prospective, randomized, controlled studies.^{7,8}

One should not conclude that nutrition support is not beneficial. Rather than assuming that delivery of nutrients per se to patients will convert a catabolic state to an anabolic state, the underlying inflammatory state must be attenuated. Similarly, physical therapy modalities must be incorporated to “exercise” skeletal muscles;⁹ an immobile patient will inevitably lose muscle mass. No amount of nutrients will decrease the degree of frailty in a bedridden patient if an exercise regimen is not incorporated into the program.¹⁰

Likewise, one should not conclude that nutrition support, broadly defined, is not of importance to anesthesiologists. If anything, the increasing prevalence of enhanced recovery after surgery (ERAS) protocols, many of which incorporate nutritional regimens into the protocol,^{11,12} means that we should be familiar with the information that supports the efficacy of these protocols. During the preoperative phase of an ERAS protocol, patients should be screened for nutritional status.¹³ Those patients who are found to be malnourished (see in the following text) are advised to include nutritional supplements in their diet to promote anabolism. However, anabolism includes more than just nutrients; patients should be advised to embark on an exercise regimen that includes resistance training.⁹ On the day of surgery, prolonged fasting should be avoided, and preoperative oral carbohydrate fluids are recommended up until 2 hours before the surgical procedure.¹² The composition of the diet is probably less important than is the presence of fluid in the stomach, promoting peristalsis up until the time of surgery.¹⁴ There is evidence that simply chewing gum (along with the administration of alvimopan) prior to surgery is associated with a lower incidence of ileus and decreased hospital LOS.¹⁵ The administration of alvimopan, a peripherally acting μ -opioid receptor antagonist that inhibits the effects of opioids within the gastrointestinal tract, by itself is associated with a lower incidence of ileus, decreased LOS, and significant cost savings.¹⁶ This underscores the role of opioids in the development of ileus, especially in patients undergoing colorectal surgery.^{17,18} The American College of Surgeons Committee on Trauma has released a Trauma Quality Improvement Program Guideline on Acute Pain Management of patients who have sustained traumatic injury, emphasizing the role that multimodal pain management has in decreasing the use of opioids in the perioperative period. However, the guideline emphasizes that

opioids remain first-line therapy for moderate to severe pain.¹⁹ Patients whose severe pain is not controlled have a higher incidence of inadequate caloric input in the perioperative period.²⁰

TABLE 36.1

Practices that negatively impact the nutritional health of patients^a

- No one assumes primary responsibility for patient care
- Failure to optimize nutrition preoperatively
- No documentation of patient's food intake
- Patients kept nothing by mouth for diagnostic tests
- Little knowledge of the importance of certain nutrients in promoting health and recovery
- Lack of understanding of the increased nutritional needs due to traumatic injury or disease processes
- No comprehension of the role of nutrition in preventing infections
- Minimal communication between physicians and dietitians
- Institution of nutritional support only when the patient is in an advanced state of decline
- Not knowing which laboratory tests are helpful in evaluating adequacy of nutrition support

Definitions

Malnutrition

The American Society of Parenteral and Enteral Nutrition and the Academy of Nutrition and Dietetics have defined *malnutrition* as reduced energy intake, unintentional weight loss, loss of subcutaneous fat, loss of muscle mass, fluid accumulation, and reduced grip strength. Its European counterpart, the European Society for Clinical Nutrition and Metabolism, combines weight loss with either age-related body mass index or fat-free mass index as a second alternative to low body mass index (less than 18.5 kg/m²).²¹ In the United States, the former definition is most widely used.

Enteral nutrition is defined as providing nourishment to a patient using a diet that is delivered directly into the gastrointestinal tract (nasogastric tube, nasointestinal tube, gastrostomy tube, jejunostomy tube).

Parenteral nutrition is defined as delivery of nutrients directly into the venous circulation (peripheral vein or central vein). The term *total parenteral nutrition* (TPN) is used when the only source of nutrient supply is via the parenteral route. Nutritional support is characterized as the use of enteral or parenteral nutrition rather than or in addition to an oral diet. Preexisting TPN should be continued during the perioperative period, whereas enteral nutrition should be discontinued about 6 hours before surgery (reflecting recommendations for food ingestion prior to elective surgery). However, relatively new guidelines promulgated in the United Kingdom for tracheally intubated patients recommend (1) enteral nutrition can be continued up until the patient is transferred to the operating theater for non-airway-related procedures and (2) prior to the procedure, itself, either the feeding tube or the oro- or nasogastric tube should be aspirated to empty the stomach. If manipulation of the airway is anticipated, for example, for a tracheostomy, the enteral feedings should be withheld for 6 hours prior to the procedure.¹¹

Nutrition Support

The TPN is intended to supply all the essential inorganic and organic nutritional elements necessary to maintain optimal body composition. Alimentation by the gastrointestinal tract, however (enteral nutrition), is preferred to intravenous (IV) alimentation (parenteral nutrition) because it is more physiologic. Enteral nutrition provides nutrients that stimulate trophic factors released from the lumen that maintains gut integrity and the absorptive activity of the small intestine. One observational study reported that greater protein and caloric intake in malnourished critically ill patients results in decreased mortality and LOS in the hospital.²² However, this was a retrospective study; in reality, the route of feeding is probably more important than is the amount of nutrition provided. There has been a great deal of interest recently in the microbiome (the community of microorganisms; eg, bacteria, fungi, viruses) of the gastrointestinal tract and how it can

influence the immune and nervous systems in both health and disease.²³ The benefits of periodic fasting to maintain weight and improve health may be related to changes within the microbiome of the gastrointestinal tract.²⁴ Even obesity has been shown to have adverse effects on the microbiome of the gut, known as dysbiosis, which affects immunity and insulin resistance.²⁵ Some of the medications we take such as statins are linked to a lower prevalence of gastrointestinal tract microbiome dysbiosis.²⁶ Of most importance in the present discussion are the effects of starvation on the microbiome, manifested by endocrine alterations, augmented inflammatory response, and decreased immune response, with adverse effects on the nervous system.²⁷ To the extent that enteral nutrition maintains the microbiome of the gastrointestinal tract, enteral nutrition should be used when possible, cognizant that, although enteral nutrition may decrease infectious complications and LOS, it has not yet been shown to decrease mortality.²⁸

Thus, even though benefit has not yet been demonstrated in terms of mortality, there are several other benefits. If the patient's caloric and nitrogen requirements cannot be met with luminal nutrition, enteral feedings should be used to partially meet needs, unless it is contraindicated (bowel obstruction, inadequate bowel surface area, intractable diarrhea). If enteral feeding is contraindicated and the patient is not malnourished or severely stressed, parenteral nutrition is not necessary for the first week following surgery or intensive care unit (ICU) admission because it has not been shown to be of benefit.^{29–31} The enteral and parenteral routes may be used simultaneously to meet nutritional requirements, although there is no evidence that the combination of the two to meet caloric needs improves outcomes.⁶ A 2019 Cochrane Review, "Enteral versus parenteral nutrition and enteral versus a combination of enteral and parenteral nutrition for adults in the intensive care unit," analyzed 25 studies that included more than 8,800 patients and found insufficient evidence to recommend whether enteral nutrition is better or worse than parenteral nutrition or better than a combination of the two. There was no difference in survivability at 90 or 180 days, no difference in adverse events, and no difference in ventilator for 3 days. Supporting the influence of enteral nutrition on the integrity of the gastrointestinal tract in decreasing the incidence of bacterial translocation, there was a lower incidence of sepsis in patients who received enteral over parenteral nutrition. Evidence that supported the concept that the amount of nutrients made a difference, was a lower mortality rate at 30 days when patients were given a combination of enteral and parenteral nutrition, but this effect did not extend to 90 or 180 days.²⁷

A recent large prospective study conducted in patients who were critically ill demonstrated that the administration of enteral glutamine supplemented with parenteral glutamine correlated with an increase in hospital mortality, 28-day mortality, and 6-month mortality.³² A subsequent meta-analysis of this and similar studies concluded, "Enteral glutamine supplementation does not confer significant clinical benefit in critically ill patients, with the exception of reduced hospital stay. There may be a significant benefit in patients with burns, but data are sparse, and larger randomized trials are warranted to confirm this effect."³³ Preoperative nutritional support should be reserved for malnourished patients undergoing major elective surgery; this recommendation is not commonly followed for a variety of reasons, but, if time permits, improvement in nutritional status is associated with an improvement in outcome.

Most patients do not need nutritional support, and clear-cut benefits of this expensive intervention have been established for only a select group of patients (**Table 36.2**). Patients not expected to resume adequate oral feedings within 7 to 10 days of surgery should begin nutritional support within 2 to 4 days postoperatively, within 1 to 2 days if they are in an ICU. Although the benefits of parenteral nutrition in the perioperative period are controversial, postoperative enteral feeding has been shown to decrease complication rates in malnourished patients, although mortality rates are unchanged.²⁸

TABLE 36.2

Established indications for use of nutritional support^a

- Major elective surgery in severely malnourished patients
- Major trauma (blunt or penetrating injury, head injury)
- Burns
- Hepatic dysfunction

- Renal dysfunction
- Bone marrow transplant recipients undergoing intensive chemotherapy
- Patients unable to eat or absorb nutrients for an indefinite period (neurologic impairment, pharyngeal dysfunction, or short bowel syndrome)
- Well-nourished, minimally stressed patients unable to eat for 7-10 days

^aAdapted from Souba WW. Nutritional support. *N Engl J Med.* 1997;336:41-48.

Severely injured patients, burn patients, and those with sepsis often are hypermetabolic, so directed nutritional support within 24 to 48 hours of admission may be beneficial. For example, energy requirements may double, and protein requirements may triple in severely burned patients.

Minimally stressed patients require about 25 to 30 cal/kg and 1 g/kg of protein daily to remain in nitrogen and energy equilibrium. Moderately to severely stressed patients should be resuscitated first and then started on a hypocaloric regimen (20 cal/kg) until the stress response abates. Lipid calories from infusions of propofol may be significant and should be included when calculating caloric intake.

Enteral Nutrition

Unless contraindicated (eg, short gut syndrome, circulatory shock), enteral nutrition is preferred over parenteral nutrition in almost every circumstance for the reasons mentioned earlier. Three decades ago, it was thought that the main goal of nutrition support in the hospitalized patient was to meet energy requirements so that an anabolic state would ensue. Current goals include meeting and attenuating the metabolic response to stress and, in addition, attenuating cellular injury and modulating the immune response to injury. Nutritional support of the moderately to severely injured patient includes enteral nutrition started sooner rather than later, pharmacotherapy (the provision of nutrients that modulate the body's response to injury), and glycemic control. Delivering early nutrition support, primarily using the enteral route, is seen as a proactive therapeutic strategy that *may* reduce disease severity, diminish complications, decrease LOS, and favorably impact patient outcome after severe injury. A variety of enteral solutions containing various amounts of protein (amino acids), carbohydrates (glucose), fat (medium- and long-chain triglycerides), micronutrients, macronutrients, and electrolytes are available. No single formulation has been found to be ideal for all patients. Carbohydrates can be the source of up to 90% of the calories, which increases the osmolarity of these solutions. Fat has a higher caloric density than do carbohydrates, and because it does not increase the osmolarity of the formula as much as carbohydrates, iso-osmolar solutions can be constituted. Unless the patient has malabsorption or maldigestion of fat (and even then a formula containing medium-chain triglycerides can be tried), formulas with a normal range of fat content (~30%) are preferred. Selection of a formula that provides sufficient total nitrogen as protein (1-1.5 g protein/kg per day) or amino acids is essential for all patients. It was once thought that low-protein formulations were indicated for patients with severe renal dysfunction; however, we now recognize that these patients require the same amount of protein as do other patients, even if one has to resort to some form of hemodialysis to maintain homeostasis. Specialized formulas are available for nutritional deficiencies associated with renal disease, but they are rarely indicated. The same can be said for patients with liver disease—standard enteral formulas work well. The only exception is the patient with hepatic encephalopathy for whom an enteral or parenteral formula containing branched-chain amino acids may improve the encephalopathy. Increased amounts of protein are indicated when the nitrogen requirement is increased, as in patients with trauma, burns, or sepsis. The efficient use of protein for anabolism depends on adequate caloric intake and implementation of an exercise program.

Enteral Tube Feeding

Enteral tube feeding may be necessary when patients are unable to orally consume nutritionally complete, liquefied food. Commercial formulations of natural foods can be so finely suspended that they pass through small-bore tubes. Defined-formula diets are necessary when luminal hydrolysis or absorption is impaired, as in malabsorption syndromes. An important consideration when using enteral nutrition is placement and positioning of the small-bore (8-12F) silastic delivery tube. Most often, patients receive continuous infusions

of enteral nutrition through a nasoenteric tube positioned in the stomach, duodenum, or jejunum. Several groups of investigators have studied whether there is a clinical significance between gastric and postpyloric feeding in various medical and surgical ICU settings. Two meta-analyses of these studies did not show a difference in the incidence of pneumonia whether the feeding tube was in the stomach or through the pylorus, nor was there a difference in mortality based on the position of the feeding tube.^{34,35} A more recent meta-analysis demonstrated similar findings,³⁶ as did a 2019 retrospective study of more than 100 patients.³⁷

Surgical placement of an esophagostomy or gastrostomy tube may be indicated for long-term feeding. For continuous enteral feeding, an automated infusion pump to control the rate of administration of the nutritional formula is useful. Absorption and tolerance are improved, and the incidence of side effects is decreased by continuous feedings. The rate of infusion is typically 60 to 90 mL per hour. This rate of infusion prevents the dumping syndrome, which may occur when hyperosmolar solutions are introduced rapidly into the small intestine.

Side Effects

Intolerance

There is a correlation between feeding intolerance and side effects, which include increased duration of time on a ventilator, greater LOS, and increased mortality.³⁸ Enteral feeding is frequently stopped when patients exhibit bloating or distention, emesis, distended abdomen on physical exam, absence of flatus, or abnormal findings on abdominal radiographs. Gastric residual volume (GRV) is frequently used as a surrogate for small intestinal intolerance in the absence of symptoms or physical findings, and in a recent survey of ICU nurses, 45% considered a GRV of less than 200 mL a reason to hold feedings.³⁹ However, nutrition specialists do not recommend interrupting enteral feedings for a GRV of less than 500 mL in the absence of other symptoms or signs of intolerance. A single measurement of an elevated GRV does not necessarily require cessation of enteral feedings, but a thorough exam should be conducted to ensure that the etiology of the intolerance would necessitate holding the feedings.⁴⁰

Because of the disparity of what is recommended based on expert opinion and what clinicians practice, there is a need for more objectivity as to when to stop enteral feedings.³⁸ Current guidelines call for the use of drugs that promote gastrointestinal motility (see [Chapter 35](#)) when GRV is increased and, if the response is inadequate, to decrease the rate of enteral feedings until the cause of the intolerance is identified and treated.^{7,8}

Diarrhea

The presence of diarrhea is always a concern, but one should consider alternative explanations before deciding that the diarrhea is caused by the osmolarity of the enteral product. Even if it is, osmotic diarrhea is usually relatively benign and short lasting. Osmotic diarrhea in this situation is a diagnosis of exclusion, and one must try to identify other causes, for example, *Clostridium difficile* infection.⁴¹ The Infectious Diseases Society of America and Society for Healthcare Epidemiology of America have recommended that, in institutions without guidelines on whom should be tested, a stool specimen should be tested for glutamate dehydrogenase antigen and toxin arbitrated by a nucleic acid amplification test. In institutions that have guidelines on whom should be tested for *C difficile* (unexplained, new onset, ≥ 3 unformed stools in 24 hours), a nucleic acid amplification test alone is sufficient.⁴² If these tests are not diagnostic, other causes of diarrhea should be considered, for example, enteral medications containing sorbitol or infections other than *C difficile*. The latter is diagnosed by sending stool for an assessment for fecal leukocytes, and, if positive, stool should be cultured. If clinically indicated, serum electrolyte levels should be measured to identify excessive loss or signs of dehydration.

Pulmonary aspiration is always a danger when enteral tube feeding is used. Patients should be maintained in a semisitting position (head of bed elevated 30 degrees), and, in patients at the highest risk for aspiration, the feeding tube should be placed through the pylorus. Preparations containing large amounts of electrolytes should be administered cautiously to patients with cardiovascular, renal, or hepatic disease. Many

commercial formulas contain large amounts of sodium. Dry preparations mixed with water are excellent culture media unless they are kept sterile and refrigerated.

PARENTERAL NUTRITION

Parentral nutrition is indicated for patients who are unable to ingest or digest nutrients or to absorb them from the gastrointestinal tract. Parenteral nutrition using isotonic solutions delivered through a peripheral vein is acceptable when the patient requires less than 2,000 calories daily and the anticipated need for nutritional support is brief. Peripheral veins do not tolerate infusion of solutions with an osmolarity that exceeds 750 mOsm/L (equivalent to 12.5% glucose), thus limiting the number of calories that can be administered. When nutritional requirements are greater than 2,000 calories daily or prolonged nutritional support is required, a catheter is placed in the central venous system to permit infusion of a hypertonic (1,900 mOsm/L) nutrition solution.

Short-Term Parenteral Therapy

Short-term parenteral therapy (3–5 days in patients without nutritional deficits) after uncomplicated surgical procedures is most often provided by hypocaloric, nonnitrogen, glucose-electrolyte solutions. For example, glucose solutions, 5% to 10%, with supplemental sodium, chloride, and other electrolytes, are commonly administered for short-term therapy. These solutions provide total fluid and electrolyte needs and sufficient calories to decrease protein catabolism and prevent ketosis. For example, daily infusion of approximately 150 g of glucose maintains brain and erythrocyte metabolism and decreases protein catabolism from skeletal muscles and viscera.

Amino acids may have a greater protein-sparing effect than does glucose, but amino acids without glucose do not completely prevent negative nitrogen balance after major surgery. The higher cost of amino-acid solutions relative to potential benefit has prevented their popularity for use in place of glucose for short-term therapy.

Peripheral infusion of fat emulsions may be administered as a nonprotein source of calories to augment those supplied by glucose.

Long-Term Total Parenteral Nutrition

The TPN (IV hyperalimentation) is the technique of providing total nutrition needs by infusion of amino acids combined with glucose and varying amounts of lipids. Lean body mass is preserved, wound healing may be enhanced, and there may even be improvement of an impaired immune-response mechanism.

The TPN solutions contain a large proportion of calories from glucose and thus are hypertonic. For this reason, these solutions must be infused into a central vein with a high blood flow to provide rapid dilution. A catheter is often placed percutaneously into the subclavian vein and guided into the right atrium. The parenteral nutrition solution is usually infused continuously over 24 hours. Because the solutions in current use are not nearly as hypertonic and hypercaloric as they once were, there is little concern about the patient becoming hypoglycemic if the infusion is discontinued abruptly but the potential for hypoglycemia should be considered.

Serum electrolytes, blood glucose concentrations, and blood urea nitrogen levels should be measured periodically during TPN. Tests of hepatic and renal function are also recommended but can be performed at less frequent intervals.

Side Effects

The side effects of TPN include infectious, mechanical, and metabolic complications. Among infectious complications, catheter-related sepsis is one of the most common and is associated with significant morbidity. The mechanical complications, such as pneumothorax and thrombosis if the catheter is left in place for extended periods, are complications related to the placement of a central line and with which anesthesiologists are familiar. A number of metabolic complications are seen more often with parenteral nutrition than with enteral nutrition ([Table 36.3](#)).

TABLE 36.3**Metabolic complications of parenteral nutrition**

Early complications	Late complications
Volume overload	Metabolic bone disease
Hyperglycemia	Hepatic steatosis
Hypophosphatemia (refeeding syndrome)	Hepatic cholestasis
Hypokalemia	Trace mineral deficiency
Hypomagnesemia	Vitamin deficiency
Hyperchloremic acidosis	

Sepsis

The TPN solutions infused through an IV catheter can support the growth of bacteria and fungi. A spiking temperature most likely reflects contamination via the delivery system or catheter. The catheter should be removed, and the tip cultured to determine the appropriate antibiotic therapy. In view of the hazard of contamination, the use of a central venous hyperalimentation catheter for administration of medications, as during the perioperative period, or for sampling of blood is not recommended.

Fatty Acid Deficiency

Fatty acid deficiency may develop during prolonged TPN but only if intralipid is not administered as part of a 3-in-1 formulation (protein, glucose, lipid). Possible immunosuppressive effects of lipid emulsions and an increased incidence of infections have led to recommendations to limit fat calories to about 30% of total TPN calories.

Hyperglycemia

Blood glucose concentrations should be monitored until glucose tolerance is demonstrated, which usually occurs after 2 to 3 days of therapy as endogenous insulin production increases. In addition, blood glucose concentrations should be periodically monitored during the perioperative period in patients maintained on TPN. The degree of hyperglycemia accompanying TPN is directly related to the rate of glucose infusion and to the degree of stress. A number of organizations have made recommendations on target glucose levels for patients undergoing an operation or in the ICU. The majority recommend a blood glucose target of 110 to 180 mg/dL,^{43,44} with some recommending lower levels of less than 150 mg/dL for cardiac surgical patients; however no benefit has been shown to more strict blood glucose control but with an increase in episodes of hypoglycemia.⁴⁵

Hypoglycemia

Accidental sudden discontinuation of the infusion of TPN solutions containing large amounts of glucose (catheter kink or disconnection) may cause hypoglycemia. The TPN infusions should be discontinued gradually over 60 to 90 minutes. Hypoglycemia occurs because the pancreatic insulin response does not always cease in parallel with discontinuation of the TPN solution. As a result, a high plasma concentration of insulin may persist in the absence of continued infusion of glucose. If administration of the TPN solution must be stopped abruptly, exogenous glucose should be infused for up to 90 minutes to prevent hypoglycemia. The incidence of hypoglycemia has decreased because clinicians have a lower daily caloric goal (eg, 1,400-2,000 kcal per day) compared with prior therapies (3,000-4,000 kcal per day).

Hepatobiliary Complications

Excessive caloric intake is associated with hepatic steatosis and steatohepatitis. An increased alkaline phosphatase or serum bilirubin concentrations warrant additional evaluation (eg, cholehepatic ultrasound).

Metabolic Acidosis

Hyperchloremic metabolic acidosis may occur because most of the amino acids in TPN are administered as their chloride salts.

Hypercarbia

In a patient with inadequate respiratory reserve, respiratory failure can develop when excessive carbohydrate calories are administered because of the increased carbon dioxide production. Because glucose has a respiratory quotient of 1, excessive glucose has been blamed on the respiratory failure associated with TPN, but we now know that excessive calories per se independent of their source increase carbon dioxide production and lead to respiratory failure in susceptible patients.

Monitoring During TPN

Acutely ill patients receiving TPN must be followed closely for the development of treatment-related complications. Access sites should be observed for signs of infection. Substitution of sodium or potassium acetate (metabolized to bicarbonate) for sodium or potassium chloride may be helpful should signs of hyperchloremic metabolic acidosis appear. Plasma triglyceride concentrations may increase in patients with diabetes mellitus, sepsis, and impaired hepatic or renal function. Vitamin K may need to be added to the TPN or administered intravenously based on measurement of prothrombin and plasma thromboplastin times. Monitoring of daily caloric intake, to ensure that caloric goals are being met, and fluid intake and output is needed as patients who are critically ill often experience significant fluid shifts.

Preparation of TPN Solutions

The TPN solutions are prepared from commercially available solutions by mixing hypertonic glucose with an amino acid solution. Sodium, potassium, phosphorus, calcium, magnesium, and chloride are added to the TPN solution. Trace elements, including zinc, copper, manganese, chromium, and selenium, must also be added if the need for parenteral therapy is prolonged. Requirements for vitamins may be increased, emphasizing the need to add a multivitamin preparation to TPN solutions. Vitamin B₁₂ and folic acid may be administered as components of a multivitamin preparation or separately. Vitamin D should be used sparingly because metabolic bone diseases may be associated with use of this vitamin in some patients on long-term TPN. Vitamin K can be administered separately once every week. The U.S. Food and Drug Administration (FDA) disallowed routine addition of vitamin K to TPN because of concern about side effects, and its routine administration would complicate the use of anticoagulants such as warfarin in patients who require such therapy. The serum albumin concentration will usually increase over several days to weeks as the stress response abates and if patients receive adequate nutrition support. The administration of supplemental albumin is not necessary in the absence of symptoms or signs of hypoalbuminemia, which usually do not occur until the serum albumin concentration is less than 2.4 g/dL.

Lipid emulsions can be administered separately or together with the glucose and amino acids to create a 3-in-1 TPN solution, as mentioned previously. To decrease the possibility of bacterial contamination, TPN solutions should be prepared aseptically under a laminar airflow hood, refrigerated, and administered within 24 to 48 hours.

Immunonutrition

Cellular immunity decreases during acute stress, as may accompany multiple organ system failure, sepsis, and shock. Immunonutrition is an attempt to enhance immunity and cellular integrity by incorporating specific additives (ω -3 fatty acids, arginine to enhance lymphocyte cytotoxicity, purines as a precursor of RNA and DNA, and antioxidants) into enteral diets. Currently, no well-controlled clinical studies have demonstrated improved outcomes with immunonutrition in patient populations that might benefit from their use, and there are no clinical guidelines that recommend their routine use in these patient populations.

Vitamins, Dietary Supplements, and Herbal Remedies

Vitamins

Vitamins are a group of structurally diverse organic substances (water soluble or fat soluble) that must be provided in small amounts in the diet for subsequent synthesis of cofactors that are essential for various metabolic reactions (**Table 36.4**). Food is the best source of vitamins, and healthy persons consuming an adequate balanced diet will not benefit from supplemental vitamins. Nevertheless, many persons do not consume adequate amounts of vitamin-rich foods, especially patients with alcoholism and malabsorption syndromes, older adults, and the economically disadvantaged.

TABLE 36.4

Vitamins

	Function	Deficiency	Toxic effects	Sources
Thiamine (B ₁)	Metabolism of carbohydrates, alcohol, amino acids	Beriberi Wernicke-Korsakoff syndrome	None	Grains Legumes Poultry Meat
Riboflavin (B ₂)	Cellular oxidation-reduction reactions	Stomatitis Dermatitis Anemia	None	Grains Dairy products Meat Eggs Green vegetables
Nicotinic acid (niacin; B ₃)	Oxidative metabolism Decreases LDL cholesterol Increases HDL cholesterol	Pellagra	Flushing Headaches Pruritus Hyperglycemia Hyperuricemia	Meat Poultry Fish Grains Peanuts Tryptophan in foods
Pyridoxine (B ₆)	Amino acid metabolism Heme synthesis Neuronal excitability Decreases blood homocysteine levels	Anemia Cheilosis Dermatitis	Neurotoxicity	Liver Poultry Fish Grains Bananas
Pantothenic acid	Metabolic processes	Rare	None	Many foods
B ₁₂ (cobalamin, cyanocobalamin)	DNA synthesis Myelin synthesis Decreases blood homocysteine levels	Megaloblastic anemia Peripheral neuropathies	None	Liver Poultry Fish Dairy products
Folic acid	DNA synthesis Decreases blood homocysteine levels	Megaloblastic anemia Birth defects	None	Legumes Grains Fruit Poultry Meat
Ascorbic acid (C)	Collagen synthesis Possible protection against certain cancers	Scurvy	Nephrolithiasis Diarrhea	Fruits Green vegetables Potatoes Cereals

A (retinol, retinoic acid)	Vision Epithelial integrity	Night blindness Susceptibility to infection	Teratogenicity Hepatotoxicity Cerebral edema	Liver Dairy products Green vegetables
D (calciferol)	Intestinal calcium absorption	Osteomalacia Rickets	Hypercalcemia	Dairy products Fish Eggs Liver
E (tocopherol)	Decreases peroxidation of fatty acids Possible protection against atherosclerosis	Rare	Antagonism of vitamin K Headaches	Vegetable oils Wheat germ Nuts
K	Synthesis of clotting factors (VII, IX, X)	Hemorrhagic diathesis	None	Green vegetables Intestinal bacteria

Abbreviations: HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Antioxidant vitamins can retard atherogenesis, and antioxidants may lower the risk of carcinogenesis. There is a demonstrated relationship between low dietary intake of antioxidants or low plasma concentrations of antioxidants and an increased risk of atherosclerosis and cancer. Studies have linked low plasma concentrations of folic acid, vitamin B₆, and vitamin B₁₂ with increased plasma concentrations of homocysteine and increased cardiovascular risks. A vitamin supplement that combines antioxidants with zinc can slow progression of macular degeneration. Individuals who consume multivitamins appear to have a decreased risk of cardiovascular disease and colon cancer, which may represent protection from folic acid and the B vitamins.

It is clear that additional information and studies are necessary to clarify the need for vitamin supplements in the presence of an adequate diet. The present recommendation is for parturients, older adults, and those individuals receiving a suboptimal nutritional diet to take a single multivitamin tablet daily. Strict vegetarians should take vitamin B₁₂ supplements.

Use of megadose vitamin preparations is not encouraged. Brand name and so-called all-natural preparations are no more effective than generic vitamin preparations. Regardless, vitamin supplements should never be used as a substitute for a balanced healthful diet that provides abundant quantities of vitamin-rich foods.

Water-Soluble Vitamins

Water-soluble vitamins include members of the vitamin B complex (thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, biotin, cyanocobalamin, folic acid) and ascorbic acid (vitamin C) ([Figure 36.1](#)).

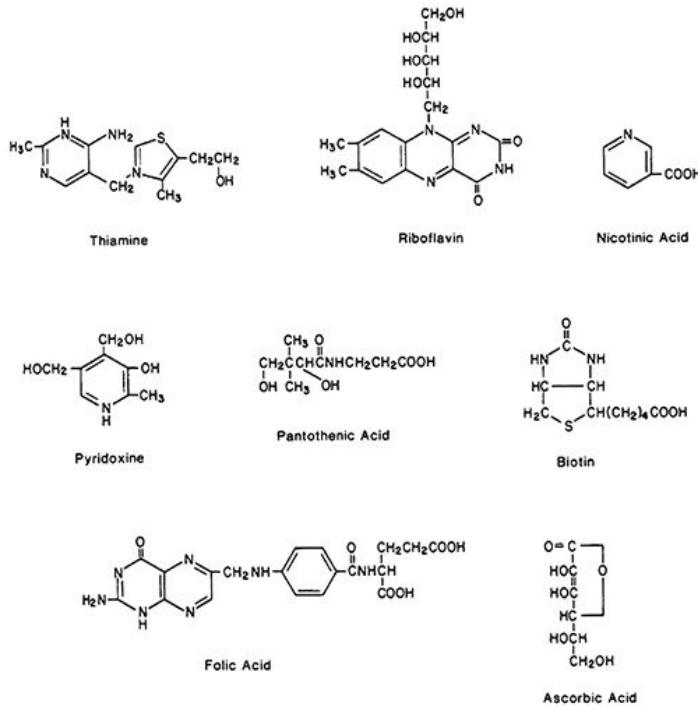

FIGURE 36.1 Chemical structure of water-soluble vitamins.

Thiamine

Thiamine (vitamin B₁) is converted to a physiologically active coenzyme known as *thiamine pyrophosphate*. This coenzyme is essential for the decarboxylation of α-keto acids such as pyruvate and in the use of pentose in the hexose-monophosphate shunt pathway. Increased plasma concentrations of pyruvate are a diagnostic sign of thiamine deficiency.

Causes of Deficiency

The requirement for thiamine is related to the metabolic rate and is greatest when carbohydrate is the source of energy. This is important in patients maintained by hyperalimentation in which the majority of calories are provided in the form of glucose. Such patients should receive supplemental amounts of thiamine. Thiamine requirements are also increased during pregnancy and lactation and in patients with chronic alcoholism.

Symptoms of Deficiency

Symptoms of mild thiamine deficiency (beriberi) include loss of appetite, skeletal muscle weakness, a tendency to develop peripheral edema, decreased systemic blood pressure, and low body temperature. Severe thiamine deficiency (Korsakoff syndrome), which may occur in alcoholics, is associated with peripheral polyneuritis, including areas of hyperesthesia and anesthesia of the legs, impairment of memory, and encephalopathy. High-output cardiac failure with extensive peripheral edema reflecting hypoproteinemia is often prominent. There is flattening or inversion of the T-wave prolongation of the QTc interval on the electrocardiogram.

Treatment of Deficiency

Severe thiamine deficiency is treated with IV administration of the vitamin. Once severe thiamine deficiency has been corrected, oral supplementation is acceptable.

Riboflavin

Riboflavin (vitamin B₂) is converted in the body to one of two physiologically active coenzymes: flavin mononucleotide or flavin adenine dinucleotide. Because of their ability to “accept” two hydrogen atoms, these coenzymes primarily influence hydrogen ion transport in oxidative enzyme systems, including cytochrome C reductase, succinic dehydrogenase, and xanthine oxidase.

Symptoms of Deficiency

Pharyngitis and angular stomatitis are typically the first signs of riboflavin deficiency. Later, glossitis, red denuded lips, seborrheic dermatitis of the face, and dermatitis over the trunk and extremities occur. Riboflavin deficiency is classically associated with angular cheilitis, photophobia, and scrotal dermatitis—the oral-ocular-genital syndrome. Anemia and peripheral neuropathy may be prominent. Corneal vascularization and cataract formation occur in some subjects. Treatment is with oral vitamin supplements that contain riboflavin.

Nicotinic Acid

Nicotinic acid (niacin; B₃) is converted to the physiologically active coenzyme nicotinamide adenine dinucleotide (NAD) and NAD phosphate; NAD is converted to NAD phosphate by phosphorylation. These coenzymes are necessary to catalyze oxidation-reduction reactions essential for tissue respiration.

Symptoms of Deficiency

Nicotinic acid is an essential dietary constituent, the lack of which leads to nausea, skin and mouth lesions, anemia, headaches, and tiredness. Chronic niacin deficiency is manifested by pellagra in which the skin characteristically becomes erythematous and rough in texture, especially in areas exposed to sun, friction, or pressure. The chief symptoms referable to the digestive tract are stomatitis, enteritis, and diarrhea. The tongue becomes very red and swollen. Salivary secretions are excessive, and nausea and vomiting are common. In addition to dementia, motor and sensory disturbances of the peripheral nerves also occur, mimicking changes that accompany a deficiency of thiamine.

The dietary requirement for niacin can be satisfied not only by nicotinic acid but also by nicotinamide and the amino acid tryptophan. The relationship between nicotinic acid requirements and the intake of tryptophan explains the association of pellagra with tryptophan-deficient corn diets. Carcinoid syndrome is associated with diversion of tryptophan from the synthesis of nicotinic acid to the production of serotonin (5-hydroxytryptamine), leading to symptoms of pellagra. Isoniazid inhibits incorporation of nicotinic acid into NAD and may produce pellagra.

Pellagra is uncommon in the United States, reflecting the supplementation of flour with nicotinic acid. Common causes of pellagra include chronic gastrointestinal disease and alcoholism, which are characteristically associated with multiple nutritional deficiencies. When pellagra is severe, IV administration of nicotinic acid is indicated. In less severe cases, oral administration of nicotinic acid is adequate. The response to nicotinic acid is dramatic, with symptoms waning within 24 hours after initiation of therapy.

Toxic effects of nicotinic acid include flushing, pruritus, hepatotoxicity, hyperuricemia, and activation of peptic ulcer disease. Nicotinic acid has also been prescribed to decrease the plasma concentrations of cholesterol and to increase the concentration of high-density lipoprotein.

Pyridoxine

Pyridoxine (vitamin B₆) is converted to its physiologically active form, pyridoxal phosphate, by the enzyme pyridoxal kinase. Pyridoxal phosphate serves an important role in metabolism as a coenzyme for the conversion of tryptophan to serotonin and methionine to cysteine.

Symptoms of Deficiency

Pyridoxine deficiency is uncommon and, when present, is associated with deficiencies of other vitamins and, if seen, is more likely to be seen in older adults, patients with alcoholism, and patients who are severely malnourished. Other patients who are at increased risk for manifesting deficiency are those with chronic renal failure on dialysis, those with hepatic failure, patients with rheumatoid arthritis, women with type 1 diabetes,

and those patients infected with human immunodeficiency virus. Certain drugs such as anticonvulsants and corticosteroids can interfere with pyridoxine metabolism, as can isoniazid, cycloserine, penicillamine, and hydrocortisone. Seizures accompanying deficiency of pyridoxine and peripheral neuritis such as carpal tunnel syndrome are common. The lowered seizure threshold may reflect decreased concentrations of the inhibitory neurotransmitter γ -aminobutyric acid, the synthesis of which requires a pyridoxal phosphate-requiring enzyme.

As described previously, a person with a deficiency of pyridoxine may also have a deficiency of the other B vitamins.

Drug Interactions

Isoniazid and hydralazine act as potent inhibitors of pyridoxal kinase, thus preventing synthesis of the active coenzyme form of the vitamin. Indeed, administration of pyridoxine decreases the incidence of neurologic side effects associated with the administration of these drugs. Pyridoxine enhances the peripheral decarboxylation of levodopa and decreases its effectiveness for the treatment of Parkinson disease. There is a decrease in the plasma concentration of pyridoxal phosphate in patients taking oral contraceptives.

Pantothenic Acid

Pantothenic acid is converted to its physiologically active form, coenzyme A, which serves as a cofactor for enzyme-catalyzed reactions involving transfer of two carbon (acetyl) groups. Such reactions are important in the oxidative metabolism of carbohydrates, gluconeogenesis, and the synthesis and degradation of fatty acids.

Pantothenic acid deficiency in humans is rare, reflecting the ubiquitous presence of this vitamin in ordinary foods as well as its production by intestinal bacteria. No clearly defined uses of pantothenic acid exist, although it is commonly included in multivitamin preparations and in hyperalimentation solutions.

Biotin

Biotin is an organic acid that functions as a coenzyme for enzyme-catalyzed carboxylation reactions and fatty acid synthesis. In adults, a deficiency of biotin manifests as glossitis, anorexia, dermatitis, and mental depression. Seborrheic dermatitis of infancy is most likely a form of biotin deficiency. For this reason, it is recommended that formulas contain supplemental biotin.

Cyanocobalamin

Cyanocobalamin (cobalamin, vitamin B₁₂) and vitamin B₁₂ are generic designations that are used interchangeably to describe several cobalt-containing compounds (cobalamins). Dietary vitamin B₁₂ in the presence of hydrogen ions in the stomach is released from proteins and subsequently binds to a glycoprotein intrinsic factor. This vitamin-intrinsic factor complex travels to the ileum, where it interacts with a specific receptor and is then transported across the intestinal endothelium. After absorption, vitamin B₁₂ binds to a β -globulin, transcobalamin II, for transport to tissues, especially the liver, which serves as its storage depot.

Causes of Deficiency

Although humans depend on exogenous sources of vitamin B₁₂, a deficient diet is rarely the cause of a deficiency state. Instead, gastric achlorhydria and decreased gastric secretion of intrinsic factor are more likely causes of vitamin B₁₂ deficiency in adults. Antibodies to intrinsic factor may interfere with attachment of the complex to gastrin receptors in the ileum. Bacterial overgrowth may also prevent an adequate amount of vitamin B₁₂ from reaching the ileum. Surgical resection or disease of the ileum predictably interferes with the absorption of vitamin B₁₂. Nitrous oxide irreversibly oxidizes the cobalt atom of vitamin B₁₂ such that the activity of two vitamin B₁₂-dependent enzymes, methionine synthetase and thymidylate synthetase, are decreased.

Diagnosis of Deficiency

The plasma concentration of vitamin B₁₂ (cobalamin) is less than 200 pg/mL when there is a deficiency state. Measurements of gastric acidity may provide indirect evidence of a defect in gastric parietal cell function, whereas the Schilling test (radioactivity in the urine measured after oral administration of labeled vitamin B₁₂) can be used to quantify ileal absorption of vitamin B₁₂. Observation of reticulocytosis after a therapeutic trial of vitamin B₁₂ confirms the diagnosis.

Symptoms of Deficiency

Deficiency of vitamin B₁₂ results in defective synthesis of DNA, especially in tissues with the greatest rate of cell turnover. In this regard, symptoms of vitamin B₁₂ deficiency manifest most often in the hematopoietic and nervous systems. Changes in the hematopoietic system are most apparent in erythrocytes, but when vitamin B₁₂ deficiency is severe, a pronounced cytopenia may occur. Clinically, the earliest sign of vitamin B₁₂ deficiency is megaloblastic (pernicious) anemia. Anemia may be so severe that cardiac failure occurs, especially in older adults with limited cardiac reserves.

Encephalopathy is a well-recognized complication of vitamin B₁₂ deficiency, manifesting as myelopathy, optic neuropathy, and peripheral neuropathy, either alone or in any combination. Neurologic complications do not parallel the presence of megaloblastic anemia. Damage to the myelin sheath is the most obvious symptom of nervous system dysfunction associated with vitamin B₁₂ deficiency. Demyelination and cell death occur in the spinal cord and cerebral cortex, manifesting as paresthesias of the hands and feet and diminution of sensation of vibration and proprioception with resultant unsteadiness of gait. Deep tendon reflexes are decreased, and, in advanced states, loss of memory and mental confusion occur. Indeed, vitamin B₁₂ deficiency should be considered in older adults with psychosis. Folic acid therapy corrects the hematopoietic, but not nervous system, effects produced by vitamin B₁₂ deficiency.

Treatment of Deficiency

Vitamin B₁₂ is available in a pure form for oral or parenteral use or in combination with other vitamins for oral administration. These preparations are of little value in the treatment of patients with deficiency of intrinsic factor or ileal disease. In the presence of clinically apparent vitamin B₁₂ deficiency, oral absorption is not reliable; the preparation of choice is cyanocobalamin administered intramuscularly. For example, in the patient with neurologic changes, leukopenia, or thrombocytopenia, treatment must be aggressive. Initial treatment is with intramuscular administration of vitamin B₁₂ and oral administration of folic acid. An increase in the hematocrit does not occur for 10 to 20 days. The plasma concentration of iron, however, usually declines within 48 hours because iron is now used in the formation of hemoglobin. Platelet counts can be expected to reach normal levels within days of initiating treatment; the granulocyte count requires a longer period to normalize. Memory and sense of well-being may improve within 24 hours after initiation of therapy. Neurologic signs and symptoms that have been present for prolonged periods, however, often regress slowly and may never return to completely normal function. Indeed, neurologic damage after pernicious anemia develops that is not reversed after 12 to 18 months of therapy is likely to be permanent. Once initiated, vitamin B₁₂ therapy must be continued indefinitely at monthly intervals. It is important to monitor plasma concentrations of vitamin B₁₂ and examine the peripheral blood cells every 3 to 6 months to confirm the adequacy of treatment.

Hydroxocobalamin has hematopoietic activity similar to that of vitamin B₁₂ but appears to offer no advantage despite its somewhat longer duration of action. Furthermore, some patients develop antibodies to the complex of hydroxocobalamin and transcobalamin II. Large doses of hydroxocobalamin have been approved for treatment of cyanide poisoning due to nitroprusside. Conceptually, cyanide reacts with the cobalt in cyanocobalamin, decreasing cyanide ion concentration.

Folic Acid

Folic acid is transported and stored as 5-methyltetrahydrofolate after absorption from the small intestine, principally the jejunum. Conversion to the metabolically active form, tetrahydrofolate, is dependent on the

activity of vitamin B₁₂. Tetrahydrofolate acts as an acceptor of 1-carbon units necessary for (1) conversion of homocysteine to methionine, (2) conversion of serine to glycine, (3) synthesis of DNA, and (4) synthesis of purines. Supplies of folic acid are maintained by ingestion of food and by enterohepatic circulation of the vitamin. Virtually, all foods contain folic acid, but protracted cooking can destroy up to 90% of the vitamin.

Causes of Deficiency

Folic acid deficiency is a common complication of diseases of the small intestine, such as sprue, that interfere with absorption of the vitamin and its enterohepatic recirculation. Patients with alcoholism have reduced intake of folic acid because of their decreased intake of food, and enterohepatic recirculation may be impaired by the toxic effect of alcohol on hepatocytes. Indeed, alcoholism is the most common cause of folic acid deficiency, with decreases in the plasma concentrations of folic acid manifesting within 24 to 48 hours of continuous alcohol ingestion. Drugs that inhibit dihydrofolate reductase (methotrexate, trimethoprim) or interfere with absorption and storage of folic acid in tissues (phenytoin) may cause folic acid deficiency.

Symptoms of Deficiency

Megaloblastic anemia is the most common manifestation of folic acid deficiency. This anemia cannot be distinguished from that caused by a deficiency of vitamin B₁₂. Folic acid deficiency, however, is confirmed by the presence of a folic acid concentration in the plasma of less than 4 ng/mL. Furthermore, the rapid onset of megaloblastic anemia produced by folic acid deficiency (1-4 weeks) reflects the limited in vivo stores of this vitamin and contrasts with the slower onset (2-3 years) of symptoms and signs of vitamin B₁₂ deficiency.

Treatment of Deficiency

Folic acid is available as an oral preparation alone or in combination with other vitamins and either an oral preparation or as a parenteral injection. The therapeutic uses of folic acid are limited to the prevention and treatment of deficiencies. For example, pregnancy increases folic acid requirements, and oral supplementation, usually in a multivitamin preparation, is indicated. In the presence of megaloblastic anemia because of folic acid deficiency, the administration of the vitamin is associated with a decrease in the plasma concentration of iron within 48 hours, reflecting new erythropoiesis. Likewise, the reticulocyte count begins to increase within 48 to 72 hours, and the hematocrit begins to increase during the second week of therapy.

Folate Therapy

Vitamin therapy to lower homocysteine levels has been recommended for the prevention of restenosis after coronary angioplasty. This is based on the belief that homocysteine is thrombogenic and is a risk factor for coronary artery disease. Folate supplementation is an effective treatment of homocystinemia. There have been three Cochrane reviews of the literature on the benefits of folate therapy in cardiovascular disease, the most recent in 2017.⁴⁶ No benefit was found to vitamins B₆, B₉, or B₁₂ in lowering the incidence of myocardial infarction or death from any cause, although there was a lower incidence of stroke. Some have argued that it is reasonable to recommend folic acid to patients at risk for coronary artery disease, especially if they have kidney disease.⁴⁷

Leucovorin

Leucovorin (citrovorum factor) is a metabolically active, reduced form of folic acid. After treatment with folic acid antagonists, such as methotrexate, patients may receive leucovorin (rescue therapy), which serves as a source of tetrahydrofolate that cannot be formed due to drug-induced inhibition of dihydrofolate reductase.

Ascorbic Acid (Vitamin C)

Ascorbic acid is a six-carbon compound structurally related to glucose. This vitamin acts as a coenzyme and is important in a number of biochemical reactions, mostly involving oxidation. For example, ascorbic acid is necessary for the synthesis of collagen, carnitine, and corticosteroids. Ascorbic acid is readily absorbed from the gastrointestinal tract, and many foods, such as orange juice and lemon juice, have a high content of

ascorbic acid. When gastrointestinal absorption is impaired, ascorbic acid can be administered intramuscularly or intravenously. Apart from its role in nutrition, ascorbic acid is commonly used as an antioxidant to protect the natural flavor and color of many foods.

Despite contrary claims, there is little evidence to support the efficacy of even large doses of ascorbic acid in treating viral respiratory tract infections. A risk of large doses of ascorbic acid is the formation of kidney stones resulting from the excessive secretion of oxalate. Excessive ascorbic acid doses can also enhance the absorption of iron and interfere with anticoagulant therapy.

One and a half grams of vitamin C, along with 100 mg of thiamine and 50 mg of hydrocortisone every 6 hours, are used by some to treat the vasoplegia occasionally seen in patients following cardiopulmonary bypass. There is as much evidence to support this practice as there is to recommend methylene blue or hydroxocobalamin or angiotensin II to treat vasoplegia; that is to say, not very much. Clinicians, though, will resort to these modalities as a last ditch effort to treat septic shock or cardiogenic shock in patients who are not responding to catecholamines or vasopressin.⁴⁸

Symptoms of Deficiency

A deficiency of ascorbic acid is known as scurvy. Humans, in contrast to many other mammals, are unable to synthesize ascorbic acid, emphasizing the need for dietary sources of the vitamin to prevent scurvy. Specifically, humans lack the hepatic enzyme necessary to produce ascorbic acid from gluconate. Manifestations of scurvy include gingivitis, rupture of the capillaries with formation of numerous petechiae, and failure of wounds to heal. An associated anemia may reflect a specific function of ascorbic acid on hemoglobin synthesis. Scurvy is evident when the plasma concentration of ascorbic acid is less than 0.15 mg/dL.

Scurvy is encountered among older adults, alcoholics, and drug addicts. Ascorbic acid requirements are increased during pregnancy, lactation, and stresses such as infection or after surgery. Infants receiving formula diets with inadequate concentrations of ascorbic acid can develop scurvy. Patients receiving TPN should receive supplemental ascorbic acid. Urinary loss of infused ascorbic acid is large, necessitating daily doses of 200 mg to maintain normal concentrations in plasma of 1 mg/dL. Increased urinary excretion of ascorbic acid is caused by salicylates, tetracyclines, and barbiturates.

Fat-Soluble Vitamins

The fat-soluble vitamins are vitamins A, D, E, and K ([Figure 36.2](#)). They are absorbed from the gastrointestinal tract by a complex process that parallels absorption of fat. Thus, any condition that causes malabsorption of fat, such as obstructive jaundice, may result in deficiency of one or all these vitamins. Fat-soluble vitamins are stored principally in the liver and excreted in the feces. Because these vitamins are metabolized very slowly, overdose may produce toxic effects.

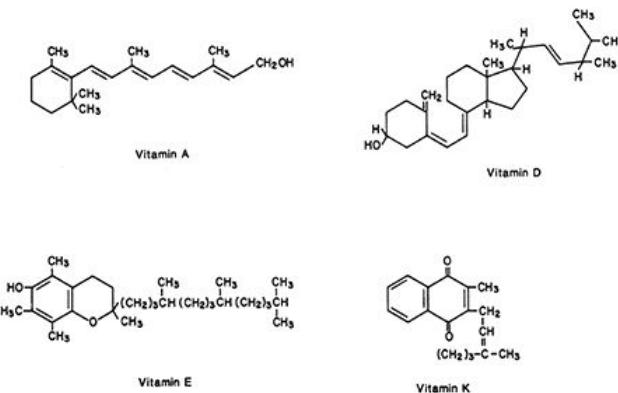

FIGURE 36.2 Chemical structure of fat-soluble vitamins.

Vitamin A (Retinol, Retinoic Acid)

Vitamin A exists in a variety of forms, including retinal and 3-dehydroretinal. This vitamin is important in the function of the retina, integrity of mucosal and epithelial surfaces, bone development and growth, reproduction, and embryonic development. It also has a stabilizing effect on various membranes and regulates membrane permeability. Vitamin A may exert transcriptional control of the production of specific proteins, a process that has important implications with respect to regulation of cellular differentiation and development of malignancies. Limitations in the therapeutic use of vitamin A for antineoplastic uses are the associated hepatotoxicity and its failure to distribute to specific organs.

Major dietary sources of vitamin A are liver, butter, cheese, milk, certain fish, and various yellow or green fruits and vegetables. Fish liver oils contain large amounts of vitamin A. Sufficient vitamin A is stored in the liver of well-nourished persons to satisfy requirements for several months. Plasma concentrations of vitamin A are maintained at the expense of hepatic reserves and thus do not always reflect a person's vitamin A status. Vitamin A may interact with cellular proteins, which function analogously to receptors for estrogens and other steroids.

Symptoms of Deficiency

Plasma concentrations of vitamin A of less than 20 µg/dL indicate the risk of deficiency. Most deficiencies occur in infants or children. Signs and symptoms of mild vitamin A deficiency are easily overlooked. Skin lesions such as follicular hyperkeratosis and infections are often the earliest signs of deficiency. Nevertheless, the most recognizable manifestation of vitamin A deficiency is night blindness (nyctalopia), which occurs only when the depletion is severe. Pulmonary infections are increased as mucous secretion from bronchial epithelium is decreased because the epithelial cells undergo keratinization. Keratinization and drying of the epidermis occurs. Urinary calculi are frequently associated with vitamin A deficiency, which may reflect epithelial changes that provide a nidus around which a calculus is formed. Abnormalities of reproduction include impairment of spermatogenesis and spontaneous abortion. Impairment of taste and smell is common in patients with vitamin A deficiency, presumably reflecting a keratinizing effect. Decreased erythropoiesis may be masked by abnormal losses of fluids.

Hypervitaminosis A

Hypervitaminosis A is the toxic syndrome that results from excessive ingestion of vitamin A, particularly in children. Typically, high vitamin A intake has resulted from overzealous prophylactic vitamin A therapy. Plasma concentrations of vitamin A of greater than 300 µg/dL are diagnostic of hypervitaminosis A. Treatment consists of withdrawal of the vitamin source, which is usually followed within 7 days by disappearance of the manifestations of excess vitamin A activity.

Early signs and symptoms of vitamin A intoxication include irritability, vomiting, and dermatitis. Fatigue, myalgia, loss of body hair, diplopia, nystagmus, gingivitis, stomatitis, and lymphadenopathy have been observed. Hepatosplenomegaly is accompanied by cirrhosis of the liver, portal vein hypertension, and ascites. Intracranial pressure may be increased, and neurologic symptoms, including papilledema, may mimic those of a brain tumor (pseudotumor cerebri). The diagnosis is confirmed by radiologic demonstration of hyperostoses underlying tender swellings on the extremities and the occipital region of the head. Plasma alkaline phosphatase concentrations are increased, reflecting osteoblastic activity. Hypercalcemia may occur because of bone destruction. Bones continue to grow in length but not in thickness, with increased susceptibility to fractures. Congenital abnormalities may occur in infants whose mothers have consumed excessive amounts of vitamin A during pregnancy. Psychiatric disturbances may mimic mental depression or schizophrenia.

Vitamin D

Vitamin D (calciferol) has two forms, D₂ (ergocalciferol) and D₃ (cholecalciferol), with identical chemical structure except that vitamin D₂ has an additional methyl group on carbon 24. Vitamin D₂ comes from the diet, whereas D₃ is synthesized in the skin by ultraviolet light's action on 7-dehydrocholesterol. Vitamin D₂ and D₃ are metabolically inert and require two chemical reactions to acquire activity. In hepatic cells, 25-hydroxylase adds a hydroxyl group to the molecule to form 25-hydroxyvitamin D or 25-(OH)D, and the

second reaction takes place in the kidney where 1α -hydroxylase converts 25-(OH)D to the biologically active 1,25(OH)₂ vitamin D (calcitriol), which regulates calcium and phosphate concentrations in the blood. A 25-(OH)D is transported in the blood by vitamin D-binding protein (DBP). Following its production in the kidney, calcitriol binds to DBP for transport to sites of action. A 25-(OH)D bound to DBP circulates in the blood, and when calcium levels decrease, 25-(OH)D is absorbed by the kidney and hydroxylated to the biologically active calcitriol and then released back into the bloodstream. The process is quite regulated, and, unless there is a need, calcitriol is not produced in the kidney. Traditionally, calcitriol has been thought to be the biologically active molecule and 25-(OH)D is a prohormone, but a study in knockout mice deficient in 1α -hydroxylase have demonstrated that sufficient calcium in diet can normalize serum calcium levels, presumably because of the action of 25-(OH)D.

Calcitriol exerts its effects by binding and activating vitamin D receptors (VDRs) in the nuclei of many different cell types. Calcitriol's primary function is to maintain calcium and phosphorous homeostasis. Calcium levels are maintained through three mechanisms: absorption of calcium in the duodenum and jejunum, release of calcium from bone, and increased uptake of calcium in the distal tubule of the kidney.

When phosphate levels are low, calcitriol increases its absorption in the small intestine, or, conversely, when phosphate levels are elevated, calcitriol acts on osteocytes to release fibroblast growth factor 23, which in turn increases the loss of phosphorous in the renal distal tubule.

The VDRs are identified in the nuclei of a wide variety of cells that do not play a role in calcium or phosphorus homeostasis, and it is not surprising then that vitamin D has a role in the regulation of many different genes.

Retrospective studies have shown a 21% reduction in mortality from cardiovascular disease and conversely a reduction by as much as 28% in mortality in those with vitamin D levels twice that of controls. However, supplementation with vitamin D to decrease the incidence of cardiovascular disease has not been shown, but there are advocates of such an approach to decrease the morbidity associated with cardiovascular disease.

Other studies have demonstrated a correlation between vitamin D concentrations and outcome in cancer patients. Calcitriol has a role in malignant disease, attenuating the proliferation of malignant cells through several mechanisms. Calcitriol may regulate the progression of malignant cell growth by suppressing the proto-oncogene myc, the cyclin-dependent kinases, and retinoblastoma protein phosphorylation and via interference of growth factor receptor-mediated signaling pathways. Calcitriol's impact on apoptosis may also have a role in its modulation of malignant cancerous cells.

Calcitriol may also influence immune function through similar metabolic pathways. In monocytes, calcitriol stimulates cathelicidin, a peptide with bactericidal and mycobactericidal properties. Calcitriol also inhibits the number and activity of T helper cells. These effects may be clinically important, with the former benefiting patients who are septic, and the latter, patients with myeloproliferative diseases.

Calcitriol might have a role in both type 1 and type 2 diabetes through its binding to the VDRs of pancreatic cells or through its effects on calcium metabolism. In addition to calcitriol's theoretical role in cardiovascular disease, cancer, immune function, and diabetes, it may also have an effect on morbidity and mortality patients who are critically ill.⁴⁹

Symptoms of Deficiency

A deficiency of vitamin D results in decreased plasma concentrations of calcium and phosphate ions, with the subsequent stimulation of parathyroid hormone secretion. Parathyroid hormone acts to restore plasma calcium concentrations at the expense of bone calcium. In infants and children, this results in failure to mineralize newly formed osteoid tissue and cartilage, causing formation of soft bone, which, with weight bearing, results in deformities known as rickets. In adults, vitamin D deficiency results in osteomalacia. Anticonvulsant therapy with phenytoin increases target organ resistance to vitamin D, resulting in an increased incidence of rickets and osteomalacia. There is evidence that vitamin D supplementation reduces the risk of falling among elderly individuals.

Hypervitaminosis D

Administration of excessive amounts of vitamin D results in hypervitaminosis, manifesting as hypercalcemia, skeletal muscle weakness, fatigue, headache, and vomiting. Early impairment of renal function from hypercalcemia manifests as polyuria, polydipsia, proteinuria, and decreased urine-concentrating ability. In addition to withdrawal of the vitamin, treatment includes increased fluid intake, diuresis, and administration of corticosteroids.

Vitamin E

Vitamin E (α -tocopherol) is not a single molecule but, rather, a group of fat-soluble substances occurring in plants. There is little persuasive evidence that vitamin E is nutritionally significant in humans. α -Tocopherol is the most abundant and important of the eight naturally occurring tocopherols that constitute vitamin E. An important chemical feature of the tocopherols is that they are antioxidants. In acting as an antioxidant, vitamin E presumably prevents oxidation of essential cellular constituents or prevents the formation of toxic oxidation products. There seems to be a relationship between vitamins A and E in which vitamin E facilitates the absorption, hepatic storage, and use of vitamin A. In addition, vitamin E seems to protect against the development of hypervitaminosis A by enhancing the use of the vitamin. Vitamin E is stored in adipose tissue and is thought to stabilize the lipid portions of cell membranes. Other functions attributed to vitamin E are inhibition of prostaglandin production and stimulation of an essential cofactor in corticosteroid metabolism.

Vitamin E requirements may be increased in individuals exposed to high oxygen environments or in those receiving therapeutic doses of iron or large doses of thyroid hormone replacement. Vitamin E may be important in hematopoiesis, with occasional forms of anemia responding favorably to the administration of α -tocopherol.

Despite absence of conclusive supportive evidence, vitamin E has been administered to women with a history of recurrent spontaneous abortions and for sterility in both sexes. In animals, vitamin E deficiency leads to the development of muscular dystrophy, but there is no evidence that a similar sequence occurs in humans. Changes similar to those observed in skeletal muscles have occurred in cardiac muscle of animals. A necrotizing myopathy with proximal skeletal muscle weakness and increased plasma concentrations of creatine kinase may occur in patients self-medicated with large doses of vitamin E. There are data that support an association between low plasma levels of vitamin E and the risk of developing lung cancer.

Epidemiologic studies have provided evidence of an inverse relationship between coronary artery disease and antioxidant intake and vitamin E supplementation in particular. This association has been attributed to finding that antioxidants prevent oxidation of lipids in low-density lipoproteins. It is proposed that oxidation of lipids in low-density lipoproteins (lipid peroxidation) initiates the process of atherogenesis.

Vitamin E is frequently recommended to prevent the development of age-related macular degeneration. The authors of a recent Cochrane review that included five randomized controlled trials involving more than 75,000 patients concluded that the consumption of vitamin E supplements does not influence the development of age-related macular degeneration. Because there is no benefit, and because of the risk of toxicity, the vitamin supplement for the prevention of age-related macular degeneration cannot be recommended.⁵⁰

Vitamin K

Vitamin K is a lipid-soluble dietary compound that is essential for the biosynthesis of several factors required for normal blood clotting. Phytonadione (vitamin K₁) is present in a variety of foods and is the only natural form of vitamin K available for therapeutic use. Vitamin K₂ represents a series of compounds that are synthesized by gram-positive bacteria in the gastrointestinal tract. Synthesis of vitamin K provides approximately 50% of the estimated daily requirement of vitamin K; the rest is supplied by the diet. Vitamin K is absorbed from the gastrointestinal tract only in the presence of adequate quantities of bile salts. Vitamin K accumulates in the liver, spleen, and lungs, but, despite its lipid solubility, significant amounts are not stored in the body for prolonged periods.

Mechanism of Action

Vitamin K functions as an essential cofactor for the hepatic microsomal enzyme that converts glutamic acid residues to γ -carboxyglutamic acid residues in factors II (prothrombin), VII, IX, and X. The γ -

carboxyglutamic acid residues make it possible for these coagulation factors to bind calcium ions and attach to phospholipid surfaces, leading to clot formation. If vitamin K deficiency occurs, the plasma concentrations of these coagulation factors decrease and a hemorrhagic disorder develops. Vitamin K deficiency is characterized by ecchymoses, epistaxis, hematuria, and gastrointestinal bleeding. Vitamin K activity is assessed by monitoring the prothrombin time.

Clinical Uses

Vitamin K is administered to treat its deficiency and attendant decrease in plasma concentrations of prothrombin and related clotting factors. Deficiency of vitamin K may be due to (1) inadequate dietary intake, (2) decreased bacterial synthesis due to antibiotic therapy, (3) impaired gastrointestinal absorption resulting from obstructive biliary tract disease and absence of bile salts, or (4) hepatocellular disease. Neonates have hypoprothrombinemia due to vitamin K deficiency until adequate dietary intake of the vitamin occurs and normal intestinal bacterial floras are established. Indeed, at birth, the normal infant has only 20% to 40% of the adult plasma concentrations of clotting factors II, VII, IX, and X. These plasma concentrations decrease even further during the first 2 to 3 days after birth and then begin to increase toward adult values after approximately 6 days. In premature infants, plasma concentrations of clotting factors are even lower. Human breast milk has low concentrations of vitamin K. Administration of vitamin K, 0.5 to 1.0 mg intramuscularly at birth, to the normal neonate prevents the decrease in concentration of vitamin K-dependent clotting factors in the first days after birth but does not increase these concentrations to adult levels.

Vitamin K replacement therapy is not effective when severe hepatocellular disease is responsible for the decreased production of clotting factors. In the absence of severe hepatocellular disease and the presence of adequate bile salts, the administration of oral vitamin K preparations is effective in reversing hypoprothrombinemia. Phytonadione and menadione are the vitamin K preparations most often used to treat hypoprothrombinemia.

Phytonadione

Phytonadione (vitamin K₁) is the preferred drug to treat hypoprothrombinemia, particularly if large doses or prolonged therapy is necessary. Hypoprothrombinemia of the neonate is treated with phytonadione, 0.5 to 1.0 mg intramuscularly, within 24 hours of birth.⁵¹ One indication for phytonadione is to reverse the effects of warfarin. Phytonadione, 10 to 20 mg orally or administered intravenously at a rate of 1 mg per minute, is usually adequate to reverse the effects of warfarin. The oral and intramuscular routes of administration are less likely than the IV injections of phytonadione to cause side effects and are thus preferred for nonemergency reversal of oral anticoagulants. Even large doses of phytonadione are ineffective against heparin-induced anticoagulation. Vitamin K supplementation is also indicated for patients receiving prolonged TPN, especially if antibiotics are concomitantly administered.

The IV injection of phytonadione may cause life-threatening allergic reactions characterized by hypotension and bronchospasm. Intramuscular administration may produce local hemorrhage at the injection site in hypoprothrombinemic patients. In neonates, doses of phytonadione of greater than 1 mg may cause hemolytic anemia and increase the plasma concentrations of unbound bilirubin, thus increasing the risk of kernicterus. The occurrence of hemolytic anemia reflects a deficiency of glycolytic enzymes in some neonates.

Menadione

Menadione has the same actions and uses as phytonadione ([Figure 36.3](#)). Water-soluble salts of menadione do not require the presence of bile salts for their systemic absorption after oral administration. This characteristic becomes important when malabsorption of vitamin K is due to biliary obstruction.

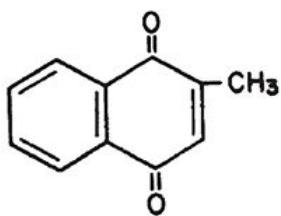

FIGURE 36.3 Chemical structure of menadione.

Menadione hemolyses erythrocytes in patients genetically deficient in glucose-6-phosphate dehydrogenase, as well as in neonates, particularly premature infants. This hemolysis and occasionally hepatic toxicity reflect a combination of menadione with sulphydryl groups in tissues. Kernicterus has occurred after menadione administration to neonates. For this reason, menadione is not recommended for treatment of hemorrhagic disease of the neonate. Administration of large doses of menadione or phytonadione may depress liver function, particularly in the presence of preexisting liver disease.

Dietary Supplements

Dietary supplements (vitamins, minerals, herbs, amino acids, enzymes) are products ingested orally and intended to supplement the diet with nutrients thought to improve health. Herbs include flowering plants, shrubs, seaweed, and algae. It is estimated that 25% of patients use alternative therapies characterized as dietary supplements or herbal remedies (more than 3 billion doses). These products are not subject to FDA approval because they are considered nutrients (do not undergo scientific testing to prove efficacy, and plants and parts of plants are not patent eligible), although they cannot be promoted specifically for treatment, prevention, or cure of disease. Nevertheless, these products can be labeled with statements describing their alleged effects. The FDA has no control over the herbal industry in terms of safety guidelines that would regulate purity and consistency of therapeutic medications.

Adverse Effects and Drug Interactions

Individuals who take dietary supplements and/or herbal remedies in combination with prescription drugs may be at risk for experiencing adverse interactions ([Tables 36.5](#) and [36.6](#)). The most serious side effects associated with these substances include cardiovascular instability, bleeding tendency (particularly in conjunction with other anticoagulants such as warfarin), and delayed awakening from anesthesia.

TABLE 36.5

Suggested uses, potential toxicities, and drug interactions of dietary supplements and herbal remedies

	Suggested uses	Potential toxicity	Drug interactions
Black cohosh	Menopausal symptoms	Gastrointestinal discomfort	Unknown
Chaste tree berries	Premenstrual symptoms	Pruritus	Dopamine-receptor antagonists
Cranberry	Urinary tract infections	Nephrolithiasis	Unknown
Dong quai	Menopausal symptoms	Rash	Warfarin
Echinacea	Upper respiratory infections	Hypersensitivity reactions Hepatic inflammation	
Evening primrose	Eczema Irritable bowel syndrome Premenstrual symptoms Rheumatoid arthritis	Nausea Vomiting Diarrhea Flatulence	Antiepileptic drugs
Feverfew	Prevent migraine	Hypersensitivity	Warfarin

	Arthritis Allergies	reactions Inhibits platelet activity	
Garlic	Hypertension Hypertriglyceridemia Hypercholesterolemia	Gastrointestinal discomfort Hemorrhage	Warfarin
Ginger	Motion sickness Vertigo	Unknown	Warfarin
Ginkgo biloba	Dementia Claudication Tinnitus	Gastrointestinal discomfort Headache Dizziness Bleeding Seizures	Warfarin
Ginseng	Fatigue Diabetes	Tachycardia Hypertension	Warfarin
Goldenseal	Laxative	Hypertension Edema	Unknown
Kava-kava	Anxiety	Rash Sedation Liver toxicity	Benzodiazepines Alcohol Anesthetic drugs
Kola nut	Fatigue	Irritability Insomnia	Stimulants
Licorice	Gastric ulcers	Hypertension	
Saw palmetto	Prostatic hyperplasia	Gastrointestinal discomfort	
St. John's wort	Depression Anxiety	Headache Insomnia Dizziness Gastrointestinal discomfort	Digoxin Oral contraceptives Serotonin antagonists Anesthetic drugs
Valerian	Insomnia	Headaches	Benzodiazepines Anesthetic drugs Antiepileptic drugs

TABLE 36.6

Suggested uses, potential toxicities, and drug interactions of nonherbal dietary supplements

	Suggested uses	Potential toxicity	Drug interactions
Coenzyme Q10	Congestive heart failure Hypertension	Dyspepsia Nausea Diarrhea	Warfarin
Glucosamine	Osteoarthritis	Gastrointestinal discomfort	Warfarin
Melatonin	Insomnia Jet lag	Fatigue Sedation	Unknown
S-adenosylmethionine	Osteoarthritis Depression	Nausea Gastrointestinal discomfort	Tricyclic antidepressants

Ephedra (*ma huang*) is a common ingredient in herbal weight loss products, stimulants, decongestants, and bronchodilators. The active moiety in ephedra is ephedrine, a sympathomimetic amine structurally related to amphetamines. Serious adverse reactions, including hypertension, cardiac arrhythmias, prolonged

QTc interval on the electrocardiogram, myocardial infarction, stroke, and death, have been described in patients taking ephedra. The chances of experiencing an adverse reaction when taking ephedra are estimated to be 100-fold greater than with any other dietary supplement or herbal remedy. Although tachycardia and vasoconstriction can occur in healthy patients, those with heart disease or systemic hypertension, or those who engage in strenuous physical exercise, seem to be at greatest risk for ephedra-related side effects. Based on the risk of adverse reactions, the FDA has concluded that dietary supplements containing ephedra present an unreasonable risk of illness or injury. The FDA banned sales of dietary supplements containing ephedra in April 2004.

Ginseng may cause tachycardia or systemic hypertension, particularly in combinations with other cardiac stimulant drugs. In addition, ginseng may decrease the anticoagulant effects of warfarin. Fever may enhance bleeding by inhibition of platelet activity. Warfarin may also be potentiated by concomitant use of garlic, ginkgo biloba, and ginger. Ginkgo biloba has been suggested to possess antiplatelet effects, and spontaneous hemorrhage has been reported. St. John's wort, which is alleged to be a natural antidepressant, has been shown to inhibit serotonin, dopamine, and norepinephrine reuptake and thus presents the possibility of interactions with monoamine oxidase inhibitors and other serotonergic drugs. Valerian, kava-kava, and possibly St. John's wort may delay awakening from anesthesia by prolonging sedative effects of anesthetic drugs.

PART VII Endocrine System

Normal Endocrine Function

Priya Patidar • Vivek K. Moitra

Anesthesiologists face several preoperative challenges when patients with endocrine disorders need surgery. Patients may present with an endocrinopathy requiring surgery or more commonly have an endocrine abnormality, which complicates surgical and anesthetic management. Physiologic perturbations from the stress response of surgery may precipitate an endocrine crisis perioperatively.

Endocrine glands secrete hormones into the blood, which can act at distant sites (endocrine), adjacent to the site of origin (paracrine), at the site of origin (autocrine), and even within the site of origin (intracrine) to provoke a physiologic response. The endocrine system is evaluated by measuring hormone levels. In most cases, hormone output is regulated by a negative feedback system in which increased circulating plasma concentrations of the hormone decrease its subsequent release from the parent gland. The nervous system (via hypothalamic-releasing factors and peptides produced by the brain) and the immune system (via cortisol, cytokines, and interleukins) also modulate the endocrine system to regulate hormone levels. Defects in the pathway such as genetic receptor mutations or excessive circulating serum factors can cause endocrinologic dysfunction (hormone excess, hormone deficiency, and hormone resistance). Management of endocrinopathies includes hormone replacement and medical or surgical reduction of hormone levels produced by tumors.

Mechanism of Hormone Action

Hormones bind to membrane and nuclear receptors and act as the first messenger to trigger selective and diverse cellular responses. Membrane receptor binding (peptides and catecholamines) initiates signal transduction via four families of receptors: G protein-coupled receptors, tyrosine kinase receptors, serine kinases, and cytokine receptor-linked kinases. These receptors activate a second messenger system which includes cyclic adenosine monophosphate (cAMP), protein kinases, cyclic guanosine monophosphate, and calcium.¹ Receptor binding in the nucleus (steroids, thyroid hormone, and vitamin D) regulates gene expression in the cytoplasm and nucleus to produce specific intracellular proteins and enzymes.

Hypothalamus and Pituitary Gland

The hypothalamus is located at the base of the brain and above the pituitary gland. It receives input from multiple avenues to maintain homeostasis and affect growth and reproduction. Environmental factors such as light and temperature, autonomic inputs, adrenergic and dopaminergic receptors, pain signals, emotions, olfactory sensations, and peripheral endocrine organ feedback stimulate the hypothalamus to secrete hypothalamic-releasing and hypothalamic inhibitory hormones, which, in turn, control secretions from the anterior pituitary ([Table 37.1](#)).

TABLE 37.1

Hypothalamic hormones

Hormone	Target anterior pituitary hormone
Human growth hormone–releasing hormone	HGH
Human growth hormone–inhibiting hormone (somatostatin)	HGH, prolactin, TSH
Prolactin-releasing factor	Prolactin
Prolactin-inhibiting factor	Prolactin
Luteinizing hormone–releasing hormone	LH, FSH

Corticotropin-releasing hormone	ACTH, β -lipotropins, endorphins
Thyrotropin-releasing hormone	TSH

Abbreviations: ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; HGH, human growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Hormones designated as hypothalamic-releasing or hypothalamic inhibitory hormones originate in the hypothalamus and control secretions from the anterior pituitary ([Table 37.1](#)). Hypothalamic-releasing and inhibitory hormones travel via hypothalamic-hypophyseal portal vessels, which directs these hormones from a capillary bed in the hypothalamus directly to the anterior pituitary, without being diluted in the systemic circulation. When this high concentration of hormones reaches the pituitary, they bind G protein-coupled receptors and activate the cAMP second messenger system which subsequently leads to pituitary hormone release. Hypothalamic hormones have pulsatile secretion, which is superimposed on broader biologic rhythms such as the circadian release of adrenocorticotrophic hormone (ACTH), the sleep-entrained release of human growth hormone (HGH), and the monthly cycle of gonadotropins in females.²

The pituitary gland lies in the sella turcica at the base of the brain and is connected to the hypothalamus by the pituitary stalk. Physiologically, the gland is outside the blood-brain barrier and is divided into the anterior pituitary (adenohypophysis), derived from the embryological upper part of the gastrointestinal tract, and posterior pituitary (neurohypophysis), derived from neural tissue. The anterior pituitary synthesizes, stores, and secretes five tropic hormones that act on a secondary endocrine organ to secrete their own hormones. The ACTH and HGH are polypeptides; thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) are glycoproteins, with a common α subunit and specific β subunit. The ACTH is derived from proopiomelanocortin, which is cleaved to create melanocyte-stimulating hormone, a pigment hormone that also plays a role in host immune response, and β -endorphin, which binds opioid receptors to produce pain relief.³ The posterior pituitary stores and secretes two hormones—arginine vasopressin (AVP), formerly designated antidiuretic hormone, and oxytocin. Both are initially synthesized in the hypothalamus and subsequently transported (via axons) to the posterior pituitary ([Table 37.2](#)). During the perioperative period, secretion of pituitary hormones increases with activation of the sympathetic nervous system.⁴

TABLE 37.2

Pituitary hormones

Hormone	Cell type	Principal action
Anterior pituitary		
Human growth hormone (somatotropin)	Somatotropes	Accelerates body growth; insulin antagonism
Prolactin	Lactotropes	Stimulates secretion of milk and maternal behavior; inhibits ovulation
Luteinizing hormone	Gonadotropes	Stimulates ovulation in females and testosterone secretion in males
Follicle-stimulating hormone	Gonadotropes	Stimulates ovarian follicle growth in females and spermatogenesis in males
Adrenocorticotrophic hormone	Corticotropes	Stimulates adrenal cortex secretion and growth; steroid production
Thyroid-stimulating hormone	Thyrotropes	Stimulates thyroid secretion and growth
β -Lipotropin	Corticotropes	Precursor of endorphins
Posterior pituitary		
Arginine vasopressin	Supraoptic nuclei	Promotes water retention and regulates plasma osmolarity
Oxytocin	Paraventricular nuclei	Causes ejection of milk and uterine contraction

The response to pituitary stalk destruction differs in the anterior and posterior pituitary gland. Stalk destruction causes axonal atrophy and subsequent loss of posterior pituitary function. After stalk destruction, the anterior pituitary can still respond to hypothalamic hormones in the peripheral blood via the inferior hypophyseal artery.

Anterior Pituitary

Anterior pituitary cells have been traditionally classified on the basis of their staining characteristics as agranular chromophobes or granular chromophils. Chromophils are subdivided into acidophils and basophils depending on the staining response to acidic or basic dyes. With more modern techniques, including electron microscopy and immunochemistry, it is possible to identify at least five types of cells, some of which secrete more than one tropic hormone (see [Table 37.2](#)).

Growth Hormone (Somatotropin)

Growth hormone (GH) is the most abundant anterior pituitary hormone. The GH stimulates growth of all tissues in the body and evokes intense metabolic effects ([Figure 37.1](#)).⁵ The most striking and specific effect is stimulation of linear bone growth that results from direct GH action on the epiphyseal cartilage plates of long bones. The GH indirectly stimulates growth through upregulation of insulin-like growth factor expression from the liver and local tissues. Excess secretion of GH before epiphyseal closure occurs causes gigantism. When GH secretion is excessive after epiphyseal closure and long bones can no longer increase in length but only in thickness, acromegaly results. The metabolic effects of GH include increased rates of protein synthesis (anabolic effect), increased mobilization of free fatty acids (ketogenic effect), antagonism of insulin action (diabetogenic effect), and sodium and water retention.

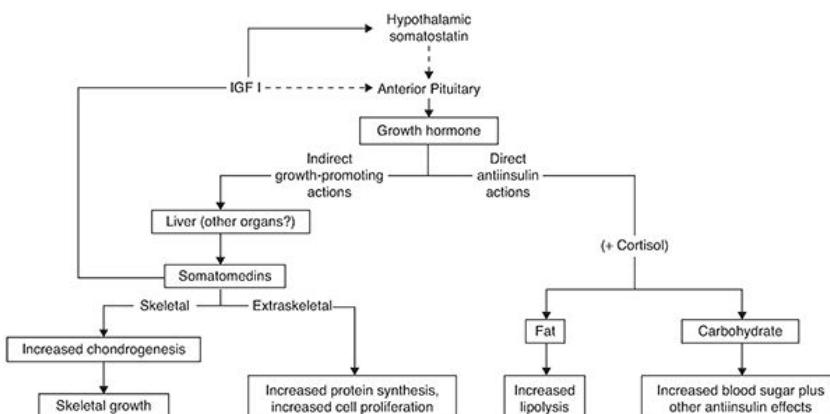

FIGURE 37.1 Effects of human growth hormone manifesting as direct effects or via production of somatomedins in the liver. Abbreviation: IGF I, insulin-like growth factor 1. Republished with permission of McGraw Hill LLC from Ganong WF. Review of Medical Physiology. 21st ed. New York, NY: Lange Medical Books/McGraw Hill, 2003; permission conveyed through Copyright Clearance Center, Inc.

Releasing (GH-releasing hormone) and inhibitory (somatostatin) hormones, physiologic events, and medications regulate GH secretion ([Table 37.3](#)). For example, perioperative anxiety and stress may evoke the release of GH.⁴ Plasma concentrations of GH characteristically increase during physiologic sleep. Drugs may influence the secretion of GH, presumably via effects on the hypothalamus. In this regard, large doses of corticosteroids suppress secretion of GH, which may be responsible for the inhibitory effects on growth observed in children receiving high doses of corticosteroids for prolonged periods of time. Conversely, dopaminergic agonists acutely increase the secretion of GH.

TABLE 37.3
Regulation of growth hormone (GH) secretion

Stimulation	Inhibition
GH-releasing hormone	GH-inhibiting hormone (somatostatin)
Stress	
Physiologic sleep	IGF-1
Hypoglycemia	
Free fatty acid decrease	Pregnancy
Amino acid increase	Hyperglycemia
Fasting	Free fatty acid increase
Estrogens	Cortisol
Dopamine	Obesity
α -Adrenergic agonists	

Abbreviation: IGF-1, insulin-like growth factor 1.

Prolactin

Prolactin is a nontropic hormone and has little metabolic activity, but it prompts the growth and development of the mammary gland and breast milk production itself. Pregnancy, via elevated levels of estrogen, nursing, and stress, stimulates the release of prolactin; dopamine inhibits its release ([Table 37.4](#)). Preoperative anxiety is an example of stress which increases plasma concentrations of prolactin.⁴ Prolactin secretion in response to suckling inhibits ovarian function, explaining the usual lack of ovulation and resulting infertility during breast-feeding. Prolactin also plays a role in the immune system, modulating immune cell activation and differentiation. Although not fully elucidated, high prolactin levels have been shown to be associated with autoimmune diseases like lupus, rheumatoid arthritis, and multiple sclerosis.⁶

TABLE 37.4

Regulation of prolactin secretion

Stimulation	Inhibition
Prolactin-releasing factor	Prolactin-inhibiting factor
Pregnancy	Prolactin
Suckling	Dopamine
Stress	L-Dopa
Physiologic sleep	
Metoclopramide	
Cimetidine	
Opioids	
α -Methyldopa	

Gonadotropins

The LH and FSH are gonadotropins responsible for pubertal maturation and secretion of steroid sex hormones by the gonads of either sex. These hormones bind to G protein-coupled cell membrane receptors in the ovaries or testes to stimulate the synthesis of cAMP, which then influences the production of sex steroids and triggers ovulation in females.

Adrenocorticotrophic Hormone

The ACTH regulates secretion of cortisol and androgens from the adrenal cortex via the cAMP second messenger system, which isolates cholesterol from lipid droplets. Cholesterol is the initial building block for the synthesis of corticosteroids. Secretion of ACTH is under the control of corticotropin-releasing hormone from the hypothalamus and conversely gets negative feedback from the circulating plasma concentration of

cortisol ([Table 37.5](#)).⁷ Secretory rates of corticotropin-releasing hormone and ACTH are high in the morning and low in the evening. This diurnal variation results in high plasma cortisol concentrations in the morning (~20 µg/dL) and low levels (~5 µg/dL) around midnight. For this reason, plasma concentrations of cortisol are interpreted in terms of the time of day of the measurement. Stress, surgical incision, reversal of anesthesia, and postoperative pain stimulate ACTH release.^{4,8,9}

TABLE 37.5

Regulation of adrenocorticotropic hormone (ACTH) secretion

Stimulation	Inhibition
Corticotropin-releasing hormone	ACTH
Cortisol decrease	Cortisol increase
Stress	Opioids
Sleep-wake transition	Etomidate
Hypoglycemia	Suppression of the hypothalamic-pituitary axis
Trauma	
α-Adrenergic agonists	
β-Adrenergic antagonists	

In the absence of ACTH, the adrenal cortex undergoes atrophy, but the zona glomerulosa, which secretes aldosterone under the influence of potassium and renin, is least affected. Indeed, hypophysectomy has minimal effects on electrolyte balance because of the continued release of aldosterone from the adrenal cortex. Pigmentary changes that may accompany certain endocrine diseases most likely reflect changes in plasma concentrations of ACTH, as it is derived from proopiomelanocortin, which also creates melanocyte-stimulating hormone. For example, pallor is a hallmark of hypopituitarism. Conversely, hyperpigmentation in patients with adrenal insufficiency from primary adrenal gland disease reflects high concentrations of ACTH circulating in plasma as the anterior pituitary attempts to stimulate corticosteroid secretion.

Chronic administration of corticosteroids suppresses corticotropin-releasing hormone and leads to atrophy the hypothalamic-pituitary axis. Several months may be required for recovery of this axis after removal of the suppressive influence. In such patients, stressful events during the perioperative period might evoke life-threatening hypotension. For this reason, it is a common practice to administer supplemental exogenous corticosteroids (based on the magnitude of stress) to patients considered at risk for suppression of the hypothalamic-pituitary axis. There is little evidence, however, that supplemental corticosteroids in excess of normal daily physiologic secretion are necessary or beneficial intra- or postoperatively.¹⁰ It is also unclear when the hypothalamic-pituitary-adrenal (HPA) axis is considered suppressed although general consensus is noted as taking more than 20 mg prednisone or its equivalent daily for greater than 3 weeks. See [Chapter 40](#) for dosing of corticosteroids during the perioperative period.

Thyroid-Stimulating Hormone

The TSH accelerates all the steps in the formation of thyroid hormones, including initial uptake of iodide into the thyroid gland, iodination of thyroglobulin, and internalization of thyroglobulin, which is needed to release thyroid hormone into blood. Secretion of TSH from the anterior pituitary is under the control of thyrotropin-releasing hormone from the hypothalamus as well as a negative feedback mechanism, depending on the concentrations of thyroid hormones circulating in plasma. Sympathetic nervous system stimulation and corticosteroids also suppress the secretion of TSH and thus diminish activity of the thyroid gland.

A long-acting thyroid stimulator is an immunoglobulin A antibody that binds to receptor sites on thyroid cells. Binding can mimic the effects of TSH and account for hyperthyroidism, and patients with hyperthyroidism often have detectable circulating concentrations of these proteins. Hypothyroidism with increased plasma concentrations of TSH indicates a primary defect at the thyroid gland (primary hypothyroidism) and an attempt by the anterior pituitary to stimulate hormonal output by releasing TSH. A

defect at the hypothalamus or anterior pituitary is indicated by low concentrations of both TSH and thyroid hormones circulating in plasma (secondary hypothyroidism).

Posterior Pituitary

The posterior pituitary acts as a reservoir for AVP and oxytocin in neurosecretory vesicles. The AVP is synthesized in the supraoptic nuclei and oxytocin in the paraventricular nuclei. These hormones are transported in secretory granules along axons from corresponding nuclei in the hypothalamus to the posterior pituitary for subsequent release in response to appropriate stimuli.

Arginine Vasopressin

The physiologic functions of AVP include vasoconstriction, water retention and corticotropin secretion. Changes in plasma osmolality and blood pressure are the main regulators of AVP secretion. The hypothalamus releases AVP to the posterior pituitary in response to feedback from osmoreceptors, which sense small changes in plasma osmolality, and aortic arch and carotid baroreceptors, which detect changes in blood pressure ([Table 37.6](#)).¹¹ Other inducers of AVP include stress and painful stimuli from surgery. Adequate hydration before induction of anesthesia can help blunt that response and maintain urine output. On the other hand, with general and/or epidural anesthesia and especially in patients taking ACE inhibitors, vasopressin becomes a vital factor in maintaining blood pressure since the sympathetic system and renin system are dampened.¹² Decreases in urine output and fluid retention previously attributed to release of AVP during positive pressure ventilation of the lungs are more likely the result of changes in cardiac filling pressures that impair the release of atrial natriuretic hormone.

TABLE 37.6

Regulation of arginine vasopressin secretion

Stimulation	Inhibition
Increased plasma osmolarity	Decreased plasma osmolarity
Hypovolemia	
Pain	Ethanol
Hypotension	α -Adrenergic agonists
Hyperthermia	Cortisol
Stress	Hypothermia
Nausea and vomiting	
Opioids	

There are three subtypes of AVP receptors: V1, V2, and V3. Stimulation of V1 receptors (found on vascular smooth muscle) causes vasoconstriction. In cases of hemorrhage and sepsis, large amounts of endogenous vasopressin are released initially, causing vasoconstriction and blood flow to be diverted from nonvital to vital organs. In continued refractory septic shock or cardiogenic shock, endogenous levels of vasopressin drop.¹² Thus, exogenous AVP is used as a vasopressor during intraoperative hypotension, sepsis, and cardiopulmonary resuscitation.

Activation of the V2 receptors, which are located on collecting duct cells in the kidney, increases reabsorption of water. The AVP is transported in the blood to the kidneys, where it attaches to receptors on the capillary side of epithelial cells lining the distal convoluted renal tubules and collecting ducts of the renal medulla. The receptor-hormone interaction results in the formation of large amounts of cAMP, which causes insertion of aquaporin-2 into the collecting duct walls for exit of water to minimize osmolality. Hypokalemia, hypercalcemia, cortisol, and lithium also interfere with renal responsiveness to AVP. The AVP binds to V3 receptors in the adenohypophysis to release corticotropin, which suggests that this hormone affects the stress response.¹¹

Destruction of neurons in or near the supraoptic and paraventricular nuclei of the hypothalamus from pituitary surgery, trauma, cerebral ischemia, or malignancy may decrease vasopressin release to cause central

diabetes insipidus.¹¹ If the posterior pituitary alone is damaged, however, the transected fibers of the pituitary stalk can still continue to secrete AVP. Diabetes insipidus from lack of vasopressin release during pituitary surgery is usually transient. (See [Chapter 40](#) for hormonal treatment of central diabetes insipidus.)

Unnecessary or excessive secretion of AVP with subsequent retention of water and dilutional hyponatremia may result from head injuries, intracranial tumors, meningitis, certain medications, or pulmonary infections. Aberrant production of AVP is observed most commonly in patients with cancer, especially small cell lung cancer. In cancer patients, the antibiotic demeclocycline promotes diuresis by antagonizing the effects of AVP on renal tubules.

Oxytocin

Breast suckling and cervical and vaginal stimulation, as from the fetus during labor, increases oxytocin secretion. Oxytocin causes milk ejection from the lactating mammary gland via contraction of the myoepithelial cells that surround the alveoli of the mammary glands. Oxytocin binds to G proteins on the surface of uterine myocytes to trigger the release of calcium from the sarcoplasmic reticulum, exerting a contracting effect on the pregnant uterus.¹³ Oxytocin also augments the action potential of the uterine smooth muscle.¹⁴ Large amounts of oxytocin cause sustained uterine contraction as necessary for postpartum hemostasis. Oxytocin has only 0.5% to 1.0% the antidiuretic activity of AVP and can be released abruptly and independently of AVP.

Thyroid Gland

Anatomically, the thyroid gland consists of two lobes connected by a bridge of tissues known as the **thyroid isthmus** ([Figure 37.2](#)). The gland is highly vascularized and receives innervation from the autonomic nervous system. Structurally, the gland consists of multiple follicles (acini) that are filled with colloid, which consists principally of thyroglobulin. Thyroid hormones are stored in combination with thyroglobulin. Stimulation of proteases by TSH results in cleavage of hormones from thyroglobulin and their release into the systemic circulation.

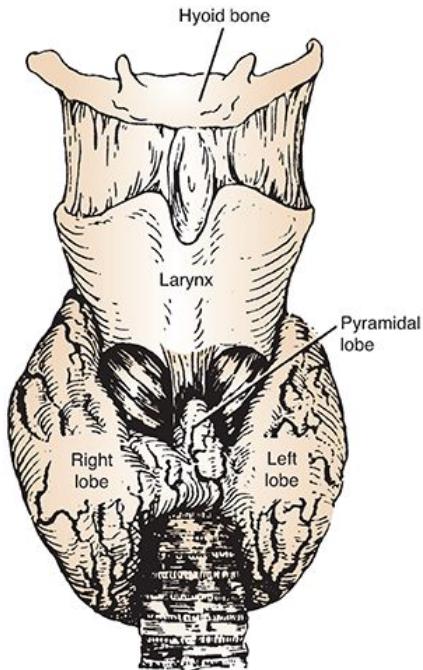

FIGURE 37.2 The two lobes of the thyroid and their relationship to the larynx and trachea.

The thyroid gland maintains optimal metabolism for normal tissue function.¹⁵ The principal hormonal secretions of the thyroid gland are thyroxine (T₄) and triiodothyronine (T₃) ([Figure 37.3](#)). The T₄, a

prohormone synthesized from tyrosine, represents 80% of the body's thyroid hormone production. The T₃, 5 times more active than T₄, is produced directly from tyrosine metabolism or from conversion of T₄ in peripheral tissues (mostly liver but also heart, muscle, nerves, intestines). This conversion is done by D1 or D2 deiodinases, which convert one-third of all T₄ into T₃. These deiodinases also further metabolize T₄ and T₃ to inactive compounds. The half-lives of endogenously or exogenously administered T₃ and T₄ are 1.5 and 7 days, respectively. The T₃ and T₄ are both highly protein bound to albumin, thyroid-binding prealbumin, and thyroid-binding globulin with only 0.2% of T₃ and 0.3% of T₄ freely circulating unbound and pharmacologically active.¹⁵ It is of interest that iodine present in thyroid hormones is not necessary for biologic activity (see [Figure 37.3](#)). In addition to thyroid hormones, the thyroid gland secretes calcitonin, which is important for calcium ion use.

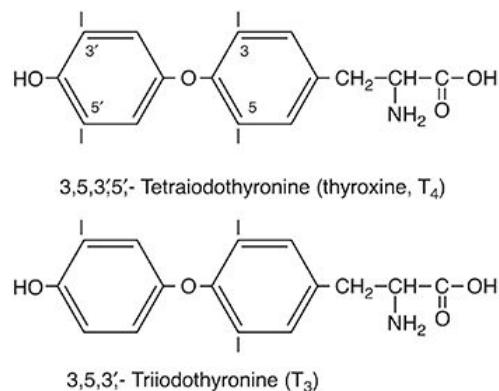

FIGURE 37.3 Chemical structure of thyroid hormones.

The thyroid hormones increase oxygen consumption in nearly all tissues, except for the brain, testicles, lymph nodes, and spleen. Failure of thyroid hormones to greatly alter the oxygen consumption of the brain is consistent with the minimal changes in anesthetic requirements minimum alveolar concentration (MAC) that accompany hyperthyroidism or hypothyroidism.¹⁶ Cardiovascular changes are often the earliest clinical manifestations of abnormal thyroid hormone levels. Absence of thyroid gland hormones decreases minute oxygen consumption to approximately 40% less than normal; excesses of thyroid hormones can expand oxygen consumption as much as 100% more than normal. Thyroid hormones stimulate carbohydrate metabolism and facilitate the mobilization of free fatty acids. Despite the latter effect, plasma concentrations of cholesterol usually decrease, reflecting stimulation of low-density lipoprotein receptor synthesis by thyroid hormones.

Mechanism of Action

When thyroid hormones enter cells, T₃ binds to nuclear receptors. The T₄ also binds to these receptors but not as avidly. Indeed, T₄ serves principally as a prohormone for T₃ so that the biologic effects of T₄ are largely a result of its intracellular conversion to T₃.

Thyroid hormones exert most, if not all, of their effects through control of protein synthesis. Thyroid hormones activate the DNA transcription process in the cell nucleus to form new cell proteins and enzymes. Sympathomimetic effects that accompany thyroid hormone stimulation most likely reflect a greater sensitivity of β-adrenergic receptors to the release of T₄ and T₃, although this is controversial.

When thyroid hormones accelerate metabolism, tissues vasodilate and blood flow delivers necessary oxygen and carries away metabolites and heat. As a result, cardiac output often increases, but systemic blood pressure is unchanged because peripheral vasodilation offsets the impact of more blood flow. Excess protein catabolism associated with greater secretion of thyroid hormones is the mechanism behind skeletal muscle weakness characteristic of hyperthyroidism. The fine muscle tremor that accompanies hyperthyroidism stems

from the sensitivity of neuronal synapses in the area of the spinal cord that controls skeletal muscle tone. Diarrhea reflects additional motility in the gastrointestinal tract with excessive activity of the thyroid gland.

Calcitonin

Calcitonin, a polypeptide hormone secreted by the thyroid gland, decreases the concentration of calcium ions in plasma by weakening the activity of osteoclasts and strengthening the activity of osteoblasts. In the kidneys, calcitonin decreases tubular absorption of calcium and phosphates. A total thyroidectomy and subsequent absence of calcitonin, however, does not measurably influence the plasma concentration of calcium because of the predominance of parathyroid hormone (PTH).

Parathyroid Glands

The four parathyroid glands secrete PTH, an amino acid polypeptide that regulates plasma concentration of calcium ions. Secretion of PTH is inversely related to plasma ionized calcium concentration. Small declines in the plasma concentration of calcium ions stimulate the release of PTH. The PTH promotes mobilization of bone calcium (osteoclastic activity); enhances conversion of vitamin D to its active form, 1,25-dihydroxycholecalciferol, to increase gastrointestinal absorption of calcium; increases renal tubular absorption of calcium; and inhibits renal reabsorption of phosphate to increase calcium and to decrease phosphate concentrations in plasma.

The PTH exerts its effect on target cells in bones, renal tubules, and the gastrointestinal tract by stimulating the formation of cAMP. Because a portion of cAMP synthesized in the kidneys escapes into the urine, its assay serves as a measure of parathyroid gland activity.

Adrenal Cortex

The adrenal cortex secretes three major classes of corticosteroids: mineralocorticoids, glucocorticoids, and androgens. The precursor of all corticosteroids is cholesterol. More than 30 different corticosteroids have been isolated from the adrenal cortex, but only two are important: aldosterone, a mineralocorticoid, and cortisol, the principal glucocorticoid ([Table 37.7](#)). The corticosteroids are not stored in the adrenal cortex; the rate of synthesis determines the subsequent plasma concentration. Anatomically, the adrenal cortex is divided into three zones designated the (1) **zona glomerulosa** that secretes mineralocorticoids, (2) **zona fasciculata** that secretes glucocorticoids, and (3) **zona reticularis** that secretes androgens and estrogens.

TABLE 37.7

Physiologic effects of endogenous corticosteroids (mg)

	Daily secretion	Sodium retention ^a	Glucocorticoid effect ^a	Antiinflammatory effect ^a
Aldosterone	0.125	3,000	0.3	Insignificant
Desoxycorticosterone	—	100	0	0
Cortisol	20	1	1	1
Corticosterone	Minimal	15	0.35	0.3
Cortisone	Minimal	0.8	0.8	0.8

^aRelative to cortisol.

Mineralocorticoids: Aldosterone

Aldosterone accounts for approximately 95% of the mineralocorticoid activity of the corticosteroids. Desoxycorticosterone, the other naturally occurring mineralocorticoid, has only 3% of the sodium ion-retaining potency of aldosterone. Cortisol induces retention of sodium ions and secretion of potassium ions but much less effectively than aldosterone.

Physiologic Effects

Aldosterone sustains extracellular fluid volume by conserving sodium and by maintaining a normal plasma concentration of potassium. Sodium ions are absorbed at the same time potassium ions are secreted by the lining of epithelial cells of the distal renal tubules and collecting ducts. As a result, sodium is conserved in the extracellular fluid, and potassium is excreted in the urine. Water follows sodium such that extracellular fluid volume changes in proportion to the rate of aldosterone secretion. If aldosterone secretion is excessive, extracellular fluid volume, cardiac output, and systemic blood pressure increase. If plasma concentration of potassium decreases approximately 50% after excess secretion of aldosterone, skeletal muscle weakens or paralysis occurs because nerve and muscle membranes are hyperpolarized and the transmission of action potentials is prevented.

Aldosterone affects sweat glands and salivary glands. It increases the reabsorption of sodium and secretion of potassium by sweat glands. This effect conserves sodium in hot environments or during excess salivation. Aldosterone also enhances sodium ion reabsorption by the gastrointestinal tract.

Mechanism of Action

Aldosterone diffuses to the interior of renal tubular epithelial cells, where it induces DNA to form messenger RNA (mRNA) necessary for the transport of sodium and potassium ions. It is speculated that this mRNA is a specific adenosine triphosphatase that catalyzes energy from cytoplasmic adenosine triphosphate to the sodium ion transport mechanism of cell membranes. It takes as long as 30 minutes before the new mRNA appears and approximately 45 minutes before the rate of sodium ion transport begins to increase.

Regulation of Secretion

The most important stimulus for aldosterone secretion is an accumulation of potassium in the plasma. A powerful negative feedback system maintains the plasma concentration of potassium ions in a normal range. The renin-angiotensin system also affects aldosterone secretion (see [Chapter 16](#)). The elimination half-time of aldosterone is approximately 20 minutes, and nearly 90% is cleared by the liver in a single passage. Mineralocorticoid secretion is not under the primary control of ACTH. For this reason, hypoadosteronism does not accompany loss of ACTH secretion from the anterior pituitary.

Glucocorticoids: Cortisol

At least 95% of the glucocorticoid activity results from the secretion of cortisol. A small amount of glucocorticoid activity is provided by corticosterone and an even smaller amount by cortisone. Cortisol is one of the few hormones essential for life.

Physiologic Effects

Cortisol (1) increases gluconeogenesis, (2) breaks down protein, (3) mobilizes fatty acid, and (4) has antiinflammatory effects. Cortisol may improve cardiac function by increasing the number or responsiveness of β -adrenergic receptors. In addition to sustaining cardiac function and maintaining systemic blood pressure, cortisol promotes the normal responsiveness of arterioles to the constrictive action of catecholamines. Cortisol inhibits bone formation.

Developmental Changes

Plasma concentrations of cortisol increase progressively during the last trimester of pregnancy to reach a peak plasma concentration at term so that systems critical for survival are mature for the onset of extrauterine life. These systems include production of pulmonary surfactant, maturation of various enzyme systems in the liver, increased production of T_3 , and the expression of phenylethanolamine *N*-methyltransferase, the enzyme necessary for the synthesis of epinephrine from norepinephrine. The T_3 and catecholamines are both in preparation for the increase in metabolic rate associated with breathing and living in a colder environment.

Gluconeogenesis

Cortisol stimulates gluconeogenesis by the liver as much as 10-fold. Amino acids are mobilized from extrahepatic sites and transferred to the liver for conversion to glucose. An accelerated rate of

gluconeogenesis with a moderate decline in glucose use caused by a prolonged high level of cortisol can result in larger concentrations of blood glucose known as **adrenal diabetes**. Increased muscle wasting and thus decreased glucose utilization, insulin resistance, and visceral fat deposition (see the following text) associated with high cortisol levels also contribute to the development of diabetes. Adrenal diabetes may be responsive to the administration of insulin, but the overall cure is to treat the underlying cause of high cortisol.

Protein Catabolism

Cortisol breaks down protein stores in nearly all cells except hepatocytes to mobilize amino acids for gluconeogenesis. When excesses of cortisol are sustained, skeletal muscle weakness may become pronounced.

Fatty Acid Mobilization

Cortisol promotes mobilization of fatty acids from adipose tissue and enhances oxidation of fatty acids in cells. Despite these effects, with excess amounts of cortisol, fat is deposited in the neck and chest regions, giving rise to a “buffalo-like” torso. Fat deposits at these sites at a rate that exceeds its mobilization.

Antiinflammatory Effects

In large amounts, cortisol has antiinflammatory effects when it stabilizes lysosomal membranes and stops migration of leukocytes into the inflamed area. When lysosomal membranes are stable, the release of inflammation-causing lysosomes is attenuated. Cortisol lessens capillary permeability to prevent loss of plasma into tissues. Even after inflammation has been well established, the administration of cortisol weakens its manifestations. This effect of cortisol is useful for disease states with inflammation such as rheumatoid arthritis and acute glomerulonephritis.

Cortisol minimizes the number of eosinophils and leukocytes in the blood within a few minutes after its administration. Atrophy of lymphoid tissue throughout the body reduces the production of antibodies. As a result, the level of immunity against bacterial or viral infection is diminished, and infection can fulminate. Conversely, suppressing immunity is useful to prevent immunologic rejection of transplanted tissues.

In the treatment of allergic reactions, cortisol prevents the life-threatening inflammatory responses of allergic reactions such as laryngeal edema. Cortisol may also interfere with activation of the complement pathway and formation of chemical mediators derived from arachidonic acid, such as leukotrienes. Cortisol does not, however, alter the antigen-antibody interaction or histamine release associated with allergic reactions.

Mechanism of Action

Steroids are intracrine hormones that interact with intracellular (often nuclear) receptors. Cortisol stimulates DNA-dependent synthesis of mRNA in the nuclei of responsive cells, leading to the synthesis of necessary enzymes.

Regulation of Secretion

The most important stimulus for the secretion of cortisol (13–20 mg daily) is the release of ACTH from the anterior pituitary (see [Table 37.5](#)). The secretion of ACTH in the anterior pituitary is determined by two hypothalamic neurohormones: diurnal release of corticotropin-releasing hormone and AVP that act synergistically. Circulating cortisol has a direct negative feedback effect on the hypothalamus and anterior pituitary to decrease the discharge of corticotropin-releasing hormone and ACTH from these respective sites. Immediately following migration from the adrenal gland, cortisol is bound to the α -globulin, transcortin (cortisol-binding globulin). Plasma concentrations of cortisol are higher in females than in males with additional concentrations accompanying the menstrual cycle just before ovulation. If stress from the perioperative period overrides the normal negative feedback control mechanisms, plasma concentrations of cortisol increase. The beneficial effect of a greater plasma concentration of cortisol and other hormones in

response to stressful stimuli may be the acute mobilization of cellular proteins and fat stores for energy and synthesis of other compounds, including glucose.

Cortisol is secreted and released by the adrenal cortex at a basal rate of approximately 20 to 30 mg daily. In response to maximal stressful stimuli (sepsis, burns), the output of cortisol is increased to approximately 150 mg daily.¹⁷ This amount should be a sufficient replacement for patients who lack adrenal function and who are acutely ill or undergoing major surgery. The peak plasma cortisol concentration of 8 to 25 µg/dL occurs in the morning shortly after awakening. Stress-induced changes in the plasma concentration of cortisol are superimposed on the circadian tone and vary in onset, magnitude, and duration, depending on the intensity of the stress. In the systemic circulation, 80% to 90% of cortisol is bound to a specific globulin known as **transcortin**. It is the relatively small amount of unbound cortisol that exerts a biologic effect. The elimination half-time of cortisol is approximately 70 minutes. Cortisol is degraded mainly in the liver with the formation of inactive 17-hydroxycorticosteroids that appear in the urine. Cortisol is also filtered at the glomerulus and may be excreted unchanged in urine.

Effect of Anesthesia and Surgery

Perioperative stress stimulates hormonal secretion of ACTH and cortisol.⁴ This response may be diminished by less invasive surgeries such as laparoscopy and blunted by choice of anesthetic technique. During the perioperative period, ACTH stimulation, tissue damage, and proinflammatory mediators can release cortisol. As with other types of stress, the episodic release of cortisol remains intact but the amplitude of episodic releases is greater. Large concentrations of cortisol in plasma in the perioperative period may be prompted by baroreceptor and spinal reflexes that signal tissue injury to the hypothalamus.¹⁸

Plasma cortisol concentrations typically return to normal levels within 24 hours postoperatively but may remain elevated for as long as 72 hours, depending on the severity of the surgical trauma. In addition, disturbances in the circadian rhythm may be associated with postoperative fatigue and debility. Return of plasma cortisol concentrations to normal following surgery is characterized by increased plasma concentrations of ACTH and cortisol (consistent with sustained, stress-induced stimulation of the hypothalamus) followed by a second phase in which plasma ACTH concentrations are low and larger cortisol concentrations in plasma are independent of the hypothalamic-pituitary system. Cytokines released from traumatized tissue may stimulate synthesis of cortisol directly despite low plasma concentrations of ACTH. Alternatively, prior increases in ACTH concentrations in plasma may stimulate production of ACTH receptors in the adrenal glands resulting in greater cortisol production.

Plasma cortisol concentrations in the perioperative period are designed to provide protection during and after surgery. In adrenalectomized animals who received subphysiologic doses of cortisol, hemodynamic instability and mortality followed surgery. Animals treated with physiologic or supraphysiologic doses of cortisol were indistinguishable from control animals.¹⁹ A key feature of HPA physiology is negative feedback that suppresses release of ACTH by the pituitary by high levels of endogenous or exogenous glucocorticoids. Suppression of the hypothalamic-pituitary axis by regular administration of corticosteroids prevents the release of cortisol in response to stressful stimuli.

The acute phase response to surgery is also mediated by the release of proinflammatory cytokines such as interleukin-1, tumor necrosis factor- α , and interleukin-6 from damaged tissue and activation of the sympathetic nervous system. Cytokines may stimulate ACTH and cortisol production and are subject to a negative feedback system. Cytokine levels peak 24 hours after surgery and can remain elevated for several days. Hepatic production of acute phase proteins (C-reactive protein, fibrinogen, and α_2 -macroglobulin) is generated in response to trauma and surgery.⁴

In addition to surgical trauma, the choice of anesthetic drugs and techniques may influence the HPA response. Large doses of opioids may attenuate the cortisol response to surgical stimulation.^{20,21} Volatile anesthetics do not suppress the stress-induced endocrine response as much. Etomidate, unique among drugs administered to induce anesthesia, inhibits cortisol synthesis even in the absence of surgical stimulation (see [Chapter 5](#)). Although studies of regional anesthetics show a potential to decrease perioperative complications and surgical stress-induced release of cortisol, it has not been proven in abdominal or thoracic surgeries.

Reproductive Glands

In both sexes, the reproductive glands (testes and ovaries) produce germ cells and steroid sex hormones.

Testes

The testes have two main products: **androgens** and sperm. All androgens are steroid compounds that can be synthesized from cholesterol. Testosterone, the most potent and abundant of the androgens, is a key factor in primary sexual development (spermatogenesis, testicular descent, enlargement of penis and testes, increasing libido) and develops and maintains male sex characteristics. Skeletal muscle growth is an anabolic effect of testosterone in the male. Puberty is characterized by the production of testosterone rapidly in response to hypothalamic-releasing hormones that evoke the release of LH and FSH. Hypertrophy of the laryngeal mucosa accompanies secretion of testosterone, leading to changes in voice at puberty. Testosterone increases secretion of sebaceous glands, leading to acne. Testosterone causes growth spurts by increasing tissue growth at epiphyseal plates. Beard growth is the last manifestation of puberty.

The hypothalamic-pituitary axis regulates testosterone production. Gonadotropin-releasing hormone is released from the hypothalamus and causes secretion of LH and FSH from the anterior pituitary. The LH acts on Leydig cells in the gonads to increase testosterone production. The FSH and androgens act on receptors in Sertoli cells to stimulate spermatogenesis. Testosterone is part of a negative feedback loop to the hypothalamus and anterior pituitary. Testosterone production continues throughout life, although the amount produced lessens gradually after 40 years. At age 80 years, it is approximately one-fifth the peak value.

At most sites of action, testosterone is not the active form of the hormone. It is converted in target tissues to the more active dihydrotestosterone by a reductase enzyme. Dihydrotestosterone binds to a cytoplasmic protein receptor for synthesis of specific mRNA protein. In the absence of sufficient reductase enzyme, external genitalia fail to develop (pseudohermaphroditism) despite secretion of adequate amounts of testosterone. Not all target tissues, however, require the conversion of testosterone to dihydrotestosterone for activity. For example, effects of testosterone on skeletal muscles and bone marrow are mediated by the hormone or a metabolite other than dihydrotestosterone.

The adrenal cortex also secretes androgens, but the effects of these hormones are usually inconsequential unless a hormone-secreting tumor develops. For example, in males, approximately 10% of androgens are produced in the adrenal cortex, an insufficient amount to maintain spermatogenesis or secondary sexual features in an adult male. In abnormal conditions, such as the adrenogenital syndrome, the adrenal cortex can secrete large quantities of steroids and androgenic precursors.

Ovaries

The two ovarian hormones, estrogen and progesterone, are secreted in response to LH and FSH, which are released from the anterior pituitary in response to hypothalamic-releasing hormones. In postpubertal females, an orderly secretion of LH and FSH is necessary for menstruation, pregnancy, and lactation. The Stein-Leventhal syndrome is characterized by virilization when ovarian secretion of androgens is excessive.

Estrogens

Estrogens give the female sexual characteristics. In the nonpregnant female, most of the estrogen comes from the ovaries; small amounts are also secreted by the adrenal cortex. The three most important estrogens are β -estradiol, estrone, and estriol. These estrogens are conjugated in the liver to inactive metabolites that appear in urine.

Progesterone

Progesterone prepares the uterus for pregnancy and the breasts for lactation. Almost all of the progesterone in the nonpregnant female is secreted by the corpus luteum during the lateral phase of the menstrual cycle. The adrenal cortex forms small amounts of progesterone. Progesterone is metabolized to pregnanediol, which appears in the urine and is a valuable index of the secretion and metabolism of this hormone.

Menstruation

The overall duration of a normal menstrual cycle is 21 to 35 days and consists of three phases designated as follicular, ovulatory, and luteal. The follicular phase begins with the onset of menstrual bleeding after the plasma concentration of progesterone decreases. After a variable length of time, the follicular phase is followed by the ovulatory phase lasting 1 to 3 days and culminating in ovulation. The increase in body temperature ($\sim 0.5^{\circ}\text{C}$) that accompanies ovulation most likely reflects a thermogenic effect of progesterone. The luteal phase follows ovulation and is characterized by the development of a corpus luteum that secretes progesterone and estrogen. The corpus luteum degenerates after a fairly constant period of 13 to 14 days, and the menstrual cycle repeats.

Pregnancy

During pregnancy, the placenta forms large amounts of estrogens, progesterone, chorionic gonadotropin, and chorionic somatomammotropin. Chorionic gonadotropin prevents the usual involution of the corpus luteum or the onset of menstrual bleeding. The first key hormone of pregnancy, chorionic gonadotropin, which can be detected in the maternal plasma within 9 days after conception, is the basis for pregnancy tests. After approximately 12 weeks, the placenta secretes sufficient amounts of progesterone and estrogens to maintain pregnancy and the corpus luteum involutes. Chorionic somatomammotropin attenuates insulin activity, making more glucose available to the fetus.

Circulating concentrations of estrogen enlarge the breasts and uterus; progesterone is necessary to develop decidual cells in the uterine endometrium and to suppress uterine contractions that could result in spontaneous abortion. Greater concentrations of progesterone in plasma and associated sedative effects during pregnancy may explain why requirements for volatile anesthetics lessen in gravid animals. In animals, anesthetic requirements return to nonpregnant values within 5 days postpartum, whereas the plasma concentration of progesterone remains increased, suggesting that the decrease in MAC cannot be attributed entirely to progesterone.²² Progesterone increases carbon dioxide sensitivity in central respiratory centers, which is the stimulus for increased alveolar ventilation that accompanies pregnancy. Near term, the ovaries secrete the hormone relaxin, which relaxes pelvic ligaments, so the sacroiliac joints become limber and the symphysis pubis becomes elastic.

The parturient with asthma may experience unpredictable changes in airway reactivity. Exacerbation of asthma from bronchoconstriction is evoked by prostaglandins of the F series, which are present in all trimesters of pregnancy but especially during labor. Conversely, prostaglandins of the E series are bronchodilators and predominate during the third trimester. That corticosteroids alter airway responsiveness is questionable because the plasma concentrations of cortisol associated with pregnancy are offset by the carrier protein transcortin, with the net effect being an unchanged level of available cortisol.

Menopause

Between the ages of 45 and 55 years, a woman's ovaries gradually become unresponsive to the stimulatory effects of LH and FSH, and the sexual cycles disappear. Because the negative feedback control of estrogen and progesterone on the anterior pituitary is decreased, output of LH and FSH accumulates in circulating plasma concentrations. Sensations of warmth spreading from the trunk to the face (hot flashes) coincide with surges of LH secretion and are prevented by exogenous administration of estrogens.

Pancreas

The exocrine pancreas secretes digestive substances into the duodenum. The islets of Langerhans are organized endocrine cells that secrete four hormones (insulin, glucagon, somatostatin, and pancreatic polypeptide) into the systemic circulation. The pancreas contains 1 to 2 million islets, which, based on staining characteristics and morphology, are classified as α , β , δ , and pancreatic polypeptide cells.²³ β Cells account for about 60% of the islet cells and are the site of insulin production. The α cells account for 25% of islet cells and produce glucagon. Each islet receives a generous blood supply, which, unlike any other endocrine organ, drains into the portal vein.

Insulin

Insulin is a 51-amino acid peptide hormone synthesized in the β cells of the islets of Langerhans as a single polypeptide proinsulin, which is the precursor molecule to insulin (Figure 37.4).^{24,25} The peptide that connects the amino terminus of the A chain to the carboxyl terminus of the B chain is designated the connecting (C) peptide. Proinsulin is converted to insulin and C-peptide, and these two molecules are stored together in secretory granules. When pancreatic β cells are stimulated, equimolar amounts of insulin C-peptide are released. Thus, plasma concentrations of insulin C-peptide reflect functional activity of pancreatic β cells. Insulin is an anabolic hormone promoting the storage of glucose, fatty acids, and amino acids (Figure 37.5).²⁶ The amount of insulin secreted daily is equivalent to approximately 40 units. In the systemic circulation, insulin has an elimination half-time of approximately 5 minutes, with greater than 80% degraded in the liver and kidneys.

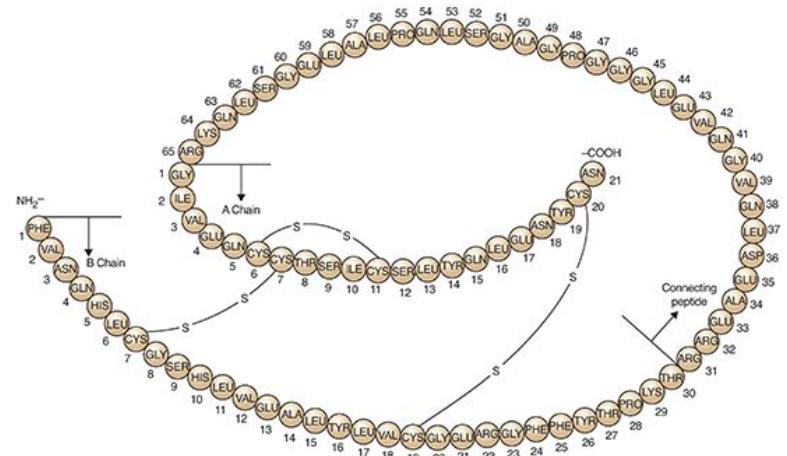

FIGURE 37.4 Proinsulin, which is converted to insulin by proteolytic cleavage of amino acids 31, 32, 64, 65, and the connecting peptide. FIGURE 37.5 Insulin stimulates tissue uptake of glucose and amino acids, whereas release of fatty acids is inhibited. As a result, the plasma concentrations of glucose, free fatty acids, amino acids, and ketoacids decrease. *From Berne RM, Levy MN, Koeppen BM, et al. Physiology. 5th ed. St Louis, MO: Mosby; 2004.* Reprinted with permission from Bruce M. Koeppen, MD.

Insulin binds to a transmembrane, glycoprotein receptor with two distinct insulin-binding domains (an extracellular domain of α subunits and an intracellular domain of β subunits) to regulate metabolic function.

When insulin binds to the extracellular domain, a conformational change of the α subunits facilitates adenosine triphosphate binding to the β subunits. As a result, tyrosine molecules in the intracellular portions of the transmembrane receptors are autophosphorylated. The phosphorylated receptor phosphorylates other protein substrates such as insulin receptor substrates that mediate enzyme activation (mitogen-activated protein), inactivation, and metabolic signaling (Figure 37.6).⁹ The insulin cascade stimulates translocation of glucose transporters (glucose transporter type 4) from the cytosol to plasma membranes to (1) facilitate glucose diffusion into cells; (2) shift intracellular glucose metabolism toward glycogen storage via glycogen synthetase activation; (3) stimulate cellular uptake of amino acids, phosphate, potassium, and magnesium; (4) stimulate protein synthesis and inhibit proteolysis; and (5) regulate gene expression via insulin regulatory elements in target DNA molecules. Activation of sodium-potassium adenosine triphosphatase in cell membranes by insulin moves potassium ions into cells and decreases concentration of potassium in plasma.

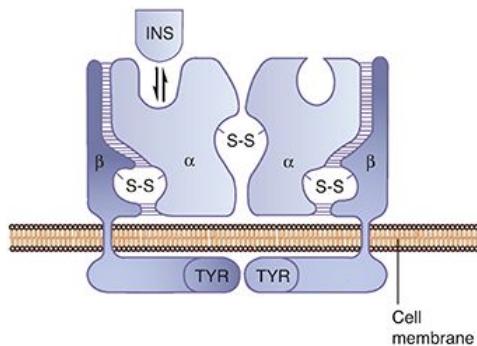

FIGURE 37.6 Schematic depiction of the insulin receptor consisting of two α and two β subunits joined by disulfide bonds ($-S-S-$). Insulin (INS) attaches to the α subunits, which triggers autophosphorylation of the tyrosine kinase (TYR) portions of the β subunits inside the cell and the resultant effects of insulin.

Regulation of Secretion

The principal control of insulin secretion is via a negative feedback effect of the blood glucose concentration in the pancreas (Table 37.8). Virtually no insulin is secreted by the pancreas when the blood glucose concentrations are less than 50 mg/dL, and maximum stimulation for release of insulin is at concentrations greater than 300 mg/dL. Thus, blood glucose concentrations are maintained within a narrow range. The pancreas is richly innervated by the autonomic nervous system so that insulin is released in response to β -adrenergic stimulation or to acetylcholine. Conversely, α -adrenergic stimulation or β -adrenergic blockade inhibits insulin release. Oral glucose is more effective than glucose administered intravenously in evoking the release of insulin, suggesting the presence of an anticipatory signal from the gastrointestinal tract to the pancreas. Glycosuria is more likely after intravenous rather than oral glucose administration. Glucagon, HGH, and corticosteroids potentiate glucose-induced stimulation of insulin secretion. Prolonged secretion of these hormones or their exogenous administration can exhaust pancreatic β cells and lead to diabetes mellitus. Indeed, diabetes mellitus is found in patients who develop acromegaly or in individuals with a diabetic tendency who are treated with corticosteroids.

Physiologic Effects

Insulin receptor expression is highest in tissues, which regulate glucose, lipid, and protein metabolism (adipose, skeletal muscle, and liver) via insulin. Insulin promotes the use of carbohydrates for energy while depressing the use of fats and amino acids. For example, insulin facilitates storage of fat in adipose cells by inhibiting lipase enzyme, which normally hydrolyzes triglycerides in fat cells. In the liver, insulin inhibits enzymes necessary for gluconeogenesis, thus conserving amino acid stores.

Insulin facilitates glucose uptake and storage in the liver through effects on specific enzymes. When insulin induces the activity of glucokinase, uptake of glucose into liver cells is enhanced. Glucokinase is the enzyme that causes initial phosphorylation of glucose after it diffuses into hepatocytes. Once phosphorylated, glucose is trapped and unable to diffuse back through cell membranes. Storage is further enhanced by insulin-induced inhibition of phosphorylase enzyme, which normally causes liver glycogen to split into glucose. The net effects of these actions of insulin on enzymes is to increase hepatic stores of glycogen up to a maximum of approximately 100 g. Ordinarily, approximately 60% of the glucose in a meal is stored in the liver as glycogen.

Resting skeletal muscles are almost impermeable to glucose except in the presence of insulin. Glucose that enters resting skeletal muscles under the influence of insulin is stored as glycogen for subsequent use as energy. The amount of glycogen that can be stored in skeletal muscles, however, is much less than the amount that can be stored in the liver. Furthermore, glycogen in skeletal muscles, unlike that stored in the liver, cannot be reconverted to glucose and released into the systemic circulation because skeletal muscles lack glucose phosphatase enzyme, which is necessary for splitting glycogen. Exercise increases the permeability of skeletal muscle membranes to glucose, perhaps because insulin is released from within the skeletal muscle itself or its vasculature.

Brain cells are unique in that the permeability of their membranes to glucose does not depend on the presence of insulin. This characteristic is crucial because brain cells use only glucose for energy, thus the importance of maintaining blood glucose concentrations above a critical level of approximately 50 mg/dL. Indeed, lack of insulin causes the use mainly of fat for energy to the exclusion of glucose, except by brain cells.

Deficiencies in insulin signaling are associated with insulin resistance. When an impaired intracellular signal decreases recruitment of proteins that transport glucose to the plasma membrane for glucose uptake, an individual is said to have insulin resistance. Compensatory hyperinsulinemia overcomes peripheral tissue resistance to insulin. A feedback loop exists between insulin responsiveness in target tissues and insulin secretion by pancreatic β cells.

Glucagon

Glucagon is a catabolic hormone acting to mobilize glucose, fatty acids, and amino acids into the systemic circulation ([Figure 37.7](#)).²⁶ These responses are the reciprocal of the insulin effects, emphasizing that these two hormones are also reciprocally secreted ([Table 37.9](#)). Indeed, the principal stimulus for secretion of glucagon is hypoglycemia. Glucagon abruptly increases the blood glucose concentration by stimulating glycogenolysis in the liver. Glucagon activates adenylate cyclase for the subsequent formation of cAMP. The metabolic effects of glucagon at the liver mimic those produced by epinephrine. Indeed, the study of the mechanism by which glucagon and epinephrine act as hyperglycemics led to the discovery of cAMP.²⁷ Glucagon also causes hyperglycemia by stimulating gluconeogenesis in hepatocytes. Enhanced myocardial contractility and more secretion of bile are effects when exogenous administration increases plasma concentrations of glucagon far above normal levels. Amino acids help the release of glucagon and thus

prevent hypoglycemia from ingestion of a pure protein meal, which stimulates insulin secretion. Glucagon undergoes enzymatic degradation to inactive metabolites in the liver and kidneys and at receptor sites in cell membranes. The elimination half-time of glucagon is brief—only 3 to 6 minutes.

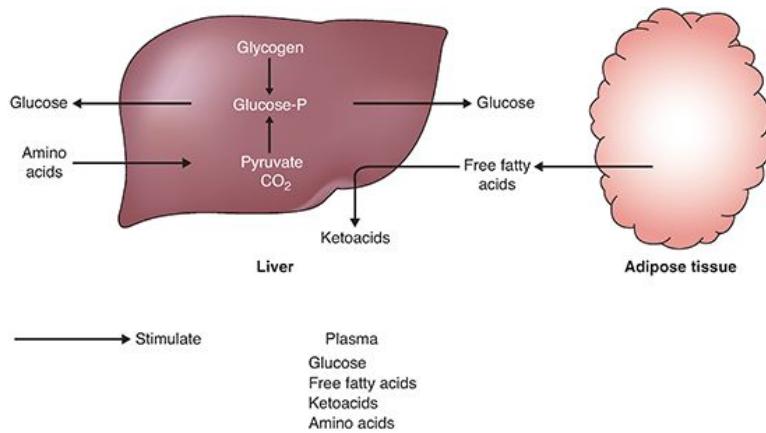

FIGURE 37.7 Glucagon stimulates tissue release of glucose, free fatty acids, and ketoacids and hepatic uptake of amino acids. *From Berne RM, Levy MN, Koeppen BM, et al. Physiology. 5th ed. St Louis, MO: Mosby; 2004. Reprinted with permission from Bruce M. Koeppen, MD.*

TABLE 37.9

Regulation of glucagon secretion

Drugs that Alter Glucose Regulation

Bianca Bromberger • Vivek K. Moitra

Diabetes Mellitus

According to recent recommendations by the American Diabetes Association and the World Health Organization, diabetes mellitus is classified by the underlying disease etiology (ie, type 1 vs type 2) rather than by age of onset (ie, juvenile-onset vs adult-onset diabetes) or treatment modality (ie, insulin-dependent vs non-insulin-dependent diabetes).¹ The insulin deficiency in type 1 diabetes is the result of autoimmune-mediated destruction of pancreatic β cells. Patients depend on exogenous insulin to regulate metabolism. Lack of insulin may precipitate diabetic ketoacidosis, a complex and potentially life-threatening metabolic derangement. Onset of type 1 diabetes is at a younger age than onset of type 2 diabetes, and sensitivity to insulin is normal. In type 2 diabetes, there is a failure to secrete insulin due to pancreatic β cell dysfunction that is coupled with peripheral insulin resistance. Oral hypoglycemic drugs are alternatives to exogenous administration of insulin to patients with type 2 diabetes. Most cases of diabetes are either type 1 or type 2 (approximately 90%); the remaining causes include gestation, exocrine pancreas disease, medications, endocrinopathies, genetic defects in insulin action and β cell function, infections, and uncommon immune-mediated disorders ([Table 38.1](#)).²

TABLE 38.1

Etiologic classification of diabetes mellitus

Type 1 diabetes mellitus (absolute insulin deficiency from pancreatic β cell destruction)
Type 2 diabetes mellitus (insulin resistance vs insulin deficiency)
Gestational diabetes mellitus
Exocrine pancreas disease (pancreatitis, pancreatectomy, cystic fibrosis, hemochromatosis)
Drug-induced (glucocorticoids, thiazides, thyroid hormone, β -adrenergic agonists)
Endocrinopathies (acromegaly, Cushing syndrome, glucagonoma)
Genetic defects in pancreatic β cell function
Genetic defects in insulin action (resistance)
Infections (congenital rubella, cytomegalovirus)
Uncommon immune-mediated diabetes (“stiff man” syndrome, anti-insulin receptor antibodies)

Under normal circumstances, insulin is released from pancreatic β cells in response to an increase in serum glucose. Insulin increases glucose uptake and use in fat and muscle and inhibits gluconeogenesis and glycogenolysis in the liver. In the setting of insulin deficiency and/or peripheral insulin resistance, hyperglycemia is caused by impaired glucose utilization, increased glycogenolysis, and generation of gluconeogenic precursors from peripheral muscle proteolysis with a subsequent increase in gluconeogenesis.

In the absence of insulin (as in type 1 diabetes), an increase in lipolysis and circulating free fatty acids leads to increased production of ketones in the liver, which serves as an energy source for skeletal muscles and cardiac muscles. Excess production of ketones can cause diabetic ketoacidosis. Urinary excretion of ketones contributes to the depletion of electrolytes, especially potassium. Hypokalemia, however, may not be apparent, because intracellular potassium ions are exchanged for extracellular ions to compensate for the acidosis.

When the primary pathology is peripheral insulin resistance and low serum levels of insulin are still present (as in type 2 diabetes), insulin may block lipolysis without preventing hyperglycemia. This explains why hyperglycemia can exist without the presence of ketone bodies. Ketosis can be reliably prevented by continuously providing all diabetic patients with glucose and insulin.³ Prevention is uniquely important in the perioperative period when nutritional intake is altered.

Hyperglycemia impairs vasodilation and induces a chronic proinflammatory, prothrombotic, and proatherogenic state and can cause vascular complications.⁴ Although all tissues are affected, the atherosclerotic changes that cause peripheral vascular disease, renal insufficiency, and cerebrovascular disease have the greatest impact on perioperative management.

The goals of therapy for patients with diabetes mellitus include preventing the adverse consequences of hypoglycemia and hyperglycemia, avoiding weight gain, and reducing microvascular and macrovascular complications. Symptoms of acute hyperglycemia (such as thirst, polyuria, or blurry vision) often resolve when blood glucose levels are less than 200 mg/dL. Long-term metabolic control of diabetes is best monitored by measurement of glycosylated hemoglobin ($\text{HbA}_{1\text{c}}$), which reflects glucose control over the previous 2 to 3 months. In general, $\text{HbA}_{1\text{c}}$ values less than 6.0% to 7.0% are associated with fewer microvascular complications. Compliance, age, comorbidities, and organ function (heart, kidney, liver) are all important considerations when prescribing therapy.⁵

Insulin

Because patients with type 1 diabetes mellitus do not produce insulin, they require exogenous administration of insulin therapy to survive. Insulin is prescribed for patients with type 2 diabetes mellitus if treatment with oral glucose regulators fails. In these patients, pancreatic β cells have been destroyed or autoantibodies have developed (see [Chapter 37](#) for insulin's mechanism of action). Insulin therapy mirrors the normal pattern of insulin secretion. Long-acting agents mimic basal insulin secretion and short-acting insulin administered before mealtimes to imitate pulsatile secretion in response to an increase in plasma glucose. At least two daily subcutaneous injections of intermediate- or long-acting insulin combined with rapid-acting insulin are nearly always required to achieve adequate glycemic control in type 1 diabetes.

Insulin receptors become fully saturated at low concentrations of insulin. For example, a continuous infusion of insulin at 1 to 2 units per hour has the same or even greater pharmacologic effect than a single larger intravenous (IV) dose that is cleared rapidly from the circulation. Large doses of insulin, however, will last longer and exert a greater net effect than small doses. The number of insulin receptors seems to be inversely related to the plasma concentration of insulin, which reflects the ability of insulin to regulate the population of its receptors.⁶ Obesity and type 2 diabetes mellitus appear to be associated with downregulation of important substrates in the insulin receptor pathway.⁷

Pharmacokinetics

In the basal state, insulin is secreted into the portal venous system at a rate of approximately 1 unit per hour. After food intake, the rate of insulin secretion increases 5- to 10-fold. The total daily secretion of insulin is approximately 40 units. The sympathetic and parasympathetic nervous systems innervate the insulin-producing islet cells to influence the basal rate of hormone secretion. For example, α -adrenergic stimulation decreases and β -adrenergic or parasympathetic nervous system stimulation increases the basal secretion of insulin. The insulin response to glucose is greater after oral ingestion than after IV infusion of glucose because glucose-dependent insulinotropic polypeptide is released after oral ingestion and the pancreatic β cell response is augmented.

The elimination half-time of IV insulin is 5 to 10 minutes in both healthy and diabetic patients. Insulin is metabolized in the kidneys and liver by a proteolytic enzyme. Approximately 50% of the insulin that reaches the liver through its portal vein is metabolized in a single passage. Nevertheless, renal dysfunction alters the disappearance rate of circulating insulin to a greater extent than does hepatic disease. Indeed, prolonged effects of insulin are found in patients with renal disease, reflecting impairment of both its metabolism and excretion by the kidneys. Peripheral tissues such as skeletal muscles and fat can bind and inactivate insulin, but this effect is of minor quantitative significance. Despite rapid clearance from plasma after IV injection of insulin, the pharmacologic effect lasts for 30 to 60 minutes because insulin is tightly bound to tissue receptors. Insulin administered subcutaneously releases slowly into the circulation to produce a sustained biologic effect.

Insulin Preparations and Delivery

Human insulin manufactured using recombinant DNA technology has replaced insulin extracted from beef and pork pancreas. Allergy or immunoresistance to animal insulins is no longer a serious problem. The basic principle of replacement is to provide a slow, long-acting, continuous supply of insulin (neutral protamine Hagedorn [NPH] insulin, insulin glargine, insulin detemir, or insulin degludec) that mimics the nocturnal and interprandial basal secretion of normal pancreatic β cells.⁸ A rapid and relatively short-acting form of insulin (insulin aspart, lispro, or glulisine) delivered before meals mimics the normal meal-stimulated (prandial) release of insulin.

A number of insulin preparations for subcutaneous administration are available (**Table 38.2**).⁹ The pharmacokinetics of these insulins vary from individual to individual and even within the same individual from day to day. Rates of insulin absorption from subcutaneous sites differ with the injection site (absorption from abdominal sites is least variable), depth and angle of injection, ambient temperature, and exercise of an injected extremity.

TABLE 38.2

Classification of insulin preparations

Insulin preparation	Hours after subcutaneous administration		
	Onset	Peak	Duration (hours)
Very rapid-acting			
Lispro	15-30 minutes	30-90 minutes	3-5
Insulin aspart	12-18 minutes	30-90 minutes	3-5
Glulisine	12-30 minutes	30-90 minutes	3-5
Rapid-acting			
Regular	30-60 minutes	2-4 hours	5-8
Intermediate-acting			
NPH	1-2 hours	4-12 hours	12-16
Lispro protamine	30-60 minutes	4-12 hours	12-16
Long-acting			
Detemir	1-2 hours	6-8 hours	6-24
Glargine	1-2 hours	None	20-26
Ultra long-acting			
Degludec	30-90 minutes	None	>40

Abbreviation: NPH, neutral protamine Hagedorn.

Commercially prepared insulin is bioassayed, and its physiologic activity (potency), based on the ability to decrease blood glucose concentration, is expressed in units. Insulin U-100 (100 U/mL) is the most commonly used commercial preparation. The total daily exogenous dose of insulin for treatment of type 1 diabetes mellitus is usually in the range of 0.5 to 1 U/kg per day. This insulin requirement, however, may be increased dramatically by stress associated with sepsis or trauma.

Continuous subcutaneous insulin infusion through an external pump delivers basal insulin (0.01-0.015 U/kg per hour) and bolus doses before meals. With this system, nocturnal versus daytime basal requirements can be accommodated, infusions can be altered during exercise, and doses can be calculated via algorithms of previous glucose values and insulin delivery. Short-acting insulin (regular) and ultra-rapid-acting insulins (lispro, aspart, and glulisine) are the only preparations used for continuous subcutaneous insulin infusion delivery pumps.

Lispro

Lispro is a short-acting insulin analogue that more closely parallels physiologic insulin secretion and needs. A feature of natural or synthetic human insulin is that six molecules associate with a zinc molecule to form hexamers. Insulin hexamers must dissociate to monomers before absorption from subcutaneous injection

sites. This feature is the reason that crystalline zinc insulin (regular insulin) has a peak action 2 to 4 hours after its subcutaneous injection. It must be administered 30 to 60 minutes before eating to effectively limit postprandial hyperglycemia. Lispro insulin is created by exchanging lysine and proline at positions 28 and 29 of the insulin B chain. As a result of this, hexamer formation is prevented, and the monomer is rapidly absorbed from the injection site. Therefore, lispro insulin injected subcutaneously begins to act within 15 minutes, the peak effect is reached in 30 to 90 minutes, and the duration of action is only 3 to 5 hours. Lispro injected just before eating provides a postprandial plasma insulin concentration profile like that of normal insulin secretion. An important benefit of lispro is a decrease in postprandial hyperglycemia and less risk of hypoglycemia, which may follow injection of regular insulin. Loss of the late action of regular insulin, however, may result in recurrent hyperglycemia before the next meal. In patients treated with lispro, HbA_{1c} may not decrease unless the doses of basal insulin (NPH, detemir, or glargine) are increased to better control between-meal hyperglycemia.

Insulin Aspart and Glulisine

Insulin aspart and glulisine are synthetic rapid-acting analogues with a profile of action and therapeutic benefits similar to those of lispro.

Regular Insulin (Crystalline Zinc Insulin)

Regular insulin is a fast-acting preparation and is the only form of insulin that can be administered IV as well as subcutaneously. This form can be mixed in the same syringe with other insulin preparations if the pH of the solutions is similar.

Administration of regular insulin is preferred for treating the abrupt onset of hyperglycemia or the appearance of ketoacidosis. In the perioperative period, regular insulin is administered as a single IV injection (1-5 units) or as a continuous infusion (0.5-2.0 units per hour) to treat metabolic derangements associated with diabetes mellitus.

Neutral Protamine Hagedorn

The NPH is an intermediate-acting preparation whose absorption from its subcutaneous injection site is delayed because the insulin is conjugated with protamine. The acronym NPH designates a neutral solution (N), protamine (P), and origin in Hagedorn's (H) laboratory.¹⁰ This insulin preparation contains 0.005 mg protamine per unit of insulin.

Glargine, Detemir, and Degludec

Glargine, detemir, and degludec are long-acting insulin analogues for basal insulin replacement. Compared to NPH insulin, these long-acting insulins have a later onset of action and less pronounced peaks. Glargin or detemir can be administered as a single bedtime injection to provide basal insulin for 24 hours with less nocturnal hypoglycemia.¹¹ Unlike glargin and detemir, degludec can be mixed with rapid-acting insulins. Degludec is not approved for use in the United States.

Side Effects

Side effects of treatment with insulin include (1) hypoglycemia, (2) allergic reactions, (3) lipodystrophy, (4) insulin resistance, or (5) drug interactions.

Hypoglycemia

The most serious side effect of insulin therapy is hypoglycemia. Patients are vulnerable to hypoglycemia if they receive exogenous insulin in the absence of carbohydrate intake, such as the perioperative fasting period before surgery. The first symptoms of hypoglycemia (diaphoresis, tachycardia, and hypertension) are from increased epinephrine secretion to raise the blood glucose concentration. Rebound hyperglycemia caused by sympathetic nervous system activity in response to hypoglycemia (Somogyi effect) may mask the correct diagnosis. Symptoms of hypoglycemia involving the central nervous system (CNS) include mental confusion progressing to seizures and coma. The CNS effects are intense because the brain depends on glucose as a

selective substrate for oxidative metabolism. A prolonged period of hypoglycemia may result in irreversible brain damage.

The diagnosis of hypoglycemia during general anesthesia is difficult because anesthetic drugs mask the classic signs of sympathetic nervous system stimulation. Hypoglycemia may cause changes in heart rate and systemic blood pressure.¹² The signs of sympathetic nervous system stimulation are likely to be confused with responses evoked by painful surgical stimulation in an anesthetized patient. The anesthesiologist may then decide to increase the dose of anesthetic drugs. Nonselective β-adrenergic antagonists also may mask the symptoms of hypoglycemia.

Severe hypoglycemia is treated with 50 to 100 mL of 50% glucose solution administered IV. Alternatively, glucagon, 0.5 to 1.0 mg administered IV or subcutaneously, is given. Nausea and vomiting are frequent side effects of glucagon treatment. In the absence of CNS depression, carbohydrates may be administered orally.

Allergic Reactions

Use of human insulin preparations has eliminated the problem of systemic allergic reactions that could result from administration of animal-derived insulins. Reactions to insulin preparations can be from either noninsulin components or the insulin itself. Insulin analogues, such as insulin lispro or aspart, are observed to be less allergenic, although still have the potential to cause allergic reactions. Type I hypersensitivity reactions are the most frequent and can range from local injection site swelling and erythema to less common systemic reactions, such as urticaria. Although rare, anaphylactic reactions are possible.¹³ Chronic exposure to low doses of protamine in NPH insulin may stimulate the production of antibodies against protamine. Patients may remain asymptomatic until a large dose of protamine is administered IV to antagonize the anticoagulant effects of heparin. Although patients who are treated with NPH insulin have had allergic reactions to protamine, allergic reactions to protamine are not more common in diabetic patients treated with NPH insulin than in nondiabetics.^{14,15}

Lipodystrophy

Lipodystrophy results when fat atrophies at the site of subcutaneous injection of insulin. This side effect is minimized by frequently changing the site used for injection of insulin.

Insulin Resistance

Given that insulin requirements for pancreatectomized adults are often as low as 30 units per day, diabetic patients requiring greater than 100 units of exogenous insulin per day are in a state of insulin resistance. The use of human insulins has eliminated the problem of immunoinsensitivity that could accompany administration of animal insulins. Acute insulin resistance can be seen in stress situations, such as infection or trauma, when an excess of counterregulatory hormones such as cortisol and catecholamines predominates.

Drug Interactions

Certain hormones that are administered as drugs may counter the hypoglycemic effect of insulin, including adrenocorticotropic hormone, estrogens, and glucagon. Epinephrine inhibits the secretion of insulin and stimulates glycogenolysis. Certain antibiotics (tetracycline or chloramphenicol), salicylates, and phenylbutazone increase the duration of action of insulin and may have a direct hypoglycemic effect. The hypoglycemic effect of insulin may be potentiated by monoamine oxidase inhibitors.

Other Glucose Regulators

Oral drugs with different mechanisms of action are available for controlling plasma glucose concentrations in patients with type 2 diabetes mellitus ([Table 38.3](#)). None of these drugs will adequately control hyperglycemia indefinitely. Therefore, use of combinations of oral drugs from the onset of treatment may be indicated.¹⁶ Insulin itself may be administered with oral glucose regulators. The effect on HbA_{1c} is similar for these drugs.

TABLE 38.3**Oral drugs for treatment of type 2 diabetes mellitus****Sulfonylureas (stimulate insulin secretion; hypoglycemia a risk)**

Glyburide

Glipizide

Glimepiride

Gliclazide

Dipeptidyl-peptidase-4 inhibitors (increase insulin secretion; hypoglycemia not a risk)

Sitagliptin

Saxagliptin

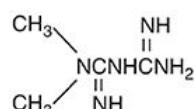

Vildagliptin

Linagliptin

Alogliptin

Metformin

Metformin is an oral biguanide that is often prescribed as the initial agent to prevent hyperglycemia in patients with type 2 diabetes ([Figure 38.1](#)). Metformin decreases blood glucose concentrations in both the fasting and postprandial state and rarely causes hypoglycemia. It can be used in combination with other medications such as insulin and sulfonylureas. Metformin should not be prescribed for patients with lactic acidosis, acute kidney injury, gastrointestinal intolerance, or acute hepatic disease. In addition to lowering blood glucose levels, metformin improves lipid profiles and fibrinolysis and promotes mild to moderate weight loss.¹⁷ Metformin also has been used in patients with polycystic ovarian disease, nonalcoholic fatty liver disease, and premature puberty.

**FIGURE 38.1** Metformin.**Pharmacokinetics**

In contrast to sulfonylureas, metformin is not bound to plasma proteins and does not undergo metabolism. It is eliminated by the kidneys, with 90% of an oral dose excreted in approximately 12 hours. Peak plasma concentrations of metformin occur approximately 2 hours after oral administration. The drug has an elimination half-time of 2 to 4 hours, which means that it is taken up to three times a day (500-1,000 mg with meals). In view of its dependence on renal clearance, metformin is prescribed with caution, if at all, to patients with renal dysfunction.

Mechanism of Action

The blood glucose-lowering effect of metformin is not mediated through stimulation of endogenous insulin secretion.¹⁸ Metformin suppresses hepatic glucose production by decreasing gluconeogenesis and glycogenolysis and enhances postprandial insulin suppression of hepatic glucose production. Metformin also regulates glucose levels by decreasing gastrointestinal glucose absorption, increasing insulin sensitivity in peripheral tissues, and enhancing synthesis of glucagon-like peptide-1 (GLP-1) in the ileum, to stimulate insulin release from pancreatic β cells.¹⁷

Side Effects

The most common side effects of metformin are anorexia, nausea, and diarrhea, which are dose related. Up to 15% of patients experience side effects sufficient to warrant withdrawal of the drug.⁵ In contrast to sulfonylureas, metformin does not cause hypoglycemia. Metformin is associated with vitamin B₁₂ deficiency.⁵ The most serious, although rare, side effect of metformin therapy is lactic acidosis.

Lactic Acidosis

Lactic acidosis is a possible side effect associated with metformin that has been described during the intraoperative period.¹⁸⁻²⁰ For this reason, some have recommended discontinuing metformin 48 hours or longer before elective operations.¹⁹ If metformin cannot be discontinued before surgery, the patient is monitored for the development of lactic acidosis (arterial blood gases and pH, serum lactate concentrations, renal function) in the perioperative period.

Metformin inhibits the mitochondrial enzyme glycerophosphate dehydrogenase to suppress glucogenogenesis in hepatocytes, which results in a decrease in the conversion of lactate to pyruvate.²¹ In patient with normal hepatic function, lactate is usually metabolized quickly in the liver. For this reason, metformin should be administered with caution, if at all, to patients with a history of hepatic dysfunction, renal insufficiency (creatinine level >1.5 mg/dL), acute myocardial infarction, congestive heart failure, arterial hypoxemia, or sepsis. For patients in need of an imaging study that requires IV administration of radiographic iodinated contrast media, metformin may be continued only if the patient has normal renal function and no evidence of acute kidney injury.²² Hemodialysis along with bicarbonate administration can be effective therapy for metformin-induced lactic acidosis. Management of biguanide-induced lactic acidosis is supportive because the underlying pathologic change (blockade of the mitochondrial respiratory chain) cannot be treated.

Sulfonylureas

Sulfonylurea compounds are drugs capable of lowering blood glucose concentrations even to hypoglycemic levels (**Figure 38.2**).^{18,23} Successful management of glucose control with sulfonylureas requires some β cell function, and its use is ineffective in the treatment of patients with type 1 diabetes mellitus. As many as 20% of patients with type 2 diabetes mellitus who begin sulfonylurea therapy do not have an adequate hypoglycemic response to maximal doses (*primary failures*), and each year, an additional 5% to 10% of patients who responded initially fail to respond to sulfonylurea therapy (*secondary failure*).^{23,24} Although sulfonylureas are derivatives of sulfonamides, they have no antibacterial actions. These drugs should not be administered to patients with known allergy to sulfa drugs.

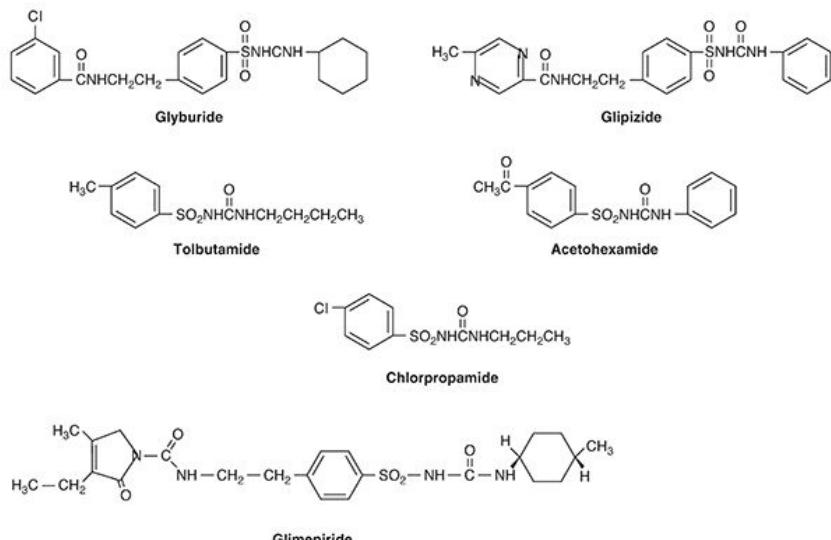

FIGURE 38.2 Oral hypoglycemics derived from sulfonylurea.

Mechanism of Action

Sulfonylurea receptors are found on pancreatic and cardiac cells. These drugs inhibit adenosine triphosphate-sensitive potassium ion channels (now known as the **sulfonylurea receptor-1**) on pancreatic β cells.⁵ As a result, there is an influx of calcium and stimulation of exocytosis (release) of insulin storage granules. Although sulfonylureas decrease insulin resistance, this effect is minor, if at all, in decreasing blood glucose concentrations.

Pharmacokinetics

Sulfonylureas are readily absorbed from the gastrointestinal tract, with the most important distinguishing features being differences in duration of action and elimination half-time (Table 38.4).²³ The biologic effects of sulfonylureas such as glyburide may be longer than plasma half-lives because of the formation of active metabolites.²⁵ Weakly acidic, sulfonylureas circulate bound to protein (90%–98%), principally to albumin. Metabolism in the liver is extensive, and the active and inactive metabolites are eliminated by renal tubular secretion. Approximately 50% of glyburide is excreted in feces.

TABLE 38.4

Classification and pharmacokinetics of sulfonylurea oral hypoglycemics

	Equivalent daily dose (mg)	Daily dose range (mg)	Doses per day	Duration of action (hours)	Elimination half-time (hours) ^a
Glyburide	2.5-5	2.5-20	1-2	18-24	4.6-12
Glipizide	5-10	5-40	1-2	12-24	4-7
Glimepiride	2	2-4	1	24+	5-8

^aApproximate.

Side Effects

Sulfonylureas are generally well tolerated; the most common severe complication of these drugs is hypoglycemia. The greatest risk of hypoglycemia occurs with drugs with the longest elimination half-times, specifically glyburide and chlorpropamide. Although hypoglycemia from sulfonylureas may be infrequent, it is often more prolonged and more dangerous than hypoglycemia from insulin (Table 38.5).

TABLE 38.5**Comparison of sulfonylurea therapy with insulin therapy**

Sulfonylurea	Insulin
Failed initial response in 10%-15% of patients	No maximum dose
Secondary failure rate each year among treated patients is about 10%.	
Hypoglycemia may be more severe.	Hypoglycemia may be more frequent.
Associated cardiac complications	Lipid levels lowered
Patients may prefer oral medication.	Patients may resist injections.

Hypoglycemia caused by sulfonylureas is treated with prolonged infusion of glucose-containing solutions. Risk factors for sulfonylurea-induced hypoglycemia include (1) impaired nutrition, as in the perioperative period; (2) age older than 60 years; (3) impaired renal function; and (4) concomitant drug therapy that potentiates sulfonylureas (phenylbutazone, sulfonamide antibiotics, warfarin) or itself produces hypoglycemia (alcohol or salicylates). Renal disease decreases elimination of sulfonylureas and their active metabolites, thus increasing the likelihood of hypoglycemia. Sulfonylurea metabolites are renally cleared, thus rendering those with short-half lives and relatively inactive metabolites (such as glipizide or glimepiride) preferable to others with longer durations of action and active metabolites (such as glyburide) for use in patients with renal insufficiency.²⁶ Sulfonylureas cross the placenta and may produce fetal hypoglycemia.

Sulfonylureas close adenosine triphosphate–sensitive potassium channels and inhibit ischemic preconditioning, a cardioprotective mechanism.²⁷ Cardiovascular mortality has been associated with some older sulfonylureas (such as tolbutamide or chlorpropamide), especially in patients who have had a prior myocardial infarction.^{28,29} Newer sulfonylureas that are selective for pancreatic β cells, such as glimepiride and gliclazide, may not be associated with the same cardiac morbidity.^{30,31} For this reason, sulfonylureas may be discontinued 24 to 48 hours before elective surgery in high-risk patients.

Approximately 1% to 3% of patients treated with sulfonylureas experience gastrointestinal disturbances including nausea, vomiting, abnormal liver function tests, and cholestasis. Sulfonylureas are not recommended for patients with hepatic dysfunction as liver disease prolongs their elimination half-time and enhances their hypoglycemic action, except for acetohexamide. Disulfiram-like reactions and inappropriate secretion of arginine vasopressin hormone that results in hyponatremia are unique side effects of chlorpropamide.

Glyburide

Glyburide stimulates insulin secretion over a 24-hour period after a morning oral dose.³² Peak plasma levels occur approximately 3 hours after an oral dose. Glyburide increases sensitivity to insulin and inhibits the production of glucose by the liver. Metabolism is in the liver, with metabolites excreted equally in urine and feces. One of the hepatic metabolites of glyburide has approximately 15% of the activity of the parent compound. A mild diuretic effect accompanies use of this drug. When administration is discontinued, the drug is cleared from plasma in about 36 hours.

Glipizide

Glipizide stimulates insulin secretion over a 12-hour period after a morning oral dose. Peak plasma levels occur approximately 1 hour after oral administration. Glipizide increases glucose uptake and suppresses glucose output by the liver.³³ These effects persist for prolonged periods (at least 3 years) without evidence of tolerance. Unlike glyburide, metabolism of glipizide in the liver produces inactive substances that are excreted in urine. A mild diuretic effect accompanies use of this drug. Relatively rapid clearance from the plasma minimizes the potential for long-lasting hypoglycemia.

Glimepiride

Glimepiride decreases blood glucose concentrations by stimulating release of insulin from the pancreas and may decrease hepatic glucose production.

Thiazolidinediones

Thiazolidinediones (TZDs), such as rosiglitazone and pioglitazone, act principally at skeletal muscle, liver, and adipose tissue via peroxisome proliferator activator receptors to decrease insulin resistance and hepatic glucose production and to increase use of glucose by the liver.³⁵ As monotherapy, these drugs decrease HbA_{1c} 1% to 1.5%. The clinical effect takes 4 to 12 weeks. The TZDs tend to decrease plasma concentrations of triglycerides and increase high-density lipoprotein and low-density lipoprotein cholesterol levels. The TZDs can cause weight gain, from an increase in extracellular fluid. The accumulation of extracellular fluid as edema is undesirable in patients with congestive heart failure. Although rosiglitazone has been associated with cardiovascular risk, particularly heart failure, this risk may be similar to the cardiovascular risks observed with other standard diabetes medications.³⁴ These drugs also are contraindicated in patients with liver failure. The possibility of drug-induced liver dysfunction is the reason that plasma concentrations of hepatic transaminases must be measured periodically.

Glucagon-like Peptide-1 Receptor Agonists

The GLP-1 receptor agonists are injectable agents that bind to receptors in the pancreas, gastrointestinal tract, and brain. These drugs exert a multitude of effects, including increasing insulin secretion from β cells, decreasing glucagon production from α cells, slowing gastric emptying, and reducing appetite, and are associated with weight loss. The GLP-1 receptor antagonists are associated with reductions in adverse cardiovascular outcomes (such as stroke or acute coronary syndrome), particularly in patients with preexisting cardiovascular disease. Not all GLP-1 receptor antagonists are known to confer such benefits; the current evidence suggests liraglutide and semaglutide are associated with improvement in cardiovascular outcomes.^{35,36} Recent consensus guidelines promote the use of such GLP-1 receptor antagonists in patients with type 2 diabetes failing to achieve adequate reduction in hyperglycemia with metformin, particularly if they have atherosclerotic cardiovascular disease.³⁷

Side Effects

Nausea, vomiting, and diarrhea are associated with GLP-1 receptor agonists. The GLP-1 receptor agonists do not cause hypoglycemia unless combined with other medications that are known to cause hypoglycemia, such as sulfonylureas and insulin.

Pharmacokinetics

The GLP-1 receptor agonists vary in their duration of action. Short-acting GLP-1 receptor agonists are more effective at lowering postprandial glucose levels, whereas long-acting agents have a greater effect on fasting glucose levels. Short-acting GLP-1 receptor agonists include lixisenatide (administered once daily) and the short-acting formulation of exenatide (administered twice daily). They are excreted in the urine and are not recommended for use in patients with renal failure.

Long-acting GLP-1 receptor agonists range from dosing once daily (liraglutide) to once weekly (dulaglutide, semaglutide, and the extended-release formulation of exenatide). Semaglutide also exists in an oral formulation, but it must be taken once daily. The longer acting GLP-1 receptor agonists undergo systemic proteolysis. Data is limited on GLP-1 receptor agonists' safety in patients with renal impairment, but current evidence does not suggest a contraindication to their use in patients with kidney disease.³⁸

Sodium-Glucose Cotransporter 2 Inhibitors

The sodium-glucose cotransporter type 2 (SGLT2) is a transport protein present in the proximal tubule and responsible for approximately 90% of glucose reabsorption in the kidneys.³⁹ The SGLT2 inhibitors, also known as gliflozins, are orally administered and rely on normal renal function to effectively lower serum glucose levels via increasing glucose excretion in the kidneys. The gliflozins are also associated with weight loss and a reduction in blood pressure. Data suggests that SGLT2 inhibitors are associated with a reduction in risk of cardiovascular events (such as stroke and myocardial infarction) and heart failure in patients with

established cardiovascular disease.^{40,41} The best evidence for such risk reduction exists for empagliflozin and canagliflozin.

Side Effects

Given that SGLT2 inhibitors lower serum glucose levels by incurring an osmotic diuresis, the resultant volume loss may cause hypotension or acute kidney injury, particularly in patients concurrently taking diuretics, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers. Thus, assessment of renal function should be conducted prior to initiation of and at regular intervals while taking SGLT2 inhibitors. Use of SGLT2 inhibitors is associated with increased risk of urinary tract and genital infections.⁴² The SGLT2 inhibitors may also reduce bone mineral density and increase the risk of fracture.

Dipeptidyl-Peptidase-4 Inhibitors

Dipeptidyl-peptidase-4 (DPP-4) is an enzyme that degrades incretin hormones (hormones that are released after eating and have glucose-lowering properties), such as GLP-1. Similar to GLP-1 receptor agonists, DPP-4 inhibitors (including saxagliptin, sitagliptin, linagliptin, alogliptin, and vildagliptin) increase insulin secretion from β cells (glucose dependent) and reduce pancreatic α cell secretion of glucagon.⁵ As opposed to SGLT2 inhibitors and GLP-1 receptor agonists, DPP-4 inhibitors have not demonstrated a reduction in cardiovascular events, and variable evidence exists for an increased risk of heart failure associated with saxagliptin.³⁷ This class of drugs is orally administered and has a duration of action of 12 to 24 hours. Dose reductions are required for patients with renal insufficiency, with the exception of linagliptin, which is primarily cleared via the enterohepatic system. However, dose adjustments are made solely because less medication is needed to reach therapeutic levels, not because of any known adverse effects of accumulation of the drug.⁴³ The DPP-4 inhibitors are overall well tolerated. Reported side effects that may be associated with DPP-4 inhibitors include musculoskeletal pain and pancreatitis.^{44,45}

Other Medications

A myriad of other medications that lower blood glucose exist but are not commonly in use in the treatment of diabetes. Meglitinides exert effects on β cells similar to sulfonylurea drugs and are associated with hypoglycemia. Acarbose and miglitol are α -glucosidase inhibitors that decrease carbohydrate digestion and absorption of disaccharides by interfering with intestinal glucosidase activity.²³ As a result, both drugs release glucose from food and are slowly absorbed from the gastrointestinal tract. Flatulence, abdominal cramping, and diarrhea are side effects that frequently result from undigested carbohydrates that reach bacteria in the lower colon. Pramlintide is an injectable medication that mimics the effects of the hormone amylin, which is secreted from pancreatic β cells and suppresses gastric emptying, increases satiety, and inhibits glucagon release. Side effects include hypoglycemia and gastrointestinal upset. Colesevelam (a bile acid sequestrant) and bromocriptine mesylate (a dopamine receptor agonist) lower glucose levels and decrease HbA_{1c} values, but the mechanisms are unclear. Neither of these medications is associated with hypoglycemia and both may cause gastrointestinal intolerance.⁵

Combination Therapy

Combination therapies target two or more different causes of hyperglycemia simultaneously. For example, insulin resistance in the liver is decreased with metformin while insulin secretion is increased with sulfonylureas. Exogenous insulin also may be part of combination therapy. The primary aim of combination therapy is to decrease HbA_{1c}; reductions in the daily insulin dose are a secondary benefit.

Drugs for the Treatment of Hypothyroidism and Hyperthyroidism

Dasun Peramunage • Vivek K. Moitra

Hypothyroidism

Hypothyroidism is defined as a deficiency in thyroid hormone and presents with signs and symptoms outlined in **Table 39.1**. Diagnostic evaluation of hypothyroidism involves measuring serum thyroid-stimulating hormone (TSH) and serum free and total thyroxine (T_4)/triiodothyronine (T_3) (**Table 39.2**). The primary treatment of hypothyroidism is hormone replacement therapy. In primary hypothyroidism, TSH concentrations can be used to monitor this treatment. Free T_4 is an insensitive indicator and may be within the normal range when TSH is inhibited. However, measurement of free T_4 is warranted in secondary hypothyroidism when TSH release is impaired. The goals of therapy include correction of hypothyroidism to a euthyroid state (reduction of symptoms and normalization of TSH secretion), reduction in goiter size, and/or prevention of thyroid cancer recurrence.

TABLE 39.1

Signs and symptoms associated with hyperthyroidism and hypothyroidism

	Hyperthyroidism	Hypothyroidism
Constitutional	Weight loss, despite gain in appetite; heat intolerance; fatigue	Weight gain, cold intolerance, fatigue, hypothermia; myxedema
Cardiovascular	Palpitations; tachycardia; atrial fibrillation	Bradycardia; hypertension; diastolic dysfunction; pericardial effusion
Neuromuscular	Tremors; hyperreflexia	Hoarseness; neuropathy; hyporeflexia
CNS/psychiatric	Anxiety; poor concentration; insomnia	Cognitive impairment; myxedema coma; dysthymia/depression
Pulmonary	Dyspnea; tachypnea	
Gastrointestinal	Diarrhea; nausea/vomiting	Constipation
Dermatologic	Hyperhidrosis	Alopecia; dry skin
Reproductive	Disruption in menstruation	infertility
Ocular	Diplopia; proptosis; chemosis; ophthalmoplegia	
Renal/electrolytes		Hyponatremia; decreased GFR
Hematologic		Macrocytic anemia

Abbreviations: CNS, central nervous system; GFR, glomerular filtration rate.

TABLE 39.2

Laboratory assessment of thyroid function

Laboratory test	Clinical considerations
TSH	<ul style="list-style-type: none">Biotin will falsely reduce TSH measurements.
Total T_4/T_3	<ul style="list-style-type: none">Measures total bound and unbound serum T_4/T_3 hormone
Free T_4/T_3	<ul style="list-style-type: none">Heparin will falsely increase free T_4 measurements.Accuracy of free hormone assays is questionable in pregnancy and acute illness where changes in binding protein (albumin and thyroglobulin) occur.

Abbreviations: T_3 , triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone.

Synthetic Thyroxine (Levothyroxine)

Synthetic T₄ is the treatment of choice for primary hypothyroidism. In the peripheral tissues, T₄ is deiodinated to form T₃ (the active form of thyroid hormone) ([Figure 39.1](#)). In young healthy patients, initial doses range from 50 to 200 µg per day. Although formulations of T₄ (Synthroid, Levoxyl, generic preparations) may have minor differences in bioavailability, one study suggests that bioequivalence among formulations may be equivalent.^{1,2} Doses may be decreased in older patients and in patients with coronary artery disease and increased by up to 30% during pregnancy.^{3–5} The TSH levels are measured approximately 4 to 12 weeks after initiation of therapy and then every 6 months until a steady dose is established; after achieving steady state, TSH levels can be monitored yearly. Because T₄ has a half-life of 7 to 10 days, hypothyroid patients can miss several days of T₄ without adverse consequences. If the patient is unable to eat for more than a week, parenteral T₄ (80% of the patient's oral dose) can be administered.

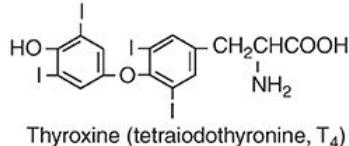

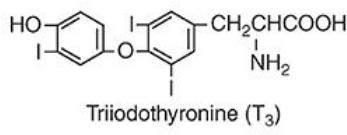

FIGURE 39.1 Thyroid gland hormones.

Triiodothyronine Formulations (Liothyronine)

Liothyronine is the levorotatory isomer of T₃ and is 2.5 to 3.0 times more potent than levothyroxine. Its rapid onset and short duration of action preclude the use of liothyronine for long-term thyroid replacement. A T₄-T₃ combination therapy may improve symptoms in a small subgroup of patients with a polymorphism in type 2 deiodinase, which converts T₄ to T₃.⁶ Both the European Thyroid Association and American Thyroid Association guidelines recommend against the routine use of combination therapy to treat hypothyroidism because outcomes with combination therapy are not significantly improved compared to monotherapy with levothyroxine.⁵

Hyperthyroidism

Excessive thyroid hormone synthesis and secretion underlie the pathophysiology of hyperthyroidism and can present clinically with signs and symptoms outlined in [Table 39.2](#). The treatments for hyperthyroidism are antithyroid drugs, radioiodine, and/or surgery. The TSH levels are useful for the diagnosis of hyperthyroidism but not for determining its degree of severity. Therefore, measuring free T₃ and T₄ is necessary to assess the efficacy of treatment. Once steady state is achieved, TSH can be used to assess the efficacy of therapy.

A large number of substances interfere with the synthesis of thyroid hormones or reduce the amount of thyroid tissue. These compounds include (1) thionamides, (2) inhibitors of the iodide transport mechanism, (3) iodide, and (4) radioactive iodine. Of these compounds, only thionamides, iodide, and radioactive iodine are used to treat hyperthyroidism.

Thionamides (Methimazole, Propylthiouracil, Carbimazole)

Thionamides are antithyroid drugs that inhibit the formation of thyroid hormone by inhibiting thyroid peroxidase to prevent incorporation of iodine into tyrosine residues of thyroglobulin ([Figure 39.2](#)).

Thionamides exert immunosuppressive effects via a reduction in concentrations of antithyrotropin-receptor antibodies. In addition to blocking hormone synthesis, propylthiouracil also inhibits the peripheral deiodination of T₄ and T₃.⁵ Carbimazole is a prodrug that is metabolized into its active form, methimazole. Antithyroid drugs are useful in the treatment of hyperthyroidism before elective thyroidectomy.

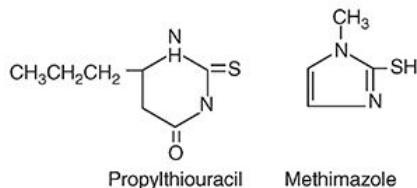

FIGURE 39.2 Antithyroid drugs.

Serum levels of thionamides peak 1 to 2 hours after ingestion.⁵ Thionamides are not available as parenteral preparations. The half-life of methimazole (4–6 h, dosed once daily) is longer than the half-life of propylthiouracil (75 min, dosed several times per day). Drug-induced decreases in excessive thyroid activity usually require several days because preformed hormone must be depleted before symptoms begin to wane. In a few patients, especially those with severe hyperthyroidism, definite improvement is evident in 1 to 2 days. Thyroid function, namely, serum T₄ and T₃ levels, is checked 4 to 6 weeks after induction of therapy and then every 2 to 3 months once the patient is euthyroid.⁸

Side Effects

Minor side effects of thionamide therapy are observed in approximately 5% of patients and include urticarial or macular skin rash, arthralgias, and gastrointestinal discomfort.⁷ Granulocytopenia and agranulocytosis are serious but rare side effects that are most likely to occur in the first 3 months of therapy with an antithyroid drug.⁷ Periodic white blood cell counts, although helpful for detecting gradual decreases in the leukocyte count, should not be relied on to detect agranulocytosis because of the rapidity with which this complication can develop. Fever or pharyngitis may be the earliest manifestation of the development of agranulocytosis. Recovery is likely if the antithyroid drug is discontinued at the first sign of this side effect. Hepatic toxicity has been reported with thionamide use, particularly propylthiouracil.^{9,10} Methimazole crosses the placenta and appears in breast milk. Placental passage, however, is limited for propylthiouracil, making it the preferred drug for use in the parturient.⁷

Iodine (Saturated Potassium Iodide Solutions, Potassium Iodide-Iodine [Lugol Solution])

Iodide is the oldest available therapy for hyperthyroidism, providing a paradoxical treatment that is effective for reasons that are not fully understood. The response of the patient with hyperthyroidism to iodide is acute and often discernible within 24 hours, emphasizing that release of hormone into the circulation is quickly interrupted. Indeed, the most important clinical effect of high doses of iodide is inhibition of the release of thyroid hormone. This may reflect the ability of iodide to antagonize the ability of TSH and cyclic adenosine monophosphate to stimulate hormone release.

Iodide is particularly useful in the treatment of hyperthyroidism before elective thyroidectomy. Indeed, the combination of oral potassium iodide and propranolol is a recommended approach.¹¹ The vascularity of the thyroid gland is also decreased by iodide therapy.¹² Chronic treatment with iodide, however, is often associated with a recurrence of previously suppressed excessive thyroid gland activity.¹³

Allergic reactions may accompany treatment with iodide or administration of organic preparations that contain iodide. Angioedema and laryngeal edema may become life threatening.

Radioactive Iodine

Radioiodine is commonly administered as the therapy of choice for Graves hyperthyroidism.¹⁴ Many practitioners administer radioactive iodine therapy to patients after euthyroidism is achieved via thionamides.

Among the radioactive isotopes of iodine, iodine 131 (^{131}I) is the most frequently administered. This isotope is rapidly and efficiently trapped by thyroid gland cells, and the subsequent emission of destructive β rays acts almost exclusively on these cells, with little or no damage to surrounding tissue. It is possible to completely destroy the thyroid gland with ^{131}I within 6 to 18 weeks.¹⁵ Indeed, hypothyroidism occurs in about 10% of treated patients in the first year after ^{131}I administration and increases about 2% to 3% each year thereafter. For this reason, iatrogenic hypothyroidism must be considered preoperatively in any patient who has previously been treated with ^{131}I .

Hyperthyroidism is treated with orally administered ^{131}I , with symptoms of excessive thyroid gland activity gradually abating over a period of 2 to 3 months. One-half to two-thirds of patients are cured by a single dose of isotope, and the remainder require an additional one to two doses. Patients should be monitored closely for hypothyroidism, and thyroid hormone replacement therapy with levothyroxine should be started once detected. The use of ^{131}I is contraindicated during pregnancy because the fetal thyroid gland would concentrate the isotope and for patients who are breastfeeding. Furthermore, radioiodine is contraindicated in patients with severe Graves orbitopathy because therapy can worsen orbitopathy.⁸ Most thyroid cancers except for follicular cancer accumulate little radioactive iodine. As a result, the therapeutic effectiveness of ^{131}I for treatment of thyroid cancer is limited.

Thyroid Storm

Thyroid storm is a rare presentation of thyrotoxicosis with a high mortality rate of 8% to 25% despite an incidence of about 0.2 per 100,000 person-years.⁸ The pathology of thyroid storm is not well understood, but risk factors include stressors such as surgery, pregnancy, trauma, and acute illness. The diagnosis of thyroid storm is based on clinical presentation along with evidence of hyperthyroidism. The Burch and Wartofsky scoring system (Table 39.3) can be used to assist in the diagnosis of suspected thyroid storm. Once the diagnosis of thyroid storm is determined, therapeutic goals should include the reduction of thyroid hormone synthesis and secretion; reduction of circulating thyroid hormone levels and their effects peripherally; and treating the underlying inciting factors. Thyroid hormone synthesis and secretion is regulated with the administration of inorganic iodine and antithyroid drugs, propylthiouracil being preferred over thiamazole for its effect of blocking T_4 to T_3 conversion. Cholestyramine is given to facilitate the excretion of free thyroid hormone and prevent reabsorption into the circulation. β -Blockade, glucocorticoids, and acetaminophen are used to regulate the systemic manifestations of thyroid storm. Propranolol, which can decrease T_4 to T_3 conversion, is the preferred β -blocker, and glucocorticoids are used to treat underlying adrenal insufficiency. Once treatment is initiated, improvement in thyroid function can be seen in about 24 hours, and definitive therapy with surgery or radioactive iodine should be considered once the patient becomes euthyroid.

TABLE 39.3

The Burch and Wartofsky scoring system for thyroid storm^a

Diagnostic criteria		Scoring points
Temperature (°C)	37.2-37.7	5
	37.8-38.2	10
	38.3-38.8	15
	38.9-39.4	20
	39.5-39.9	25
	>40	30
CNS effects	Mild (agitation)	10
	Moderate (delirium/psychosis)	20
	Severe (seizure/coma)	30
Gastrointestinal/hepatic dysfunction	Moderate (diarrhea)	10
	Severe (jaundice)	20

Tachycardia	99-109	5
	110-119	10
	120-129	15
	130-139	20
	>140	25
Congestive heart failure	Mild (pedal edema)	5
	Moderate (bibasilar rales)	10
	Severe (pulmonary edema)	15
Atrial fibrillation	Absent	0
	Present	10
Precipitant history	Negative	0
	Positive	10

Abbreviation: CNS, central nervous system.

^aA score >45 is suggestive of thyroid storm, a score of 25 to 44 is suggestive of impending thyroid storm, and a score <25 indicates that thyroid storm is unlikely.¹⁶

Other Endocrine Drugs

Artem Emple • Vivek K. Moitra

Preparations that contain synthetic hormones identical to those secreted endogenously by endocrine glands may be administered as drugs. These synthetic hormones resemble the endogenous substances in structure and activity. Typically, the clinical application of these drugs is for hormone replacement to provide a physiologic effect. In certain patients, however, large doses of synthetic hormones are used to exert a pharmacologic effect. Recombinant DNA technology permits the incorporation of synthetic genes that code for the synthesis of specific human hormones by bacteria, thus permitting production of pure hormones devoid of allergic properties.

Corticosteroids

The actions of corticosteroids are classified according to the potencies of these compounds to (1) evoke distal renal tubular reabsorption of sodium in exchange for potassium ions (mineralocorticoid effect) or (2) produce an antiinflammatory response (glucocorticoid effect). Naturally occurring corticosteroids are cortisol (hydrocortisone), cortisone, corticosterone, desoxycorticosterone, and aldosterone ([Figure 40.1](#)). Several synthetic corticosteroids are available, principally for use to produce antiinflammatory effects. Although it is possible to separate mineralocorticoid and glucocorticoid effects using synthetic drugs, it has not been possible to separate the various components of glucocorticoid effects. Consequently, all synthetic corticosteroids, when used in pharmacologic doses for their inflammatory effects, also produce less desirable effects, such as suppression of the hypothalamic-pituitary-adrenal (HPA) axis, delirium, weight gain, and skeletal muscle wasting.

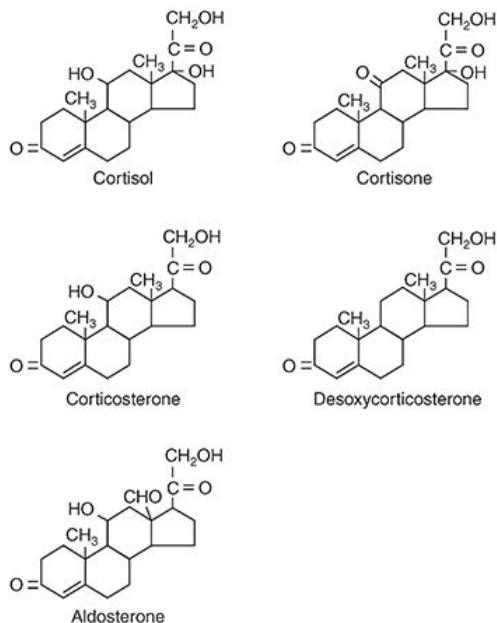

FIGURE 40.1 Endogenous corticosteroids.

Structure-Activity Relationships

All corticosteroids are constructed on the same primary molecular framework, designated as the steroid nucleus (see [Figure 40.1](#)). Changes in molecular structure may result in altered biologic responses due to

changes in absorption, protein binding, rate of metabolism, and intrinsic effectiveness of the drug at receptors. Modifications of structure, such as introduction of a double bond in prednisolone and prednisone, have resulted in synthetic corticosteroids with more potent glucocorticoid effects than the two closely related natural hormones, cortisol and cortisone, respectively (**Table 40.1**). At the same time, mineralocorticoid effects and the rate of hepatic metabolism of these synthetic drugs are less than those of the natural hormones. Despite increased antiinflammatory effects, it has not been possible to separate this response from alterations in carbohydrate and protein metabolism. This suggests that the multiple manifestations of drug-induced glucocorticoid effects are mediated by the same receptor.

TABLE 40.1

Comparative pharmacology of endogenous and synthetic corticosteroids

	Antiinflammatory potency	Sodium-retaining potency	Equivalent dose (mg)	Elimination half-time (hours)	Duration of action (hours)	Route of administration
Cortisol	1	1	20	1.5-3.0	8-12	Oral, topical, IV, IM, IA
Cortisone	0.8	0.8	25	0.5	8-36	Oral, topical, IV, IM, IA
Prednisolone	4	0.8	5	2-4	12-36	Oral, topical, IV, IM, IA
Prednisone	4	0.8	5	2-4	12-36	Oral
Methylprednisolone	5	0.5	4	2-4	12-36	Oral, topical, IV, IM, IA, epidural
Betamethasone	25	0	0.6	5	36-54	Oral, topical, IV, IM, IA
Dexamethasone	25	0	0.75	3.5-5.0	36-54	Oral, topical, IV, IM, IA
Triamcinolone	5	0	4	3.5	12-36	Oral, topical, IV, IM, epidural
Fludrocortisone	10	250	0	3.5-4.0	24	Oral, topical, IV, IM
Aldosterone	0	3,000	0	0.3	—	

Abbreviations: IA, intra-articular; IM, intramuscular; IV, intravenous.

Mechanism of Action

Glucocorticoids attach to cytoplasmic receptors to enhance or suppress changes in the transcription of DNA and thus the synthesis of proteins. Glucocorticoids also inhibit the secretion of cytokines via posttranslational effects.¹ Two distinct types of corticosteroid receptors have been identified (mineralocorticoid and glucocorticoid). Mineralocorticoid receptors are present in distal renal tubules, colon, salivary glands, and the hippocampus. In contrast, glucocorticoids receptors are more widely distributed and do not bind aldosterone, making these receptors glucocorticoid selective. Local mechanisms that result in release of steroids from their carrier proteins serve to facilitate steroid entry into cells. Target cells also contain an enzyme, 11 β -hydroxysteroid dehydrogenase that controls the interconversion of cortisol (active) and cortisone (inert). The concentration of glucocorticoid receptors may fluctuate and thus influence responsiveness to glucocorticoids.

Maintenance of Homeostasis

Permissive and protective effects of glucocorticoids are critical for the maintenance of homeostasis during severe stress. The permissive and protective actions of glucocorticoids are complementary and permit the individual to affect an appropriate stress response and to maintain homeostasis.

Permissive Actions

Permissive actions of glucocorticoids occur at low physiologic steroid concentrations and serve to prepare the individual for responding to stress. These permissive actions of glucocorticoids maintain basal activity of the HPA by providing negative feedback and by setting the threshold for a response to stress.

Protective Actions

The protective mode of glucocorticoids occurs when high plasma concentrations of steroids exert antiinflammatory and immunosuppressive effects. This protective response prevents the host-defense mechanisms that are activated during stress from overshooting and damaging the organism. Other important protective actions of glucocorticoids include redirection of metabolism to meet energy needs during stress.

Pharmacokinetics

Synthetic cortisol and its derivatives are effective orally (see [Table 40.1](#)). Antacids, but not food, interfere with the oral absorption of corticosteroids. Water-soluble cortisol succinate can be administered IV to achieve prompt increases in plasma concentrations. More prolonged effects are possible with IM injection. Cortisone acetate may be given orally or intramuscularly but cannot be administered IV. The acetate preparation is a slow-release preparation lasting 8 to 12 hours. After release, cortisone is converted to cortisol in the liver. Corticosteroids are also promptly absorbed after topical application or aerosol administration.

Cortisol is highly bound (90% or more) in the plasma to corticosteroid-binding globulin. Cortisol also binds albumin and erythrocytes.² Nevertheless, cortisol and related compounds readily cross the placenta. Small amounts of cortisol appear unchanged in the urine, but at least 70% is conjugated in the liver to inactive or poorly active metabolites. These water-soluble conjugated metabolites appear in the urine and bile. The elimination half-time of cortisol is 1.5 to 3.0 hours, but its biologic effects persist for several hours. The half-lives of synthetic glucocorticoids range from 1 hour (prednisolone) to more than 4 hours (dexamethasone), and clearance may be prolonged in older individuals.³ Individuals who clear glucocorticoids slowly may be subject to an increased incidence of side effects.⁴

Cortisol is released from the adrenal glands in an episodic manner and the frequency of pulses follows a circadian rhythm that is linked to the sleep-wake cycle. Maximal plasma concentrations of cortisol occur just before awakening and the lowest levels occur 8 to 10 hours later. Stress-induced changes in the plasma concentrations of cortisol are superimposed on the background baseline release of cortisol. Synthesis of cortisol is governed by adrenocorticotrophic hormone (ACTH) that is controlled by the hypothalamic hormones, corticotropin-releasing hormone, and arginine vasopressin (AVP).

Synthetic Corticosteroids

Synthetic corticosteroids administered for their glucocorticoid effects include prednisolone, prednisone, methylprednisolone, betamethasone, dexamethasone, and triamcinolone ([Figure 40.2](#); see [Table 40.1](#)). Fludrocortisone is a synthetic halogenated derivative of cortisol that is administered for its mineralocorticoid effect (see [Table 40.1](#) and [Figure 40.2](#)). Naturally occurring corticosteroids, such as cortisol and cortisone, are also available as synthetic drugs (see [Table 40.1](#) and [Figure 40.1](#)).

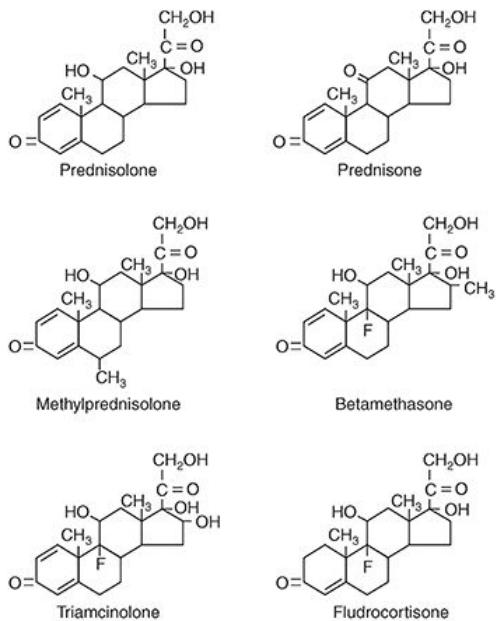

FIGURE 40.2 Synthetic corticosteroids.

Prednisolone

Prednisolone is an analogue of cortisol that is available as an oral or parenteral preparation. The antiinflammatory effect of 5 mg of prednisolone is equivalent to that of 20 mg of cortisol. This drug and prednisone are suitable for sole replacement therapy in adrenocortical insufficiency because of the presence of glucocorticoid and mineralocorticoid effects.

Prednisone

Prednisone is an analogue of cortisone that is available as an oral or a parenteral preparation. It is rapidly converted to prednisolone after its absorption from the gastrointestinal tract. Its antiinflammatory effect and clinical uses are similar to those of prednisolone.

Methylprednisolone

Methylprednisolone is the methyl derivative of prednisolone. The antiinflammatory effect of 4 mg of methylprednisolone is equivalent to that of 20 mg of cortisol. The acetate preparation administered intra-articularly has a prolonged effect. Methylprednisolone succinate is highly soluble in water and is used IV to produce an intense glucocorticoid effect.

Betamethasone

Betamethasone is a fluorinated derivative of prednisolone. The antiinflammatory effect of 0.75 mg is equivalent to that of 20 mg of cortisol. Betamethasone lacks the mineralocorticoid properties of cortisol and thus is not acceptable for sole replacement therapy in adrenocortical insufficiency. Oral or parenteral administration is acceptable.

Dexamethasone

Dexamethasone is a fluorinated derivative of prednisolone and an isomer of betamethasone. The antiinflammatory effect of 0.75 mg is equivalent to that of 20 mg of cortisol. Oral and parenteral preparations are available. The acetate preparation is used as a long-acting repository suspension. Dexamethasone sodium phosphate is water soluble, rendering it appropriate for parenteral use. This corticosteroid is commonly chosen to treat certain types of cerebral edema and prevent postoperative nausea and vomiting.

Triamcinolone

Triamcinolone is a fluorinated derivative of prednisolone. The antiinflammatory effect of 4 mg is equivalent to that of 20 mg of cortisol. Triamcinolone has less mineralocorticoid effect than does prednisolone. Oral and parenteral preparations are available. The hexacetonide preparation injected intra-articularly may provide therapeutic effects for 3 months or longer. This drug is often used for epidural injections in the treatment of lumbar disc disease.

During the first days of treatment with triamcinolone, mild diuresis with sodium loss may occur. Conversely, edema may occur in patients with decreased glomerular filtration rates. Triamcinolone does not increase urinary potassium loss except when administered in large doses.

An unusual adverse side effect of triamcinolone is an increased incidence of skeletal muscle weakness. Likewise, anorexia rather than appetite stimulation, and sedation rather than euphoria may accompany administration of triamcinolone.

Clinical Uses

The only universally accepted clinical use of corticosteroids and their synthetic derivatives is as replacement therapy for deficiency states. With this exception, the use of corticosteroids in disease states is empirical and not curative, although antiinflammatory responses exert an intense palliative effect. The safety of corticosteroids is such that it is acceptable to administer a single large dose in a life-threatening situation on the presumption that unrecognized adrenal or pituitary insufficiency may be present.

Prednisolone or prednisone is recommended when an antiinflammatory effect is desired. The low mineralocorticoid potency of these drugs limits sodium and water retention when large doses are administered to produce the desired glucocorticoid effect. It must be recognized, however, that the antiinflammatory effect of corticosteroids is palliative because the underlying cause of the response remains. Nevertheless, suppression of the inflammatory response may be lifesaving in some situations. Conversely, masking of the symptoms of inflammation may delay diagnosis of life-threatening illness, such as peritonitis due to perforation of a peptic ulcer.

Deficiency States

Acute adrenal insufficiency requires electrolyte and fluid replacement as well as supplemental corticosteroids. Cortisol is administered at a rate of 100 mg IV every 8 hours after an initial injection of 100 mg. Management of chronic adrenal insufficiency in adults is with the daily oral administration of cortisone, 25.0 to 37.5 mg. A typical regimen is 25.0 mg in the morning and 12.5 mg in the late afternoon.⁵ This schedule mimics the normal diurnal cycle of adrenal secretion. An orally effective mineralocorticoid such as fludrocortisone, 0.1 to 0.3 mg daily, is required by most patients.

Allergic Therapy

Topical corticosteroids are capable of potent antiinflammatory effects and are the mainstay of allergic therapy. These medications interfere with the inflammatory response, induce cutaneous vasoconstriction, and have antimitotic activity.⁶ Corticosteroids work by inhibiting the production of inflammatory cytokines and chemokines, thus decreasing inflammation, cellular edema, and cellular recruitment to sites of disease. Oral administration of steroids is effective but the risk of unacceptable side effects with chronic treatment limits use by this route. Side effects, although possible with topical administration of corticosteroids, are usually not significant. Unlike antihistamines that provide pharmacologic effects within 1 to 2 hours, topical corticosteroids may require 3 to 5 days of treatment to produce a therapeutic effect.

Manifestations of allergic diseases that are of limited duration, such as hay fever, contact dermatitis, drug reactions, angioneurotic edema, and anaphylaxis, can be suppressed by adequate doses of corticosteroids. Life-threatening allergic reactions, however, must be treated with epinephrine because the onset of the antiinflammatory effect produced by corticosteroids is delayed. Indeed, any beneficial effect of corticosteroids in the management of severe allergic reactions is probably related to suppression of the antiinflammatory response rather than to inhibition of production of immunoglobulins.

Asthma

Asthma is an inflammatory disease of the lungs, and inhaled glucocorticoids (beclomethasone, budesonide, fluticasone, ciclesonide, and triamcinolone) are often recommended as first-line therapy for controlling the symptoms of asthma, improving quality of life and lung function, and in preventing exacerbations.⁷ Inhaled glucocorticoids are highly lipophilic and rapidly enter airway cells, where they have direct inhibitory effects on many of the cells involved in airway inflammation. One possible antiinflammatory mechanism is the modulation of the release of cytokines from inflammatory cells. It is estimated that 80% to 90% of the dose inhaled from the metered-dose inhaler is deposited in the oropharynx and swallowed. Inhaled glucocorticoids have oropharyngeal side effects that include dysphonia and candidiasis. Dysphonia occurs in approximately one-third of treated patients and may reflect myopathy of the laryngeal muscles that is reversible when treatment is stopped. Inhaled glucocorticoids, in doses of 1,500 µg per day or less in adults and 400 µg per day or less in children, have little, if any, effect on pituitary adrenal function.

Parenteral corticosteroids are important in the emergent preoperative preparation of patients with active reactive airway disease and in the treatment of intraoperative bronchospasm. Doses equivalent to 1 to 2 mg/kg of cortisol (or the equivalent dose of prednisolone) are commonly recommended. Preoperative corticosteroid administration 1 to 2 hours before induction of anesthesia is important because the beneficial effects of corticosteroids may not be fully manifested for several hours. Corticosteroids also enhance and prolong the responses to β-adrenergic agonists. Some enhancement of β-agonist effect may be present within 1 hour, but 4 to 6 hours are required for an antiinflammatory effect. In noncompliant or newly diagnosed patients with bronchial hyperactivity, preoperative treatment with combined corticosteroids (40 mg orally for 5 days) and salbutamol (0.2 mg puffs for 5 days) but not salbutamol alone minimizes intubation-evoked bronchoconstriction.⁸

Antiemetic Effect

Dexamethasone prevents postoperative nausea and vomiting only when administered near the beginning of surgery, probably by reducing surgery-induced inflammation due to inhibition of prostaglandin synthesis.⁹ In addition, dexamethasone may exert antiemetic effects by increasing the release of endorphins resulting in mood elevation and appetite stimulation. Prophylactic administration of dexamethasone 4 mg, ondansetron 4 mg, or droperidol 1.25 mg produced similar decreases (about 26%) in the incidence of postoperative nausea and vomiting.¹⁰ Because antiemetic interventions are similarly effective and act independently, it is recommended that the safest and least expensive antiemetic should be selected for prophylaxis. Prophylaxis is rarely warranted in low-risk patients; moderate-risk patients should receive at least one intervention, and high-risk patients should receive at least two multimodal interventions.¹¹ Rescue treatments are ineffective when the same drug has already been administered for prophylaxis. A suggested treatment strategy is to administer dexamethasone in conjunction with either droperidol or ondansetron as first-line prophylaxis and to reserve the other agent as a rescue treatment.¹¹ Total intravenous anesthesia is a useful multimodal approach in those patients at high risk for postoperative nausea and vomiting. Administration of higher doses (8-10 mg) of dexamethasone are associated with reduced rates of postdischarge nausea, pain, and fatigue. This, however, must be weighed against a slightly higher rate of postoperative infection and hyperglycemia in fragile diabetic patients.¹¹ Dexamethasone is also effective in suppressing chemotherapy-induced nausea and vomiting. The elimination half-time of dexamethasone is about 3 hours, but antiemetic effects, unlike other classes of antiemetics, often persist as long as 24 hours.

Postoperative Analgesia

Glucocorticoids peripherally inhibit phospholipase enzyme that is necessary for the inflammatory chain reaction along both the cyclooxygenase and lipoxygenase pathways.¹² As a result, glucocorticoids may be effective in decreasing postoperative pain but with a different side effect profile than nonsteroidal antiinflammatory drugs. For example, administration of betamethasone 12 mg intramuscularly 30 minutes before induction of anesthesia for outpatient foot or hemorrhoid surgery, resulted in reductions in postoperative pain and the incidence of postoperative nausea and vomiting.¹³ A meta-analysis of

perioperative intravenous dexamethasone suggests that dexamethasone at doses more than 0.1 mg/kg decreases acute postoperative pain and reduces opioid use, especially when administered preoperatively.¹⁴

Cerebral Edema

Corticosteroids in large doses can reduce and prevent vasogenic cerebral edema and the resulting increases in intracranial pressure that may accompany intracranial tumors and metastatic lesions and bacterial meningitis.¹⁵ Dexamethasone, with minimal mineralocorticoid activity, is frequently selected to decrease cerebral edema and associated increases in intracranial pressure. Conversely, the administration of glucocorticoids to patients with severe head injury, cerebral infarction, and intracranial hemorrhage is not useful and can be associated with worse outcomes.^{16,17}

Aspiration Pneumonitis

The use of corticosteroids in the treatment of aspiration pneumonitis is controversial. There is evidence in animals that corticosteroids administered immediately after the inhalation of acidic gastric fluid may be effective in decreasing pulmonary damage.¹⁸ Conversely, other data show no beneficial effect or suggest that the use of corticosteroids may enhance the likelihood of gram-negative pneumonia.^{19,20} Despite the absence of confirming evidence that corticosteroids are beneficial, it is not uncommon for the treatment of aspiration pneumonitis to include the empiric use of pharmacologic doses of these drugs.

Lumbar Disc Disease

An alternative to surgical treatment of lumbar disc disease is the epidural placement of corticosteroids.²¹ Corticosteroids may decrease inflammation and edema of the nerve root that has resulted from compression. A common regimen is epidural injection of 25 to 50 mg of triamcinolone, or 40 to 80 mg of methylprednisolone, in a solution containing lidocaine at or near the interspace corresponding to the distribution of pain. Corticosteroids can be delivered to the epidural space in a variety of ways—interlaminar, transforaminal, or caudal. Advantages of an interlaminar block include ability to treat bilateral pain and need for a lower volume. Transforaminal injection carries a lower risk of inadvertent dural puncture and better ventral spread.²² In animals, the epidural injection of triamcinolone, 2 mg/kg, interferes with the ability of the adrenal cortex to release cortisol in response to hypoglycemia for 4 weeks. Injection of triamcinolone, 80 mg, into the lumbar epidural space of patients with lumbar disc disease results in acute suppression of plasma concentrations of ACTH and cortisol between 15 (midazolam sedation) and 45 minutes (midazolam not administered) of corticosteroid injection.²³ Median suppression of the HPA axis was less than 1 month, and all patients had recovered by 3 months. Exogenous corticosteroid coverage during this potentially vulnerable period should be considered in patients undergoing major stress, especially if the adrenocortical response to ACTH is subnormal. Although epidural injections of methylprednisolone may result in short-term improvement of symptoms (pain, sensory loss) due to sciatic nerve compression from a herniated nucleus pulposus, this treatment's long-term benefits such as improved functional outcomes and decreased need for surgery are less clear.^{21,24} Most studies were unable to demonstrate a change in surgical rates with epidural steroid injections. However, certain studies of surgical patients who met operative criteria have found that the use of epidural steroid injections may prevent surgery.²²

Immunosuppression

In organ transplantation, high doses of corticosteroids are often administered at the time of surgery to produce immunosuppression and decrease the risk of rejection of the newly transplanted organ. Smaller maintenance doses of corticosteroids are continued indefinitely, and the dosage is increased if rejection of the transplanted organ is threatened.

Arthritis

The criterion for initiating corticosteroid therapy in patients with rheumatoid arthritis is rapid control of symptomatic flares and progressive disability despite maximal medical therapy. Corticosteroids are

administered in the smallest dose possible that provides significant but not complete symptomatic relief. The usual initial dose is prednisolone, 10 mg or its equivalent, in divided doses. Intra-articular injection of corticosteroids is recommended for treatment of episodic manifestations of acute joint inflammation associated with osteoarthritis. However, painless destruction of the joint is a risk of this treatment.

Collagen Diseases

Manifestations of collagen diseases, such as polymyositis, polyarteritis nodosa, and Wegener granulomatosis, but not scleroderma, are decreased and longevity is improved by corticosteroid therapy. Fulminating systemic lupus erythematosus is a life-threatening illness that is aggressively treated initially with large doses of prednisone, 1 mg/kg, or its equivalent. Large doses of corticosteroids are effective for inducing a remission of sarcoidosis. In temporal arteritis, corticosteroid therapy is necessary to prevent blindness, which occurs in about 20% of untreated patients. Some forms of nephrotic syndrome respond favorably to corticosteroids. Rheumatic carditis may be suppressed by large doses of corticosteroids.

Ocular Inflammation

Corticosteroids are used to suppress ocular inflammation (uveitis and iritis) and thus preserve sight. Instillation of corticosteroids into the conjunctival sac results in therapeutic concentrations in the aqueous humor. Topical and intraocular corticosteroid therapy often increases intraocular pressure and is associated with cataractogenesis. For this reason, it is recommended that intraocular pressure be monitored when topical corticosteroids are used for more than 2 weeks. Corticosteroids are not recommended in herpes simplex infections (dendritic keratitis) of the eye. Topical corticosteroids should not be used for treatment of ocular abrasions because delayed healing and infections may occur.

Cutaneous Disorders

Topical administration of corticosteroids is frequently effective in the treatment of skin diseases. Effectiveness is increased by application of the corticosteroid as an ointment under an occlusive dressing. Systemic absorption is also occasionally enhanced to the degree that suppression of the HPA axis occurs or manifestations of Cushing syndrome appear. Corticosteroids may also be administered systemically for treatment of severe episodes of acute skin disorders and exacerbations of chronic disorders.

Postintubation Laryngeal Edema

The administration of corticosteroids is associated with a reduction in postextubation airway events and reintubation.²⁵ Prevention and treatment of postintubation laryngeal edema includes inhaled or parenteral corticosteroids, such as methylprednisolone 20-40 mg IV, or budesonide 1 mg inhaled, administered at least 4 hours before extubation. Dexamethasone, 0.6 mg/kg orally, is an effective treatment for children with mild croup.²⁶

Ulcerative Colitis

Corticosteroid therapy is indicated in selected patients with chronic ulcerative colitis. A disadvantage of this therapy is that signs and symptoms of intestinal perforation and peritonitis may be masked.

Myasthenia Gravis

Corticosteroids are usually reserved for patients with myasthenia gravis who are unresponsive to medical or surgical therapy. These drugs seem to be most effective after thymectomy. The mechanism of beneficial effects produced by corticosteroids is not known but may reflect drug-induced suppression of the production of an immunoglobulin that normally binds to the neuromuscular junction.

Respiratory Distress Syndrome

Administration of corticosteroids at least 24 hours before delivery decreases the incidence and severity of respiratory distress syndrome in neonates born between 24 and 36 weeks' gestation. Dexamethasone administered for prolonged periods (42 days) improves pulmonary and neurodevelopmental outcome of low-

birth-weight infants at risk for bronchopulmonary dysplasia.²⁷ Glucocorticoid administration in the setting of acute respiratory distress syndrome is controversial, and the effect may vary according to timing. Early administration (≤ 72 hours) of methylprednisolone in one small study has been associated with improved outcomes.²⁸ Although later administration (>14 days) of glucocorticoids is associated with an improvement in ventilator-free days, oxygenation, and lung compliance, methylprednisolone administration is also associated with increased mortality.²⁹

Leukemia

The antilymphocytic effects of glucocorticoids are used to advantage in combination chemotherapy of acute lymphocytic leukemia and lymphomas, including Hodgkin disease and multiple myeloma. For example, prednisone and vincristine produce remissions in about 90% of children with lymphoblastic leukemia.

Cardiac Arrest

Cardiac arrest is associated with lower cortisol levels (relative adrenal insufficiency), vasoplegia, and myocardial dysfunction. Recent studies preliminarily suggest that the administration of glucocorticoids (along with vasopressin and epinephrine) during a cardiac arrest may improve survival and is associated with better neurologic outcomes.³⁰ Potential explanations include attenuation of the systemic inflammatory response syndrome and enhancement of myocardial and vascular function.³¹

Septic Shock

Septic shock is associated with states of relative adrenal insufficiency, which may contribute to the vasodilated state. Corticosteroids have been shown to restore effective blood volume through increased mineralocorticoid activity and increase systemic vascular resistance due to an effect on endothelial glucocorticoid receptors.³² A meta-analysis of corticosteroid use in sepsis has reported a decrease in duration of shock, mechanical ventilation, and intensive care unit length of stay without a mortality benefit.³³ However, in 2018, the Activated Protein C and Corticosteroids for Human Septic Shock study, a randomized controlled trial of 7 days of hydrocortisone 200 mg daily with fludrocortisone 50 µg via nasogastric tube for septic shock conferred a statistically significant reduction in mortality.³⁴ A common corticosteroid regimen includes 200 to 300 mg hydrocortisone daily in divided doses for 5 to 7 days followed by a rapid taper after vasopressor withdrawal.

Side Effects

The side effects of chronic corticosteroid therapy include (1) suppression of the HPA axis, (2) electrolyte and metabolic changes, (3) osteoporosis, (4) peptic ulcer disease, (5) skeletal muscle myopathy, (6) central nervous system dysfunction, (7) peripheral blood changes, and (8) inhibition of normal growth. Increased susceptibility to bacterial or fungal infection accompanies treatment with corticosteroids. Corticosteroid administration is associated with greater clearance of salicylates and decreased effectiveness of anticoagulants. Systemic corticosteroids used for short periods of time (<7 days) even at high doses are unlikely to cause adverse side effects. Inhaled corticosteroids are unlikely to evoke adverse systemic effects.

Corticosteroid Supplementation in the Perioperative Period

Corticosteroid supplementation should be increased whenever the patient being treated for chronic hypoadrenocorticism undergoes a surgical procedure. This recommendation is based on the concern that these patients are susceptible to cardiovascular collapse because they cannot release additional endogenous cortisol in response to the stress of surgery. More controversial is the management of patients who may manifest suppression of the HPA axis because of current or previous administration of corticosteroids for treatment of a disease unrelated to pituitary or adrenal function. Recommendations that prescribe supraphysiologic doses have been advocated despite the absence of supporting scientific data.³⁵ In adrenalectomized primates undergoing general anesthesia and surgery, the animals receiving physiologic replacement doses of cortisol were indistinguishable from those receiving supraphysiologic doses (10 times the normal production rate) of

cortisol.³⁶ Subphysiologically treated animals (one-tenth the normal production rate) were hemodynamically unstable during surgery and had a significantly higher mortality rate. Based on these animal data, it was concluded that there is no advantage in supraphysiologic glucocorticoid prophylaxis during surgical stress, and replacement doses of cortisol equivalent to the daily unstressed cortisol production rate are sufficient to allow homeostatic mechanisms to function during surgery.³⁶

Patients taking greater than 20 mg per day of prednisone or its equivalent for more than 3 weeks have a suppressed HPA axis. Patients taking less than 5 mg per day of prednisone or its equivalent can be considered not to have suppression of their HPA axis. However, patients taking 5 to 20 mg per day of prednisone or its equivalent for more than 3 weeks may or may not have suppression of the HPA axis.

A rational regimen for corticosteroid supplementation in the perioperative period is to avoid steroid supplementation in patients who do not have a suppressed HPA axis (patients taking any dose of glucocorticoids for less than 3 weeks or a daily dose of prednisone <5 mg).

Patients taking 5 to 20 mg per day of prednisone or its equivalent for more than 3 weeks may or may not have suppression of the HPA axis. These patients may benefit from further assessment of their HPA axis.

Glucocorticoid supplementation considers preoperative doses and the stress of surgery.

For patients with a suppressed HPA axis (patients taking >20 mg prednisone per day for more than 3 weeks), glucocorticoid supplementation should consider the stress of surgery. For minor surgical stress (inguinal hernia repair), the daily cortisol secretion rate and static plasma cortisol measurements suggest that a glucocorticoid replacement dose of 25 mg of hydrocortisone or 5 mg of methylprednisolone is sufficient. If the postoperative course is uncomplicated, the patient can be returned the next day to the prior glucocorticoid maintenance dose. For moderate surgical stress (nonlaparoscopic cholecystectomy, colon resection, total hip replacement), cortisol production rates suggest the glucocorticoid requirement is about 50 to 75 mg daily of hydrocortisone for 1 to 2 days. For major surgical stress (pancreatoduodenectomy, esophagectomy, cardiopulmonary bypass), the glucocorticoid dose should be 100 to 150 mg of hydrocortisone daily for 2 to 3 days. Even with this coverage, vascular collapse has been described in a patient experiencing massive hemorrhage during surgery.³⁷ This approach maintains the plasma concentration of cortisol above normal during major surgery in patients receiving chronic treatment with corticosteroids and manifesting a subnormal response to the preoperative infusion of ACTH (Figure 40.3).³⁸ In those instances in which events such as burns or sepsis could exaggerate the need for exogenous corticosteroid supplementation, the continuous infusion of cortisol, 100 mg every 12 hours, should be sufficient. Indeed, endogenous cortisol production during stress introduced by major surgery or extensive burns is not greater than 150 mg daily.^{39,40} It is likely that patients undergoing minor operations will need minimal to no additional corticosteroid coverage during the perioperative period.

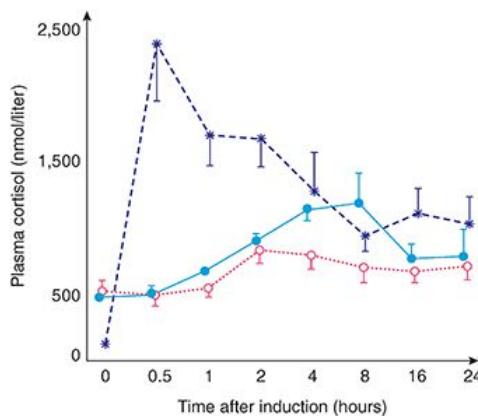

FIGURE 40.3 Administration of cortisol, 25 mg intravenously, plus a continuous infusion of 100 mg over 24 hours, maintains the plasma cortisol concentration above normal in patients (asterisk) receiving chronic treatment with corticosteroids and manifesting a subnormal response to the preoperative infusion of adrenocorticotropic hormone. Reprinted from Symreng T, Karlberg BE, Kågedal B, et al. Physiological

cortisol substitution of long-term steroid-treated patients undergoing major surgery. Br J Anesth. 1981;53(9):949-954. Copyright © 1981 Elsevier. With permission.

In addition to intravenous supplementation with cortisol, patients receiving daily maintenance doses of a corticosteroid should also receive this dose with the preoperative medication on the day of surgery. There is no objective evidence to support increasing the maintenance dose of corticosteroid preoperatively.⁴¹

Electrolyte and Metabolic Changes and Weight Gain

Hypokalemic metabolic alkalosis reflects mineralocorticoid effects of corticosteroids on distal renal tubules, leading to enhanced absorption of sodium and loss of potassium. Edema and weight gain accompany this corticosteroid effect. Corticosteroids inhibit the use of glucose in peripheral tissues and promote hepatic gluconeogenesis. The resulting corticosteroid-induced hyperglycemia can usually be managed with diet, insulin, or both. The dose requirement for oral hypoglycemic agents may be increased by corticosteroids. There is a redistribution of body fat characterized by deposition of fat in the back of the neck (buffalo hump), supraclavicular area, and face (moon facies) and loss of fat from the extremities. The mechanism by which corticosteroids elicit this redistribution of fat is not known. Peripherally, corticosteroids mobilize amino acids from tissues. This catabolic effect manifests as decreased skeletal muscle mass, osteoporosis, thinning of the skin, and a negative nitrogen balance.

Osteoporosis

Osteoporosis, vertebral compression fractures, and rib fractures are common and serious complications of corticosteroid therapy that can be found in patients of all ages. Corticosteroids appear to inhibit the activities of osteoblasts and stimulate osteoclasts by inhibition of calcium absorption from the gastrointestinal tract, which causes an increased secretion of parathyroid hormone (PTH). Osteoporosis is an indication for withdrawal of corticosteroid therapy. Evidence of osteoporosis should be sought on radiographs of the spines of patients being treated chronically with corticosteroids. The presence of osteoporosis could predispose patients to fractures during positioning in the operating room. Bisphosphonates are effective in decreasing vertebral fractures in patients taking corticosteroids.⁴²

Peptic Ulcer Disease

Although a cause-and-effect relationship has not been proved, the incidence of peptic ulcer disease seems to be increased by chronic corticosteroid therapy. Indeed, corticosteroids may decrease the normal protective barrier provided by gastric mucus.

Skeletal Muscle Myopathy

Skeletal muscle myopathy characterized by weakness of the proximal musculature is occasionally observed in patients taking large doses of corticosteroids. In some patients, this skeletal muscle weakness is so severe that ambulation is not possible and corticosteroid therapy must be discontinued.

Central Nervous System Dysfunction

Corticosteroid therapy is associated with an increased incidence of neuroses and psychoses. Behavioral changes include manic depression and suicidal tendencies. Cataracts develop in almost all patients who receive prednisone, 20 mg daily, or its equivalent for 4 years.

Peripheral Blood Changes

Corticosteroids tend to increase the hematocrit and number of circulating leukocytes. Conversely, a single dose of cortisol decreases by almost 70%—the number of circulating lymphocytes, and by more than 90%—the number of circulating monocytes in 4 to 6 hours. This acute lymphocytopenia most likely reflects sequestration from the blood rather than destruction of cells.

Inhibition of Normal Growth

Inhibition or arrest of growth can result from the administration of relatively small doses of glucocorticoids to children. The mechanism of this effect is presumed to be the generalized inhibitory effect of glucocorticoids on DNA synthesis and cell division.

Inhibitors of Corticosteroid Synthesis

Metyrapone

Metyrapone decreases cortisol synthesis by inhibition of the 11- β -hydroxylation reaction, resulting in accumulation of 11-deoxycortisol. Metyrapone may induce acute adrenal insufficiency in patients with decreased adrenocortical function. A deficiency of mineralocorticoids does not occur because metyrapone-induced inhibition of 11- β -hydroxylation results in increased production of the mineralocorticoid 11-desoxycorticosterone.

Metyrapone has been used in the diagnosis of adrenal insufficiency and treatment of excessive adrenocortical function that results from adrenal neoplasms that function autonomously or as a result of ectopic production of ACTH by tumors.

Mitotane

Mitotane, a synthetic derivative of the insecticide dichlorodiphenyltrichloroethane, has been used as adjuvant treatment for adrenocortical carcinoma as well as for nonoperative cancer. The exact mechanism has yet to be elucidated; however, it inhibits and has direct cytotoxic effects on the adrenal cortex.⁴³

Drugs That Regulate Calcium

Calcium is ingested and absorbed in the gastrointestinal tract, resorbed by bone, and filtered and reabsorbed by the kidney. The effects of PTH, calcitonin, and vitamin D metabolites regulate calcium homeostasis (see Chapter 37). The PTH regulates extracellular calcium concentration through action on the bone, kidney, and intestine. The PTH secretion is activated by hypocalcemia and elevated phosphorous levels. The net effect of PTH is to increase extracellular calcium. An excess or deficiency of calcium can disrupt coagulation, neurotransmitter and hormone secretion, neuromuscular excitability, muscle contraction, hormone action, and enzyme function.

Hypercalcemia

Hypercalcemia can be categorized as either parathyroid dependent or non-parathyroid dependent. Disorders of the parathyroid gland that result in hypercalcemia include primary and tertiary hyperparathyroidism, familial hypocalciuric hypercalcemia, and lithium-induced hypercalcemia. Hypercalcemia of malignancy is usually associated with destructive bone lesions or secretion of a PTH-like tumor peptide (PTH-related protein). Hypercalcemia from parathyroid disease is associated with bone loss and osteoporosis. Management of hypercalcemia includes intravenous fluids, bisphosphonates, calcitonin (see Chapter 37), glucocorticoids, and other less commonly used medications such as cinacalcet and denosumab.

Bisphosphonates

Bisphosphonates (pamidronate, zoledronate, alendronate, etc) are pyrophosphate analogues that lower calcium levels by inhibiting osteoclastic-mediated bone reabsorption. Hypercalcemia from malignancy, primary hyperparathyroidism, vitamin A intoxication, granulomatous disease, and Paget disease has been successfully managed with bisphosphonate therapy. Renal injury and jaw osteonecrosis has been reported in patients who take bisphosphonates. These medications should be prescribed early in the course of hypercalcemia because clinically significant reductions in calcium levels may not be observed for 2 days.

Glucocorticoids

In the setting of hypercalcemia from solid tumors and primary hyperparathyroidism, glucocorticoids are minimally effective agents. Glucocorticoids decrease synthesis of 1,25-dihydroxyvitamin D to decrease intestinal absorption of calcium and increase renal excretion of calcium.

Hypocalcemia

Preoperative patients with rhabdomyolysis, pancreatitis, sepsis, burns, fat embolism syndrome, recent massive transfusion, hypoalbuminemia, hypomagnesemia, or renal insufficiency are at risk for hypocalcemia. Chronic hypocalcemia may have few clinical signs or symptoms, whereas rapidly developing hypocalcemia may have impressive clinical effects. The most common setting for symptomatic hypocalcemia is within 12 to 24 hours after surgery, particularly after total or subtotal thyroidectomy or four-gland parathyroid exploration or removal.

Long-standing hypocalcemia with hyperphosphatemia and PTH deficiency is associated with calcification of the basal ganglia with extrapyramidal signs. Hypocalcemia can cause neuromuscular irritability, arrhythmias, congestive heart failure (decreased myocardial contractility), and hypotension. Acute, severe hypocalcemia (total serum calcium levels <7.5 mg/dL, normal albumin) is a medical emergency associated with death from laryngeal spasm or grand mal seizures. Intravenous calcium is indicated for acute symptomatic hypocalcemia. Ten percent calcium gluconate contains less elemental calcium than calcium chloride but is less likely to cause tissue necrosis during an extravasation.

Drugs for Pituitary Function

Anterior Pituitary Hormones

Anterior pituitary hormones include (1) growth hormone; (2) prolactin; (3) gonadotropins, including luteinizing hormone and follicle-stimulating hormone; (4) ACTH; and (5) thyroid-stimulating hormone. Growth hormone, gonadotropins, and ACTH can be administered in the form of synthetic drugs.

Perioperative replacement of anterior pituitary hormones may be necessary for patients receiving exogenous hormones because of a prior hypophysectomy. For example, cortisol must be provided continuously. Conversely, thyroid hormones have such a long elimination half-time that they can be omitted for several days without adverse effects. Likewise, the loss of other anterior pituitary hormones has no immediate physiologic implications.

Growth Hormone

Recombinant growth hormone is administered subcutaneously and daily to treat growth hormone deficiency. Growth hormone is also used to manage growth failure from chronic kidney disease and short stature from Turner syndrome, Prader-Willi syndrome, Noonan syndrome, and mutations in the short stature homeobox gene. Radioimmunoassays for growth hormone are used to measure plasma concentrations of the hormone. Treatment is maintained and titrated for months to years in response to growth velocity and insulin-like growth factor 1 levels (which are associated with growth velocity) and is often discontinued when linear growth decreases to less than 1 in per year.^{44,45}

Octreotide

Octreotide is a somatostatin analogue that inhibits the release of growth hormone, making it an effective treatment for patients with acromegaly.⁴⁶ Long-term treatment with octreotide (>1 month) is associated with an increased incidence of cholesterol gallstones (occurring in 20%-30% of treated patients). Because somatostatin analogues also inhibit the secretion of insulin, decreased glucose tolerance and even overt hyperglycemia might be expected during treatment with octreotide. Octreotide may be a lifesaving treatment in patients experiencing an acute carcinoid crisis although bolus injection of this somatostatin analogue may be accompanied by bradycardia and second- and third-degree heart block.⁴⁷ Octreotide is administered in acute upper gastrointestinal bleeding to decrease splanchnic blood flow and gastric acid secretion, especially prior to definitive endoscopic treatment.

Gonadotropins

Gonadotropins are used most often for the treatment of infertility and cryptorchism. Induction of ovulation can be stimulated in females who are infertile because of pituitary insufficiency. Excessive ovarian enlargement and maturation of many follicles, leading to multiple births, is a possibility. Gonadotropins are

effective only by parenteral injection. Radioimmunoassays are useful in measuring plasma and urine concentrations of gonadotropins.

Adrenocorticotrophic Hormone

The physiologic and pharmacologic effects of ACTH result from this hormone's stimulation of secretion of corticosteroids from the adrenal cortex, principally cortisol. An important clinical use of ACTH is as a diagnostic aid in patients with suspected adrenal insufficiency. For example, a normal increase in the plasma concentration of cortisol in response to the administration of ACTH rules out primary adrenocortical insufficiency. Furthermore, ACTH may be administered therapeutically to evoke the release of cortisol. Treatment of disease states with ACTH is not physiologically equivalent to administration of a specific hormone because ACTH exposes the tissues to a mixture of glucocorticoids, mineralocorticoids, and androgens. Indeed, there may be associated retention of sodium, development of hypokalemic metabolic alkalosis, and appearance of acne, which are unlikely to accompany selective-acting corticosteroids.

Absorption of ACTH after IM injection is prompt. After intravenous injection, ACTH disappears rapidly from the plasma, with an elimination half-time of about 15 minutes. Allergic reactions ranging from mild fever to life-threatening anaphylaxis may be associated with administration of ACTH.

Melatonin

Melatonin (*N*-acetyl-5-methoxytryptamine) is the principal substance secreted by the pineal gland (Figure 40.4).⁴⁸ The mammalian pineal gland is a neuroendocrine transducer. Photic information from the retina is transmitted to the pineal gland through the suprachiasmatic nucleus of the hypothalamus and the sympathetic nervous system. The neural input to the gland is norepinephrine and the output is melatonin. The synthesis and release of melatonin are stimulated by darkness and inhibited by light. As the synthesis of melatonin increases, the hormone enters the bloodstream through passive diffusion. Melatonin is rapidly metabolized, chiefly in the liver, by hydroxylation to 6-hydroxymelatonin, and, after conjugation with sulfuric or glucuronic acid, is excreted in the urine. Intravenous melatonin is rapidly distributed, and the elimination half-time is 0.5 to 5.6 minutes. The bioavailability of orally administered melatonin varies widely.

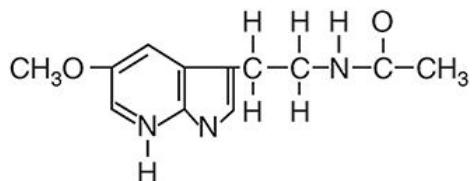

FIGURE 40.4 Melatonin.

Dose-dependent physiologic effects of melatonin include biologic regulation of circadian rhythms, sleep, mood, and perhaps reproduction, tumor growth, and aging.⁴⁸ In humans, the circadian rhythm for the release of melatonin from the pineal gland is closely synchronized with the habitual hours of sleep. Alterations in synchronization due to phase shifts (acute change in time zones or working hours) are correlated with sleep disturbances. Ingestion of melatonin affects the speed of falling asleep as well as the duration and quality of sleep and has hypnotic effects. The circadian cycle of body temperature is linked to the 24-hour cycle of subjective sleepiness and inversely related to serum melatonin concentrations. Nevertheless, sleep-promoting doses of melatonin do not have any effect on body temperature. It is unclear whether the beneficial effect of exogenous melatonin on symptoms of jet lag is due to a hypnotic effect or resynchronization of the circadian rhythm. Melatonin may improve sleep hygiene or delirium rates in the intensive care unit, but this has not been prospectively evaluated. The Prophylactic Melatonin for Delirium in Intensive Care study is a planned multicenter randomized placebo-controlled trial evaluating melatonin as a prophylactic agent to prevent delirium. The trial has completed recruitment and is in the process of data collection.⁴⁹

Posterior Pituitary Hormones

The AVP (also known as antidiuretic hormone) and oxytocin are the two principal hormones secreted by the posterior pituitary. The AVP targets the renal collecting ducts to increase permeability of cell membranes to water and promote passive water reabsorption from renal collecting ducts into extracellular fluid. The AVP also elicits intense arterial vasoconstriction via activation of vascular V₁a receptors.⁵⁰ Oxytocin elicits contractions of the uterus, which are indistinguishable from those that occur in spontaneous labor.

Arginine Vasopressin

Vasopressin is the exogenous preparation of AVP used for (1) treatment of AVP-sensitive diabetes insipidus, (2) management of refractory hypotension during anesthesia, (3) management of uncontrolled hemorrhage from esophageal varices, (4) hemodynamic stabilization in the presence of hemorrhagic and septic shock, and (5) management of refractory cardiac arrest. This drug is not effective in the management of patients with nephrogenic diabetes insipidus.

Diabetes Insipidus

Inadequate secretion of vasopressin by the posterior pituitary causes diabetes insipidus. Excessive water loss and hypernatremia via polyuria follow. Neurotrauma and surgery of the pituitary and hypothalamus, cerebral ischemia, or cerebral malignancy can cause diabetes insipidus.⁵⁰ Nephrogenic diabetes insipidus resulting from an inability of the renal tubules to respond to adequate amounts of centrally produced AVP does not respond to exogenous administration of the hormone or its congeners.

Vasopressin administered IV is used for the initial evaluation of patients with suspected diabetes insipidus, which may follow head trauma or hypophysectomy. Under these circumstances, polyuria may be transient, and a longer antidiuretic effect (1-3 days) as produced by IM vasopressin tannate in oil could produce water intoxication. Oral administration of vasopressin is followed by rapid inactivation by trypsin, which cleaves a peptide linkage. Likewise, intravenous administration of vasopressin results in a brief effect because of rapid enzymatic breakdown of peptides in the tissues, especially the kidneys.

Administration of the synthetic selective V₂ receptor agonist, desmopressin (DDAVP), treats central diabetes insipidus. The DDAVP has an intense antidiuretic (V₂) effect and decreased pressor (V₁) effect. Through its V₂ effects, DDAVP also causes endothelial cells to release von Willebrand factor, tissue-type plasminogen activator, and prostaglandins. The elimination half-time of DDAVP is 2.5 to 4.4 hours.⁵¹ There are fewer side effects produced by DDAVP than are associated with vasopressin, although nausea and increases in systemic blood pressure can occur. The DDAVP, which is not inactivated by trypsin can be administered orally (0.3-0.6 mg per day), IV (1-4 µg per day), or nasally (5-40 µg per day).⁵⁰

Administered intranasally twice daily, using a calibrated catheter (rhinyle), DDAVP is the drug of choice in the treatment of diabetes insipidus due to inadequate production of AVP by the posterior pituitary. The DDAVP, like all the AVP analogues, is not effective in the treatment of nephrogenic diabetes insipidus. Increased release of von Willebrand factor accounts for the hemostatic activity of DDAVP in patients with uremia, chronic liver disease, and certain types of hemophilia by promoting platelet adhesiveness to the vascular endothelium. The DDAVP has also been reported to minimize intraoperative blood loss in patients undergoing cardiac surgery with cardiopulmonary bypass, whereas other reports find no effect on blood loss in patients undergoing cardiac surgery or spinal fusion surgery.⁵²⁻⁵⁴ The DDAVP does not decrease bleeding following cardiopulmonary bypass in patients who were maintained on aspirin therapy until the day before surgery.⁵⁵ The DDAVP administered IV may decrease systemic vascular resistance leading to hypotension.⁵²

Lypressin is a synthetic analogue of AVP that produces antidiuresis for about 4 hours after intranasal administration. Its short duration of action limits its usefulness in the treatment of diabetes insipidus.

Hypotension During Anesthesia

Perioperative administration of angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers inhibits the renin-angiotensin system and can cause refractory hypotension after administration of anesthesia.⁵⁶ In these cases, catecholamine administration may be unsuccessful.⁵⁷ The synthetic vasopressin analogue, terlipressin (1 mg), has been used to manage refractory hypotension in patients who have taken

angiotensin-converting enzyme inhibitor or angiotensin II receptor blockers.^{58,59} Vasopressin may be effective to treat hypotension from anaphylaxis and from severe catecholamine deficiency after resection of a pheochromocytoma.^{60,61}

Septic Shock

Excess generation of nitric oxide, activation of the renin-angiotensin system, and low plasma concentrations of vasopressin contribute to progressive loss of vascular tone during sepsis.⁶² Vasopressin levels are initially elevated with the onset of sepsis but decrease to normal levels after 24 hours producing a relative vasopressin deficiency.⁶³ Vasopressin infusion (0.01-0.04 unit per minute) can reverse systemic hypotension and decrease norepinephrine dosages in catecholamine-resistant septic shock.⁶⁴

Refractory Cardiac Arrest

Vasopressin, 40 units IV, was previously used as an alternative for out of hospital cardiac arrest. In the most recent American Heart Association guidelines, vasopressin was removed from the algorithm because it did not show an advantage as a substitute for epinephrine.⁶⁵ However, in the monitored setting of the operating room, clinical progression to shock and circulatory failure is often witnessed. Precipitating causes are often known and can be readily reversed. The anesthesiologist is adept at administering titrated boluses of vasopressors, and in this setting, it is likely reasonable to give vasopressin especially in the setting of right ventricular failure or pulmonary hypertensive crisis.⁶⁶ Vasopressin functions as a vasoconstrictor when it is administered in supraphysiologic doses, which serve to displace peripheral blood volume to the central circulation without some of the adverse effects produced by epinephrine. This drug needs to only be administered once during cardiopulmonary resuscitation because of its 10- to 20-minute elimination half-time. Vasopressin administered during cardiac arrest and hemorrhagic shock may improve vital organ blood flow during cardiopulmonary resuscitation and stabilize cardiocirculatory function after successful resuscitation.⁶⁷

Esophageal Varices

Vasopressin may serve as an adjunct in the control of bleeding esophageal varices and during abdominal surgery in patients with cirrhosis and portal hypertension. Infusion of 20 units over 5 minutes results in marked decreases in hepatic blood flow lasting about 30 minutes. Only a moderate increase in systemic blood pressure occurs. This effect on the portal circulation is attributable to marked splanchnic vasoconstriction. An alternative to systemic administration is the infusion of vasopressin directly into the superior mesenteric artery. It has not been established whether selective arterial administration is safer than systemic administration with respect to cardiac and vascular side effects.

Side Effects

Vasoconstriction and increased systemic blood pressure occur only with doses of vasopressin that are much larger than those administered for the treatment of diabetes insipidus. This response is because of a direct and generalized effect on vascular smooth muscles that is not antagonized by denervation or adrenergic-blocking drugs. Facial pallor due to cutaneous vasoconstriction may also accompany large doses of vasopressin. The magnitude of increase in systemic blood pressure caused by vasopressin depends, to some extent, on the reactivity of the baroreceptor reflexes. For example, when baroreceptor reflexes are depressed by anesthesia, smaller amounts of vasopressin are capable of evoking a pressor response. Vasopressin causes a relatively larger increase in systemic vascular resistance than peripheral vascular resistance, which makes it an ideal vasopressor for patients who have pulmonary hypertension. However, higher doses of vasopressin may cause splanchnic, digit, and coronary ischemia.⁶⁸

Vasopressin, even in small doses, may produce selective vasoconstriction of the coronary arteries, with decreases in coronary blood flow manifesting as angina pectoris, electrocardiographic evidence of myocardial ischemia, and, in some instances, myocardial infarction. Ventricular cardiac dysrhythmias may accompany these cardiac effects.

Large doses of vasopressin stimulate gastrointestinal smooth muscle, and the resulting increased peristalsis may manifest as abdominal pain, nausea, and vomiting. Smooth muscle of the uterus is also stimulated by large doses of vasopressin.

A decrease in platelet count has been attributed to AVP-mediated platelet aggregation via V₁ receptors.⁶⁴ The AVP infusion in advanced vasodilatory shock does not increase plasma concentrations of factor VIII, von Willebrand factor antigen, and ristocetin cofactor. Allergic reactions ranging from urticaria to anaphylaxis may occasionally follow the administration of vasopressin. Prolonged use of vasopressin may result in antibody formation and a shortened duration of action of the drug.

Oxytocin

Oxytocin stimulates uterine muscle and is administered to induce labor at term, reduce and prevent uterine atony, and decrease hemorrhage in the postpartum or postabortion period.⁶⁹ By stimulating smooth muscle uterine contraction, blood loss at the site of placental attachment is reduced. All preparations of oxytocin used clinically are synthetic, and their potency is described in units. These synthetic preparations are identical to the hormone normally released from the posterior pituitary but devoid of contamination by other polypeptide hormones and proteins found in natural proteins.

For induction of labor, a continuous infusion is preferred because the low dose of oxytocin needed can be precisely controlled. Indeed, the sensitivity of the uterus to oxytocin increases as pregnancy progresses. To induce labor, a dilute solution (10 mU/mL) is administered by a constant infusion pump beginning at 1 to 2 mU per minute. This infusion rate is increased 1 to 2 mU per minute every 15 to 30 minutes until an optimal response (uterine contraction every 2-3 minutes) is obtained. The average dose of oxytocin to induce labor is 8 to 10 mU per minute. Infusion rates up to 40 mU per minute of oxytocin may be necessary to treat uterine atony initially after delivery. The IM injections of oxytocin are commonly used to provide sustained uterine contractions in the postpartum period.

To prevent uterine atony, slow administration (to reduce adverse side effects) of 1 to 3 international unit of oxytocin over 30 seconds is recommended. Coadministration with phenylephrine may be required if higher doses are used. To manage uterine atony and postpartum hemorrhage, 3 to 5 international unit of intravenous oxytocin over 30 seconds is recommended.⁷⁰ Prior oxytocin exposure promotes oxytocin receptor downregulation and desensitization and may be a risk factor for postpartum hemorrhage from uterine atony.^{71,72}

Side Effects

High and bolus doses of oxytocin are more likely to decrease systolic and diastolic blood pressure via a direct relaxant effect on vascular smooth muscles.⁷³ Reflex tachycardia and increased cardiac output accompany the transient decrease in systemic blood pressure.⁷⁴ The amounts of oxytocin administered for most obstetric purposes are inadequate to produce marked alterations in systemic blood pressure. A marked decrease in blood pressure, however, may occur if oxytocin is administered to patients with blunted compensatory reflex responses, as may be produced by anesthesia. Likewise, hypovolemic patients may be particularly susceptible to oxytocin-induced hypotension. The hemodynamic effects of a second dose of oxytocin are diminished compared to the initial dose.⁷⁵

In the past, oxytocin preparations were often contaminated with ergot alkaloids, resulting in exaggerated systemic blood pressure increases when administered to patients previously treated with a sympathomimetic. Modern synthetic commercial preparations are pure oxytocin and do not introduce the risk of exaggerated vasoconstriction when administered in the presence of a sympathomimetic drug.

Oxytocin exhibits a slight AVP-like activity when administered in high doses, introducing the possibility of water intoxication, hyponatremia, and neurologic dysfunction if an excessive volume of fluid is administered.⁷⁶ The risk of this complication can be minimized by infusion of oxytocin in an electrolyte-containing solution rather than glucose in water.

Drugs for Reproductive Regulation

Ovarian Hormones

An understanding of the synthesis and action of ovarian hormones, including estrogens and progesterone, permits therapeutic interventions in certain disease states. Equally important is the therapeutic use of drugs that can mimic effects of these hormones and act as contraceptives.

Estrogens

Estrogens are effective in treating unpleasant side effects of menopause (Figure 40.5). Hormone replacement therapy may reduce the depressive symptoms during menopause.⁷⁷ Senile or atrophic vaginitis responds to topical estrogen. There is no evidence that administration of estrogens delays the progression of atherosclerosis in postmenopausal women. There is abundant evidence that administration of estrogen to postmenopausal women prevents bone loss (protects against osteoporosis) and also prevents vertebral and femoral bone fractures.⁷⁸ Estrogens are administered to decrease milk production in the postpartum period. The presence of receptors for estrogen increases the likelihood of a palliative response to estrogen therapy in women with metastatic breast cancer. An important use of estrogens is in combination with progestins as oral contraceptives.

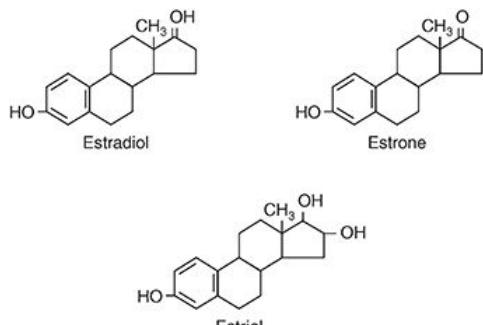

FIGURE 40.5 Estrogens.

Route of Administration

The absorption of most estrogens and their derivatives from the gastrointestinal tract is prompt and nearly complete. Metabolism in the liver, however, limits the effectiveness of orally administered estrogens. Topical and IM administration of estrogens is also effective. Radioimmunoassay methods are highly specific and sensitive for measuring the plasma concentrations of estrogens.

Side Effects

The most frequent unpleasant symptom associated with the use of estrogens is nausea. Large doses of estrogens may cause retention of sodium and water, which is particularly undesirable in patients with cardiac or renal disease. There is an increased incidence of vaginal and cervical adenocarcinoma in daughters of mothers treated with diethylstilbestrol or other synthetic estrogens during the first trimester of pregnancy. Most of the affected women have been 20 to 25 years old when diagnosed. Use of estrogen by postmenopausal women increases the risk of developing endometrial cancer.

Antiestrogens

Clomiphene and tamoxifen act as antiestrogens by binding to estrogen receptors (Figure 40.6). Tamoxifen is administered for a period of 5 years to postmenopausal women with breast cancer that was characterized by estrogen-responsive receptors. It is of interest that tamoxifen has estrogenic activity in some tissues, including bone. The loss of normal feedback inhibition of estrogen synthesis causes an increased secretion of gonadotropins. The most prominent effect on increased plasma concentrations of gonadotropins is the enlargement of the ovaries and enhancement of fertility in otherwise infertile women. Endometrial stimulation and an increased incidence of temperature disturbances ("hot flashes") may accompany treatment with tamoxifen.

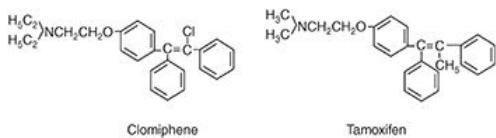

FIGURE 40.6 Antiestrogens.

Tissue-Specific Estrogens

Raloxifene is a nonsteroidal benzothiophene that acts as a selective estrogen-receptor modulator.⁷⁹ In this regard, raloxifene preserves the beneficial effects of estrogens (prevention of bone loss and lowering of plasma cholesterol concentrations) without any associated effects on reproductive organs. For example, endometrial stimulation does not accompany treatment with raloxifene. Tissue-specific estrogen agonist or antagonist actions of raloxifene may be related to estrogen receptor-mediated gene activation.

Progesterone

Orally active derivatives of progesterone are designated **progestins** (Figure 40.7). Progestins are often combined with estrogens as oral contraceptives. Dysfunctional uterine bleeding can be treated with small doses of a progestin for a few days, with the goal being induction of progesterone-withdrawal bleeding. Progestins, like estrogens, are effective in suppressing lactation in the immediate postpartum period. Palliative treatment of metastatic endometrial carcinoma is achieved with progestins. Absorption of progestins from the gastrointestinal tract is rapid, but hepatic first-pass metabolism is extensive.

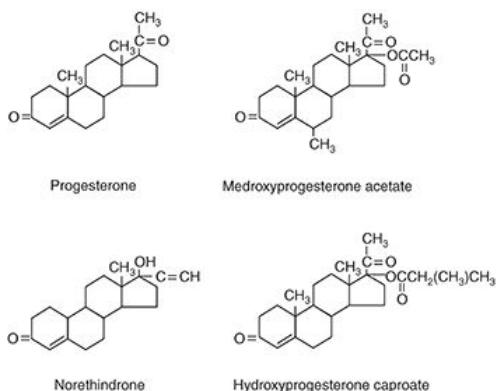

FIGURE 40.7 Progestins.

Antiprogestins

Antiprogestins inhibit the hormonal effects of progesterone and are the most effective and safest means of medical abortion.⁸⁰ In this regard, mifepristone (RU 486) can be administered in a single oral dose to produce termination of pregnancy (Figure 40.8). The combination of mifepristone with a prostaglandin administered 48 hours later by IM injection (sulprostone), by vaginal suppository (gemeprost), or orally (misoprostol) has resulted in a rate of complete abortion approaching 100%. Mifepristone has been used as a postcoital contraceptive within 72 hours of unprotected intercourse. In addition to its antiprogestin properties, mifepristone has antiglucocorticoid activity and is useful in the treatment of patients with hypercortisolism. Side effects of mifepristone include vaginal bleeding, nausea, vomiting, abdominal pain, and fatigue.

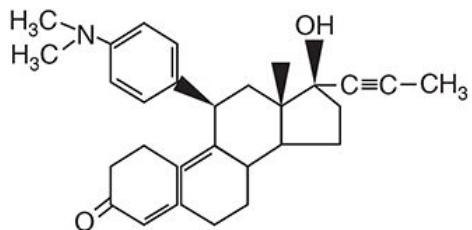

FIGURE 40.8 Mifepristone (RU 486).

Oral Contraceptives

Oral contraceptives are most often a combination of an estrogen and a progestin. This combination inhibits ovulation, presumably by preventing release of follicle-stimulating hormone by estrogen and luteinizing hormone by progesterone.

Side Effects

Estrogens in combined preparations are believed to be responsible for most, if not all, of the side effects of oral contraceptives. For example, estrogens seem to be responsible for the increased incidence of thromboembolism. Indeed, patients taking estrogens manifest increased blood concentrations of some clotting factors as well as increased platelet aggregation. Nausea, vomiting, weight gain, and breast discomfort resembling early pregnancy are attributed to the estrogen component of oral contraceptives. The incidence of myocardial infarction and stroke is increased in patients who chronically take oral contraceptives.⁸¹

Hypertension occurs in about 5% of women taking oral contraceptives chronically.⁸² This response probably reflects estrogen-induced increases in circulating plasma concentrations of renin and angiotensin, with associated retention of sodium and water.

Oral contraceptives containing high doses of estrogen may produce alterations in the glucose tolerance curves of patients with preclinical diabetes mellitus. These drugs increase the concentration of cholesterol in bile, which is consistent with an increased incidence of cholelithiasis. Benign hepatomas have been associated with the use of oral contraceptives. An increased incidence of breast cancer in patients taking oral contraceptives has not been documented. Depression of mood and fatigue have been attributed to the progestin component of oral contraceptives.

Androgens

Androgens are administered to males to stimulate the development and maintenance of secondary sexual characteristics (**Figure 40.9**). Testosterone is also prescribed to hypogonadal men who have evidence of androgen deficiency and a low serum testosterone concentration. The most common indication of androgen therapy in females is palliative management of metastatic breast cancer. Androgens enhance erythropoiesis by stimulation of renal production of erythropoietin as well as by direct dose-related stimulation of erythropoietin-sensitive elements in bone marrow. In addition, there is a drug-induced increase in 2,3-diphosphoglycerate levels, which decreases hemoglobin affinity for oxygen, thus enhancing the availability of oxygen to tissues. For these reasons, androgen therapy is often instituted in patients with aplastic anemia or hemolytic anemia. Androgen-anabolic steroids have been used in the treatment of chronic debilitating diseases. These drugs promote a feeling of well-being and may improve appetite when administered to patients with terminal illnesses. The efficacy of anabolic steroids to improve athletic performance is not documented and is condemned on ethical grounds. Certain androgens may be useful in the treatment of hereditary angioedema.

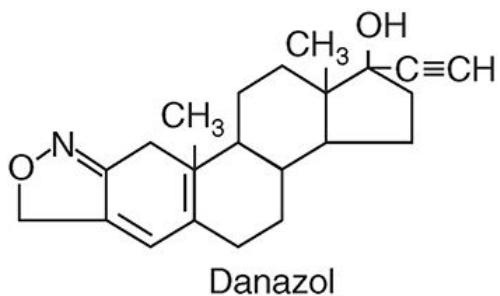

FIGURE 40.9 Androgens.

Route of Administration

About 99% of testosterone circulating in the plasma is bound to sex hormone–binding globulin. As a result, this globulin determines the concentration of free testosterone in the plasma and thus its elimination half-time, which is 10 to 20 minutes. Testosterone administered orally is readily absorbed but is metabolized so extensively by the liver that therapeutic effects do not occur. Alkylation of androgens at the 17 position retards their hepatic metabolism and permits such derivatives to be effective (see [Figure 40.9](#)). Alkylated testosterones are rarely prescribed because of their association with hepatic dysfunction. Intramuscular injection of esters of testosterone (ie, testosterone enanthate and testosterone cypionate), which are more lipophilic than testosterone alone, prolongs the duration of time that testosterone is present in the blood. Testosterone can also be delivered via patch and gels.

Side Effects

Dose-related cholestatic hepatitis and jaundice are particularly likely to accompany androgen therapy for palliation in neoplastic disease. Increases in the plasma alkaline phosphatase, hematocrit, and transaminase enzymes are also likely. Prolonged therapy (>1 year) with androgens, as for management of anemia, is associated with an increased incidence of hepatic cancer. Retention of sodium and water is also likely to accompany palliative treatment of cancer with high doses of androgens. Androgens increase the potency of coumarin anticoagulants and the likelihood of spontaneous hemorrhage. Androgens can decrease the concentration of thyroid-binding globulin in plasma and thus influence thyroid function tests.

Danazol

The low androgenic activity of danazol makes it the preferred androgen for treatment of hereditary angioedema (see [Figure 40.9](#)). In treated patients, there is a remission of symptoms as well as increased production of previously deficient plasma protein factors. As with other androgens, danazol therapy has been associated with abnormal liver function tests and jaundice. Danazol also decreases breast pain and nodularity in many women with fibrocystic breast disease. Symptoms of endometriosis are decreased, and fertility may be restored in danazol-treated women. In patients with hemophilia A, danazol increases factor VIII activity and decreases the incidence of hemorrhage.⁸³

Finasteride

Finasteride is a competitive 5- α -reductase inhibitor that does not bind to the androgen receptor ([Figure 40.10](#)).⁸⁴ As a result of this drug-induced enzyme inhibition, dihydrotestosterone production from testosterone does not occur. In the absence of dihydrotestosterone, the androgen effects on the prostate and skin do not occur. Finasteride is administered orally (5 mg once daily) for the treatment of benign prostatic hyperplasia. Treatment of male pattern baldness, hirsutism, and acne may represent other potentially useful applications for finasteride. There is no evidence that finasteride is beneficial in men with established prostate cancer. The elimination half-time after oral administration is 6 to 8 hours. The only important side effects of finasteride are related to decreased sexual function. Finasteride has no effect on serum lipids or bone density. Prostate-specific antigen concentrations are decreased by treatment with finasteride, introducing the concern that detection of prostate cancer could be masked in patients treated with this drug.

PART VIII Miscellaneous

Antimicrobials, Antiseptics, Disinfectants, and Management of Perioperative Infection

Stephanie J. Pan • Pamela Flood

Introduction

The excessive use of antimicrobials (antibiotics) for the treatment of conditions for which these drugs provide little or no benefit (upper respiratory tract infections, bronchitis) has contributed to the emergence of bacterial resistance. It is estimated that more than 25% of all prescriptions are written for conditions for which antibiotics are rarely indicated in ambulatory patients seen in physicians' offices.^{1,2} The overuse of antimicrobials for agricultural purposes dwarfs that for human use.³

Misuse of antibiotics in general is in contrast to the proven benefit of antibiotic prophylaxis for selected surgical procedures, which has been part of a national initiative to enhance compliance, the Surgical Care Improvement Project (SCIP). The SCIP, based originally on the Surgical Infection Project, was designed to combat a perceived national crisis of preventable surgical site infections, identified in the 1990s, which were associated with doubled risk of mortality, 60% higher likelihood of spending time in an intensive care unit, and fivefold risk of readmission.⁴ The original SCIP goal was a 25% reduction in surgical site infection by 2010.⁵ When this goal was not met, a subsequent goal of 25% reduction was set for 2013. Although data analysis in 2012 appeared promising, as a 20% reduction had been achieved, this reduction plateaued in the following years. The failure to meet these important but daunting goals has been attributed to several factors including a delayed launch, following inappropriate outcome variables, and outcome data that were biased by the "pay-for-performance" initiative.⁶ In 2015, the SCIP measures were retired, and The Joint Commission implemented the ORYX Performance Measures. Under The Joint Commission, hospital organizations are allowed to choose targeted surgical site infections surveillances based on their own risk assessments but are not required to include all surgical procedures.⁷

The baseline risk for perioperative infection is highly dependent on factors that require risk adjustment in clinical trials and consideration in clinical care. Patient-related risk factors for surgical site infection include extremes of age (younger than 5 and older than 65 years), higher American Society of Anesthesiologists physical status score, poor nutritional status, obesity, diabetes mellitus and perioperative glycemic control, peripheral vascular disease, tobacco use, coexistent infections, altered immune response, corticosteroid therapy, preoperative skin preparation (surgical scrub and hair removal), and length of preoperative hospitalization. Institutional variables include surgical experience and technique (ie, open vs laparoscopic), duration of procedure, quantity of blood loss, hospital environments including sterilization of instruments, and maintenance of perioperative normothermia.^{8–10} Some risk factors are surgery specific, such as the creation of an ostomy in bowel surgery and use of bilateral mammary arteries in coronary artery bypass grafting.

Of the aforementioned variables, few are modifiable at the time of surgery. For example, good perioperative glucose control can reduce infection risk. Perioperative glucose control has been studied in a variety of surgeries. In the cardiothoracic surgery population, it is associated with about a 50% decrease in deep sternal infection.¹¹ Continuous insulin infusion was associated with an additional reduction in surgical site infection compared to intermittent subcutaneous injection.¹² These findings have been generalized to bowel surgery where patients whose glucose was maintained below 200 mg/dL for 48 hours after surgery compared with those having concentrations greater than 200 mg/dL had significantly fewer surgical site infections (29.7% vs 14.3%).¹³ However, intensive insulin regimens designed to keep blood sugar ultralow have shown higher hypoglycemia and mortality compared to conventional treatment.¹⁴ In a recent meta-analysis of 15 studies, there was a benefit of intensive compared to conventional glucose monitoring

protocols in the prevention of surgical site infection (odds ratio 0.43).¹⁵ In this analysis, there was a higher risk of hypoglycemic episodes but no increase in the risk of death.

Although more difficult to achieve, smoking cessation is a perioperative goal. Perioperative education on smoking cessation by surgeons and anesthesiologists during preoperative evaluation is important. The preoperative period has been called a “teachable moment,” and even brief smoking cessation can reduce infection risk.¹⁶ A meta-analysis of four studies that have assessed the effect of 4 to 8 weeks of preoperative smoking cessation demonstrates a risk reduction of approximately 50%.¹⁷ Although electronic cigarettes do not contain tobacco, they do contain nicotine and other chemicals that have thus far shown to decrease wound healing and cutaneous blood flow.¹⁸ Whether electronic cigarettes have a similar impact on surgical site infection risk remains to be seen.

The anesthesiologist should contribute to the maintenance of perioperative normothermia. It is logical that hypothermia will result in peripheral vasoconstriction, decreased wound oxygen tension, and recruitment of leukocytes, favoring infection and impaired healing. In a meta-analysis of trials comparing intraoperative warming to control, warming was associated with a 64% decrease in surgical site infections.¹⁹ Prewarming patients before surgery reduces the peripheral-to-core temperature gradient and has the added advantage of making placement of intravenous (IV) lines easier because of peripheral vasodilation. Active prewarming of volunteers for 2 hours resulted in maintenance of core temperatures above 36°C for 60 minutes of general anesthesia at ambient temperature, whereas core temperatures in unwarmed subjects dropped an average of 1.9°C to below 35°C.

Immunosuppression on the basis of long-term use of corticosteroids is considered a risk factor for surgical site infection.²⁰ In a study of surgical site infection following lumbar fusion surgery, chronic oral steroid use in patients older than 65 years of age was found to significantly increase the risk of surgical site infections at 90 days and 1 year.²¹ Similarly, preoperative chemotherapy and corticosteroid use were independent predictors of cranial surgical site infections even when the data was controlled for leukopenia.²² There is clear evidence that a single dose of corticosteroid given to prevent nausea and vomiting and reduce pain does not promote infection. For example, in a study of open abdominal surgery for gynecologic cancer, there were no excess wound infections in patients treated with a single dose of dexamethasone for nausea and vomiting prophylaxis.²³

Antimicrobial Prophylaxis for Surgical Procedures

The use of antimicrobial prophylaxis in surgery involves a risk-to-benefit evaluation, which varies depending on the nature of the operative procedure. Previous SCIP measures retired in 2015 recommended the IV administration of prophylactic antimicrobials within 1 hour of surgical incision. This broadly accepted recommendation could not be substantiated after a systematic review and meta-analysis of all major medical databases from 1990 to 2016. Although administration of antibiotic prophylaxis more than 120 minutes before or after incision was associated with a higher risk of surgical site infections, there was no differential effect within the 120-minute time frame prior to incision.²⁴ Ideally, tissue concentration of the antibiotic should exceed the minimum inhibitory concentration associated with the procedure and/or patient characteristics from the time of incision to the completion of surgery. For short-acting antibiotics, this may require redosing (**Table 41.1**) especially when blood loss is greater than 1,500 mL.²⁵ Antibiotic treatment is not recommended for longer than 24 hours. This recommendation is based on findings of no benefit to prolonged dosing but rather an increased incidence of drug-resistant organisms.

TABLE 41.1 Recommended doses and redosing intervals for commonly used antimicrobials for surgical prophylaxis ^a				
	Recommended Dose		Half-life in adults with normal renal function (hours)	Recommended redosing interval (from initiation of preoperative dose; hours ^d)
Antimicrobial	Adults ^b	Pediatrics ^c		
Ampicillin-	3 g (ampicillin	50 mg/kg of the	0.8-1.3	2

sulbactam	2 g/sulbactam 1 g)	ampicillin component		
Ampicillin	2 g	50 mg/kg	1-1.9	2
Aztreonam	2 g	30 mg/kg	1.3-2.4	4
Cefazolin	2 g, 3 g for patients weighing \geq 120 kg	30 mg/kg	1.2-2.2	4
Cefuroxime	1.5 g	50 mg/kg	1-2	4
Cefotaxime	1 g ^e	50 mg/kg	0.9-1.7	3
Cefoxitin	2 g	40 mg/kg	0.7-1.1	2
Cefotetan	2 g	40 mg/kg	2.8-4.6	6
Ceftriaxone	2 g ^f	50-75 mg/kg	5.4-10.9	NA
Ciprofloxacin ^g	400 mg	10 mg/kg	3-7	NA
Clindamycin	900 mg	10 mg/kg	2-4	6
Ertapenem	1 g	15 mg/kg	3-5	NA
Fluconazole	400 mg	6 mg/kg	30	NA
Gentamicin ^h	5 mg/kg based on dosing weight (single dose)	2.5 mg/kg based on dosing weight	2-3	NA
Levofloxacin ^g	500 mg	10 mg/kg	6-8	NA
Metronidazole	500 mg	15 mg/kg Neonates weighing <1,200 g should receive a single 7.5-mg/kg dose.	6-8	NA
Moxifloxacin ^g	400 mg	10 mg/kg	8-15	NA
Piperacillin-tazobactam	3.375 g	Infants 2-9 mo: 80 mg/kg of the piperacillin component Children >9 mo and \leq 40 kg: 100 mg/kg of the piperacillin component	0.7-1.2	2
Vancomycin	15 mg/kg	15 mg/kg	4-8	NA
<i>Oral antibiotics for colorectal surgery prophylaxis (used in conjunction with a mechanical bowel preparation)</i>				
Erythromycin base	1 g	20 mg/kg	0.8-3	NA
Metronidazole	1 g	15 mg/kg	6-10	NA
Neomycin	1 g	15 mg/kg	2-3 (3% absorbed under normal gastrointestinal conditions)	NA

^aFrom Bratzler DW, Dellinger EP, Olsen KM, et al; American Society of Health-System Pharmacists; Infectious Diseases Society of America; Surgical Infection Society; Society for Healthcare Epidemiology of

America. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm.* 2013;70(3):195–283. Reproduced by permission of American Society of Health-System Pharmacists, Inc.
^bAdult doses are obtained from the studies cited in each section. When doses differed between studies, expert opinion used the most often recommended dose.

^cThe maximum pediatric dose should not exceed the usual adult dose.

^dFor antimicrobials with a short half-life (eg, cefazolin, cefoxitin) used before long procedures, redosing in the operating room is recommended at an interval of approximately 2 times the half-life of the agent in patients with normal renal function. Recommended redosing intervals marked as “not applicable” (NA) are based on typical case length; for unusually long procedures, redosing may be needed.

^eAlthough U.S. Food and Drug Administration–approved package insert labeling indicates 1 g, 14 experts recommend 2 g for obese patients.

^fWhen used as a single dose in combination with metronidazole for colorectal procedures.

^gAlthough fluoroquinolones have been associated with an increased risk of tendinitis/tendon rupture in all ages, use of these agents for single-dose prophylaxis is generally safe.

^hIn general, gentamicin for surgical antibiotic prophylaxis should be limited to a single dose given preoperatively. Dosing is based on the patient’s actual body weight. If the patient’s actual weight is more than 20% above ideal body weight (IBW), the dosing weight (DW) can be determined as follows: DW = IBW + 0.4 (actual weight – IBW).

The antibiotic chosen should be appropriate for the most likely microorganism related to the procedure and patient characteristics.²⁶ For clean elective surgical procedures such as mastectomy and thyroidectomy in which no tissue (other than the skin) carrying an indigenous flora is penetrated, the risks of routine antimicrobial prophylaxis outweigh the possible benefits. The predominant organisms causing surgical site infections after clean procedures are skin flora (*Staphylococcus aureus* and *Staphylococcus epidermidis*). In clean-contaminated procedures, including abdominal procedures and solid organ transplantation, the most common organisms include gram-negative rods and enterococci in addition to skin flora.²⁷ Antibiotic recommendations for specific procedure prophylaxis can be found in **Table 41.2**.²⁶ Subspecialty societies have created many enhanced recovery after surgery guidelines, where details on antibiotic recommendations can be found.^{28–33}

TABLE 41.2

Common antimicrobials used for prophylaxis in various surgical settings^{a,f}

Type of procedure	Recommended agents ^{b,c}	Alternative agents in patients with β-lactam allergy	Strength of evidence ^d
Cardiac			
Coronary artery bypass	Cefazolin, cefuroxime	Clindamycin, ^e vancomycin ^e	A
Cardiac device insertion procedures (eg, pacemaker implantation)	Cefazolin, cefuroxime	Clindamycin, vancomycin	A
Ventricular assist devices	Cefazolin, cefuroxime	Clindamycin, vancomycin	C
Thoracic			
Noncardiac procedures, including lobectomy, pneumonectomy, lung resection, and thoracotomy	Cefazolin, ampicillin-sulbactam	Clindamycin, ^e vancomycin ^e	A
Video-assisted thoracoscopic surgery	Cefazolin, ampicillin-sulbactam	Clindamycin, ^e vancomycin ^e	C
Gastrointestinal			

Procedures involving entry into lumen of gastrointestinal tract (bariatric, pancreaticoduodenectomy ^g)	Cefazolin	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	A
Procedures without entry into gastrointestinal tract (antireflux, highly selective vagotomy) for high-risk patients	Cefazolin	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	A
Biliary tract			
Open procedure	Cefazolin, cefoxitin, cefotetan, ceftriaxone, ^l ampicillin-sulbactam ⁱ	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k} Metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	A
Laparoscopic procedure			
Elective, low-risk ^m	None	None	A
Elective, high-risk ^m	Cefazolin, cefoxitin, cefotetan, ceftriaxone, ^l ampicillin-sulbactam ⁱ	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k} Metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	A
Appendectomy for uncomplicated appendicitis	Cefoxitin, cefotetan, cefazolin + metronidazole	Clindamycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k} Metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	A
Small intestine			
Nonobstructed	Cefazolin	Clindamycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	C
Obstructed	Cefazolin + metronidazole, cefoxitin, cefotetan	Metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	C
Hernia repair (hernioplasty and herniorrhaphy)	Cefazolin	Clindamycin, vancomycin	A
Colorectal ⁿ	Cefazolin + metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam, ⁱ ceftriaxone + metronidazole, ^o ertapenem	Clindamycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	A

		metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	
Head and neck			
Clean	None	None	B
Clean with placement of prosthesis (excludes tympanostomy tubes)	Cefazolin, cefuroxime	Clindamycin ^e	C
Clean-contaminated cancer surgery	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin ^e	A
Other clean-contaminated procedures with the exception of tonsillectomy and functional endoscopic sinus procedures	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin ^e	B
Neurosurgery			
Elective craniotomy and cerebrospinal fluid-shunting procedures	Cefazolin	Clindamycin, ^e vancomycin ^e	A
Implantation of intrathecal pumps	Cefazolin	Clindamycin, ^e vancomycin ^e	C
Cesarean delivery	Cefazolin	Clindamycin + aminoglycoside ^h	A
Hysterectomy (vaginal or abdominal)	Cefazolin, cefotetan, cefoxitin, ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k} Metronidazole + aminoglycoside ^h or fluoroquinolone ^{i,j,k}	A
Ophthalmic	Topical neomycin—polymyxin B—gramicidin or fourth-generation topical fluoroquinolones (gatifloxacin or moxifloxacin) given as 1 drop every 5-15 min for 5 doses ^p Addition of cefazolin 100 mg by subconjunctival injection or intracameral cefazolin 1-2.5 mg or cefuroxime 1 mg at the end of procedure is optional	None	B
Orthopedic			
Clean operations involving hand, knee, or foot and not involving implantation of foreign materials	None	None	C
Spinal procedures with and	Cefazolin	Clindamycin, ^e vancomycin ^e	A

without instrumentation			
Hip fracture repair	Cefazolin	Clindamycin, ^e vancomycin ^e	A
Implantation of internal fixation devices (eg, nails, screws, plates, wires)	Cefazolin	Clindamycin, ^e vancomycin ^e	C
Total joint replacement	Cefazolin	Clindamycin, ^e vancomycin ^e	A
Urologic			
Lower tract instrumentation with risk factors for infection (includes transrectal prostate biopsy)	Fluoroquinolone, ^{i,j,k} trimethoprim-sulfamethoxazole, cefazolin	Aminoglycoside ^h with or without clindamycin	A
Clean without entry into urinary tract	Cefazolin (the addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [eg, penile prosthesis])	Clindamycin, ^e vancomycin ^e	A
Involving implanted prosthesis	Cefazolin ± aminoglycoside, cefazolin ± aztreonam, ampicillin-sulbactam	Clindamycin ± aminoglycoside or aztreonam, vancomycin ± aminoglycoside or aztreonam	A
Clean with entry into urinary tract	Cefazolin (the addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [eg, penile prosthesis])	Fluoroquinolone, ^{i,j,k} aminoglycoside ^h with or without clindamycin	A
Clean-contaminated	Cefazolin + metronidazole, cefoxitin	Fluoroquinolone, ^{i,j,k} aminoglycoside ^h + metronidazole or clindamycin	A
Vascular^g			
Heart, lung, heart-lung transplantation ^r	Cefazolin	Clindamycin, ^e vancomycin ^e	A
Heart transplantation ^s	Cefazolin	Clindamycin, ^e vancomycin ^e	A (based on cardiac procedures)
Lung and heart-lung transplantation ^{s,t}	Cefazolin	Clindamycin, ^e vancomycin ^e	A (based on cardiac procedures)
Liver transplantation ^{r,u}	Piperacillin-tazobactam, cefotaxime + ampicillin	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	B
Pancreas and pancreas-kidney transplantation ^s	Cefazolin, fluconazole (for patients at high risk for fungal infection [eg, those with enteric drainage of the pancreas])	Clindamycin or vancomycin + aminoglycoside ^h or aztreonam or fluoroquinolone ^{i,j,k}	A
Plastic surgery	Cefazolin	Clindamycin or vancomycin + aminoglycoside ^h or	A

		aztreonam or fluoroquinolone ^{ij,k}	
Clean with risk factors or clean-contaminated	Cefazolin, ampicillin-sulbactam	Clindamycin, ^e vancomycin ^e	C

^aFrom Bratzler DW, Dellinger EP, Olsen KM, et al; American Society of Health-System Pharmacists; Infectious Diseases Society of America; Surgical Infection Society; Society for Healthcare Epidemiology of America. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm*. 2013;70(3):195–283. Reproduced by permission of American Society of Health-System Pharmacists, Inc.

^bThe antimicrobial agent should be started within 60 minutes before surgical incision (120 min for vancomycin or fluoroquinolones). Although single-dose prophylaxis is usually sufficient, the duration of prophylaxis for all procedures should be less than 24 hours. If an agent with a short half-life is used (eg, cefazolin, cefoxitin), it should be readministered if the procedure duration exceeds the recommended redosing interval (from the time of initiation of the preoperative dose [see [Table 41.2](#)]). Readministration may also be warranted if prolonged or excessive bleeding occurs or if there are other factors that may shorten the half-life of the prophylactic agent (eg, extensive burns). Readministration may not be warranted in patients in whom the half-life of the agent may be prolonged (eg, patients with renal insufficiency or failure).

^cFor patients known to be colonized with methicillin-resistant *Staphylococcus aureus*, it is reasonable to add a single preoperative dose of vancomycin to the recommended agent(s).

^dStrength of evidence that supports the use or nonuse of prophylaxis is classified as A (levels I-III), B (levels IV-VI), or C (level VII). Level I evidence is from large, well-conducted, randomized controlled clinical trials. Level II evidence is from small, well-conducted, randomized controlled clinical trials. Level III evidence is from well-conducted cohort studies. Level IV evidence is from well-conducted case control studies. Level V evidence is from uncontrolled studies that were not well conducted. Level VI evidence is conflicting evidence that tends to favor the recommendation. Level VII evidence is expert opinion.

^eFor procedures in which pathogens other than staphylococci and streptococci are likely, an additional agent with activity against those pathogens could be considered. For example, if there are surveillance data showing that gram-negative organisms are a cause of surgical-site infections (SSIs) for the procedure, practitioners may consider combining clindamycin or vancomycin with another agent (cefazolin if the patient is not β -lactam allergic; aztreonam, gentamicin, or single-dose fluoroquinolone if the patient is β -lactam allergic).

^fProphylaxis should be considered for patients at highest risk for postoperative gastroduodenal infections, such as those with increased gastric pH (eg, those receiving histamine H₂-receptor antagonists or proton-pump inhibitors), gastroduodenal perforation, decreased gastric motility, gastric outlet obstruction, gastric bleeding, morbid obesity, or cancer. Antimicrobial prophylaxis may not be needed when the lumen of the intestinal tract is not entered.

^gConsider additional antimicrobial coverage with infected biliary tract. See the biliary tract procedures section of this table.

^hGentamicin or tobramycin.

ⁱDue to increasing resistance of *Escherichia coli* to fluoroquinolones and ampicillin-sulbactam, local population susceptibility profiles should be reviewed prior to use.

^jCiprofloxacin or levofloxacin.

^kFluoroquinolones are associated with an increased risk of tendonitis and tendon rupture in all ages. However, this risk would be expected to be quite small with single-dose antibiotic prophylaxis. Although the use of fluoroquinolones may be necessary for surgical antibiotic prophylaxis in some children, they are not drugs of first choice in the pediatric population due to an increased incidence of adverse events as compared with controls in some clinical trials.

^lCeftriaxone use should be limited to patients requiring antimicrobial treatment for acute cholecystitis or acute biliary tract infections, which may not be determined prior to incision, not patients undergoing cholecystectomy for noninfected biliary conditions, including biliary colic or dyskinesia without infection.

^mFactors that indicate a high risk of infectious complications in laparoscopic cholecystectomy include emergency procedures, diabetes, long procedure duration, intraoperative gallbladder rupture, age of >70

years, conversion from laparoscopic to open cholecystectomy, American Society of Anesthesiologists classification of 3 or greater, episode of colic within 30 days before the procedure, reintervention in less than 1 month for noninfectious complication, acute cholecystitis, bile spillage, jaundice, pregnancy, nonfunctioning gallbladder, immunosuppression, and insertion of prosthetic device. Because a number of these risk factors are not possible to determine before surgical intervention, it may be reasonable to give a single dose of antimicrobial prophylaxis to all patients undergoing laparoscopic cholecystectomy.

^bFor most patients, a mechanical bowel preparation combined with oral neomycin sulfate plus oral erythromycin base or with oral neomycin sulfate plus oral metronidazole should be given in addition to IV prophylaxis.

^cWhere there is increasing resistance to first- and second-generation cephalosporins among gram-negative isolates from SSIs, a single dose of ceftriaxone plus metronidazole may be preferred over the routine use of carbapenems.

^dThe necessity of continuing topical antimicrobials postoperatively has not been established.

^eProphylaxis is not routinely indicated for brachiocephalic procedures. Although there are no data in support, patients undergoing brachiocephalic procedures involving vascular prostheses or patch implantation (eg, carotid endarterectomy) may benefit from prophylaxis.

^fThese guidelines reflect recommendations for perioperative antibiotic prophylaxis to prevent SSIs and do not provide recommendations for prevention of opportunistic infections in immunosuppressed transplantation patients (eg, for antifungal or antiviral medications).

^gPatients who have left ventricular assist devices as a bridge and who are chronically infected might also benefit from coverage of the infecting microorganism.

^hThe prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including gram-negative (eg, *P aeruginosa*) or fungal organisms, isolated from the donor lung or the recipient before transplantation. Patients undergoing lung transplantation with negative pretransplantation cultures should receive antimicrobial prophylaxis as appropriate for other types of cardiothoracic surgeries. Patients undergoing lung transplantation for cystic fibrosis should receive 7-14 days of treatment with antimicrobials selected according to pretransplantation culture and susceptibility results. This treatment may include additional antibacterial or antifungal agents.

ⁱThe prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including vancomycin-resistant enterococci, isolated from the recipient before transplantation.

Because of their wide therapeutic index and low incidence of side effects, cephalosporins (most often a cost-effective first-generation cephalosporin such as cefazolin) are the antimicrobials of choice for surgical procedures in which skin flora and normal flora of the gastrointestinal and genitourinary tracts are the most likely pathogens. Patients with documented immunoglobulin E (IgE) reaction to cephalosporins are rare and often mistaken for more common intolerances such as nausea or yeast infection. The IgE-mediated anaphylactic reactions to antimicrobials usually occur 30 to 60 minutes after dosing and often include urticaria, bronchospasm, and hemodynamic collapse. This reaction is a life-threatening emergency that precludes subsequent use of the drug. Cephalosporins can safely be used in patients with an allergic reaction to penicillins that is not an IgE-mediated reaction (eg, anaphylaxis, urticaria, bronchospasm) or exfoliative dermatitis (Stevens-Johnson syndrome, toxic epidermal necrolysis).³⁴ Although early reports of cross-reactivity were high due to contaminated drug lots, the actual rate of cross-reactivity is only 1%.³⁴ However, the consequences of true anaphylaxis are severe. Patients should be carefully questioned about the nature of any drug allergy. Documentation of allergy should be separated from medication intolerances in institutional databases where possible. For example, 90% of patients who report a penicillin allergy are found to be incorrect with comprehensive testing. This is a barrier to antibiotic stewardship, and it exposes the patient to harm from a potentially more toxic or less effective antibiotic.³⁵ In patients with documented IgE-mediated anaphylactic reactions, β-lactam antibiotics can usually be substituted with clindamycin or vancomycin.²⁶ Vancomycin may also be considered when methicillin-resistant *S aureus* (MRSA) is considered likely, for example, in children or elderly patients known to be colonized with MRSA. Nasal application of mupirocin

has been considered as an alternative and has been found to be effective in eliminating MRSA colonization in adults and children. It is U.S. Food and Drug Administration approved for eradication of colonization in adults and health care workers. Treatment with mupirocin is effective in reducing *S aureus* infection in documented carriers. Preoperative screening is recommended to identify high-risk patients who would benefit from decolonization and to guide appropriate preoperative antibiotic selection for those with resistant organisms. Routine prophylaxis with vancomycin is not recommended for any patient population in the absence of documented or highly suspected colonization or infection with MRSA (recent hospitalization of nursing home stay and hemodialysis patients) or known IgE-mediated response to β -lactam antibiotics.³⁶ The recommendation against routine prophylaxis with vancomycin is due to concerns about selection of resistant organisms, its risk of inducing hemodynamic instability due to histamine release (red man syndrome; [Figure 41.1](#)) if given rapidly, and evidence that vancomycin is less effective than cefazolin in methicillin-susceptible *S aureus*.^{37,38} With increasing prevalence of MRSA among patients, dual antibiotic regimens such as vancomycin with cefazolin supplementation has been proposed as prophylaxis against surgical site infections, particularly in joint replacement surgeries. There are limited studies supporting any clear advantage in reductions in surgical site infections without increased risk of adverse effects such as acute kidney injury with dual antibiotic regimens.³⁹ The Australian Surgical Antibiotic Prophylaxis trial is currently underway and should shed more light in the coming years on the combination of vancomycin and cefazolin for surgical antibiotic prophylaxis.⁴⁰ New vaccines and antibody therapies are in development to help prevent and treat infection where antibiotics are not effective.⁴¹

Histamine release by vancomycin. A mechanism for hypotension in man. *Anesthesiology*. 1987;67(1):122-125. Copyright © 1987 American Society of Anesthesiologists, Inc.

Clean-contaminated procedures such as colorectal and abdominal surgeries require additional coverage for gram-negative rods and anaerobes in addition to skin flora. Metronidazole can be added to cefazolin or cefoxitin, cefotetan, ampicillin-sulbactam, ertapenem, or ceftriaxone. Bowel preparation with oral antimicrobials has been studied as a potentially less costly alternative. Mechanical bowel preparation alone does not reduce infection, but selective decontamination of the digestive tract with oral topical polymyxin, tobramycin, and amphotericin eradicates the colonization gram-negative microorganisms, *S aureus*, and yeasts from oral cavity to rectum. Vancomycin would be active against MRSA but is not recommended

because gram-positive flora plays an important role in the resistance to colonization.⁴² In a meta-analysis of eight studies, the combination of oral treatment and perioperative venous prophylaxis was found to be superior to IV prophylaxis alone in preventing surgical site infection and anastomotic leak. However, older studies found that oral antibiotics alone are not a solution. A randomized controlled study was stopped because of higher rate of infection in the oral neomycin and erythromycin group (41%) compared with the single-dose IV metronidazole and ceftriaxone group.⁴³ Another trial of oral metronidazole and kanamycin compared with the same medications given IV found an increased rate of postoperative sepsis and pseudomembranous colitis in the oral group.⁴⁴ Pseudomembranous colitis is the most frequent complication of prophylactic antimicrobials, including the IV cephalosporins. Additional toxicities are covered in [Table 41.3](#).

TABLE 41.3

Direct drug toxicity associated with administration of antimicrobials

Toxicity	Antimicrobial
Allergic reactions	All antimicrobials but most often with β -lactam derivatives
Nephrotoxicity	Aminoglycosides Polymyxins Amphotericin B
Neutropenia	Penicillins Cephalosporins Vancomycin
Inhibition of platelet aggregation	Penicillins (high doses)
Prolonged prothrombin time	Cephalosporins
Bone marrow suppression (aplastic anemia, pancytopenia)	Chloramphenicol Flucytosine Linezolid (reversible)
Hemolytic anemia	Chloramphenicol Sulfonamides Nitrofurantoin Primaquine
Agranulocytosis	Macrolides Trimethoprim-sulfamethoxazole
Leukopenia and thrombocytopenia (folate deficiency)	Trimethoprim
Normocytic normochromic anemia	Amphotericin B
Ototoxicity	Aminoglycosides Vancomycin (auditory neurotoxicity) Minocycline (vestibular toxicity)
Seizures	Penicillins and other β -lactams (high doses, azotemic patients, history of epilepsy) Metronidazole
Neuromuscular blockade	Aminoglycosides
Peripheral neuropathy	Nitrofurantoin (renal failure) Isoniazid (prevent with pyridoxine) Metronidazole
Benign intracranial hypertension	Tetracyclines
Optic neuritis	Ethambutol
Hepatotoxicity	Isoniazid Rifampin

	Tetracyclines (high doses) β-Lactam antimicrobials (high doses) Nitrofurantoin Erythromycin Sulfonamides
Increased plasma bilirubin concentrations	Quinupristin-dalfopristin Erythromycin
Gastrointestinal irritation	Tetracyclines
Prolongation of QTc interval	Erythromycin Fluoroquinolones
Exaggerated sympathomimetic effects in patients receiving monoamine oxidase inhibitors	Linezolid
Hyperkalemia	Trimethoprim-sulfamethoxazole
Tendinitis	Fluoroquinolones
Arthralgias and myalgias	Quinupristin-dalfopristin
Photosensitivity	Sulfonamides Tetracyclines Fluoroquinolones
Teratogenicity	Tetracyclines Metronidazole Rifampin Trimethoprim Fluoroquinolones

Antimicrobial Selection

Prompt identification of the causative organism is essential for the selection of appropriate antimicrobial drugs to treat ongoing infection. The efficacy of antimicrobial therapy depends on drug delivery to the site of infection. Body sites with poor blood flow and with low pH such as pressure and diabetic ulcers are difficult to treat. Antimicrobial therapy is more likely to be effective if infected material (foreign body, prosthesis) is removed. Infections behind obstructing lesions such as pneumonia behind a blocked bronchus will not respond to antimicrobials until the obstruction is relieved. Transport across the blood–brain barrier varies greatly among antimicrobials and is important to consider when prescribing an antibiotic for a neuraxial infection.

Nosocomial Infections

Nearly 80% of nosocomial infections occur in three sites (urinary tract, respiratory system, and bloodstream). The incidence of nosocomial infections is highly associated with the use of devices such as ventilators, vascular access catheters, and urinary catheters. Intravascular access catheters are the most common causes of bacteremia or fungemia in hospitalized patients.⁴⁵ The organism infecting access catheters most commonly comes from the colonized hub or lumen and reflect skin flora (*S aureus* and *S epidermidis*). Initial therapy of suspected intravascular catheter infection usually includes vancomycin because of the high incidence of MRSA and methicillin-resistant *S epidermidis* in the nosocomial environment. Central line-associated bloodstream infections account for 60% of all infections related to vascular access. Effective guidelines include care bundles to ensure application of evidence-based practices including hand hygiene, appropriate skin preparation, and barrier precautions.⁴⁶

Special Patient Groups

Parturients

Administration of antimicrobials during pregnancy introduces the question of safety for the mother and fetus (**Table 41.4**). Most antimicrobials cross the placenta and enter maternal milk. The immature fetal liver may lack enzymes necessary to metabolize certain drugs such that pharmacokinetics and toxicities in the fetus are often different from those in older children and adults. Teratogenicity is a concern when any drug is administered during early pregnancy. Increases in maternal blood volume, glomerular filtration rate, and hepatic metabolic activity may decrease plasma antimicrobial concentrations (10%-50%), especially late in pregnancy and in the early postpartum period. In some parturients, delayed gastric emptying may decrease absorption of orally administered antimicrobials.⁴⁷

TABLE 41.4

Antimicrobials in pregnancy

Drug	Maternal toxicity	Fetal toxicity	Excreted in colostrum
Considered safe			
Penicillins	Allergic reactions	None known	Trace
Cephalosporins	Allergic reactions	None known	Trace
Erythromycin base	Allergic reactions Gastrointestinal irritation	None known	Yes
Use cautiously			
Aminoglycosides	Ototoxicity Nephrotoxicity	Ototoxicity	Yes
Clindamycin	Allergic reactions Colitis	None known	Trace
Ethambutol	Optic neuritis	None known	Unknown
Isoniazid	Allergic reactions Hepatotoxicity	Neuropathy Seizures	Yes
Rifampin	Allergic reactions Hepatotoxicity	None known	Yes
Sulfonamides	Allergic reactions	Kernicterus (at term) Hemolysis (G6PD deficiency)	Yes
Avoid			
Metronidazole	Allergic reactions Alcohol intolerance Peripheral neuropathy	None known (teratogenic in animals)	Yes
Contraindicated			
Chloramphenicol	Bone marrow depression	Gray syndrome	Yes
Erythromycin estolate	Hepatotoxicity	None known	Yes
Nalidixic acid	Gastrointestinal irritation	Increased intracranial pressure	Unknown
Fluoroquinolones	Gastrointestinal irritation	Arthropathies (animals)	Unknown
Nitrofurantoin	Allergic reactions Peripheral neuropathy Gastrointestinal irritation	Hemolysis (G6PD deficiency)	Trace
Tetracyclines	Hepatotoxicity Nephrotoxicity	Tooth discoloration and dysplasia Impaired bone growth	Yes
Trimethoprim	Allergic reactions	Teratogenicity	Yes

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

Elderly Patients

Physiologic changes that occur with increasing age can alter oral absorption (decreased gastric acidity, reduced gastrointestinal motility), distribution (increased total body fat, decreased plasma albumin concentrations), metabolism (decreased hepatic blood flow), and excretion (decreased glomerular filtration rate) of antimicrobials. Penicillins and cephalosporins, because of their large therapeutic index, obviate the need for significant changes in dosage schedules in elderly patients who have normal serum creatinine concentrations. Conversely, administration of aminoglycosides and vancomycin to elderly patients may require adjustments in dosing regimens. Measurement of plasma concentrations of antimicrobials and monitoring of renal function may be indicated when administering certain antimicrobials to elderly patients.

Human Immunodeficiency Virus-Infected Patients

There has been concern about increased risk of postoperative infection in human immunodeficiency virus-infected patients based on their increased risk for opportunistic infection in the setting of reduced T4 cell counts. Several recent studies have addressed this issue and produced conflicting results.⁴⁸⁻⁵⁰ Favorable results appear to be related to good preoperative control on an antiretroviral regimen with preserved T4 cell counts.⁵¹

Antibacterial Drugs Commonly Used in the Perioperative Period

Penicillins

The basic structure of penicillins is a dicyclic nucleus (aminopenicillanic acid) that consists of a thiazolidine ring connected to a β -lactam ring. The penicillins may be classified into subgroups because of their structure, β -lactamase susceptibility, and spectrum of activity. The bactericidal action of penicillins reflects the ability of these antimicrobials to interfere with the synthesis of peptidoglycan, which is an essential component of cell walls of susceptible bacteria. Penicillins also decrease the availability of an inhibitor of murein hydrolase such that the uninhibited enzyme can then destroy (lyse) the structural integrity of bacterial cell walls. Cell membranes of resistant gram-negative bacteria are in general resistant to penicillins because they prevent access to sites where synthesis of peptidoglycan is taking place.

Clinical Indications

Penicillin is the drug of choice for treatment of pneumococcal, streptococcal, and meningococcal infections. Gonococci have gradually become more resistant to penicillin, requiring higher doses for adequate treatment. Treatment of syphilis with penicillin is highly effective. Penicillin is the drug of choice for treating all forms of actinomycosis and clostridial infections causing gas gangrene.

Prophylactic administration of penicillin is highly effective against streptococcal infections, accounting for its value in patients with rheumatic fever. Transient bacteremia occurs in the majority of patients undergoing dental extractions, emphasizing the importance of prophylactic penicillin in patients with congenital or acquired heart disease or tissue implants undergoing dental procedures. Transient bacteremia may also accompany surgical procedures, such as tonsillectomy and operations on the genitourinary and gastrointestinal tracts and vaginal delivery.

Administration of high doses of penicillin G IV to patients with renal dysfunction may result in neurotoxicity and hyperkalemia (10 million units of penicillin G contains 16 mEq of potassium). If this amount of potassium introduces a risk to the patient, a sodium salt of penicillin G or a sodium salt of a similar penicillin, such as ampicillin or carbenicillin, can be substituted for the aqueous penicillin G.

Other drugs should not be mixed with penicillin as the combination may inactivate the antimicrobial. Intrathecal administration of penicillins is not recommended because these drugs are potent convulsants when administered by this route. Furthermore, arachnoiditis and encephalopathy may follow intrathecal penicillin administration.

Excretion

Renal excretion of penicillin is rapid (60%-90% of an intramuscular [IM] dose is excreted in the first hour), such that the plasma concentration decreases to 50% of its peak value within 1 hour after injection.

Approximately 10% is eliminated by glomerular filtration, and 90% is eliminated by renal tubular secretion. Anuria increases the elimination half-time of penicillin G approximately 10-fold.

Duration of Action

Methods to prolong the duration of action of penicillin include the simultaneous administration of probenecid, which blocks the renal tubular secretion of penicillin. Alternatively, the IM injection of poorly soluble salts of penicillin, such as procaine or benzathine, delays absorption and thus prolongs the duration of action. Procaine penicillin contains 120 mg of the local anesthetic for every 300,000 units of the antimicrobial. Possible hypersensitivity to procaine must be considered when selecting this form of the antimicrobial for administration.

Penicillinase-Resistant Penicillins

The major mechanism of resistance to the penicillins is bacterial production of β -lactamase enzymes that hydrolyze the β -lactam ring, rendering the antimicrobial molecule inactive. Methicillin, oxacillin, nafcillin, cloxacillin, and dicloxacillin are not susceptible to hydrolysis by staphylococcal penicillinases that would otherwise hydrolyze the cyclic amide bond of the β -lactam ring and render the antimicrobial inactive.

Specific indications for these drugs are infections caused by staphylococci known to produce this enzyme. Penetration of nafcillin into the central nervous system (CNS) is sufficient to treat staphylococcal meningitis. Parenteral methicillin has largely been superseded by oxacillin and nafcillin. Hemorrhagic cystitis and an allergic interstitial nephritis (hematuria, proteinuria) may accompany administration of methicillin. Hepatitis has been associated with high-dose oxacillin therapy. Renal excretion of methicillin, oxacillin, and cloxacillin is extensive. More than 80% of an IV dose of nafcillin is excreted in the bile, which may be an advantage when high-dose therapy is necessary in a patient with impaired renal function.

Oxacillin and nafcillin, unlike methicillin, are relatively stable in an acidic medium, resulting in adequate systemic absorption after oral administration. Nevertheless, variable absorption from the gastrointestinal tract often dictates a parenteral route of administration for treatment of serious infections caused by penicillinase-producing staphylococci. Cloxacillin and dicloxacillin are available only as oral preparations and may be preferable because they produce higher blood levels than do oxacillin and nafcillin.

Penicillinase-Susceptible Broad-Spectrum Penicillins (Second-Generation Penicillins)

Broad-spectrum penicillins, such as ampicillin, amoxicillin, and carbenicillin, have a wider range of activity than other penicillins, being bactericidal against gram-positive and gram-negative bacteria. They are, nevertheless, all inactivated by penicillinase produced by certain gram-negative and gram-positive bacteria. Therefore, these drugs are not effective against most staphylococcal infections.

Ampicillin

Ampicillin (α -aminobenzylpenicillin) has a broader range of activity than penicillin G. Its spectrum encompasses not only pneumococci, meningococci, gonococci, and various streptococci but also a number of gram-negative bacilli, such as *Haemophilus influenzae* and *Escherichia coli*. Ampicillin is stable in acid and thus is well absorbed after oral administration, although peak plasma concentrations are lower than those achieved after administration of penicillin V. Approximately 50% of an oral dose of ampicillin is excreted unchanged by the kidneys in the first 6 hours, emphasizing that renal function greatly influences the duration of action of this antimicrobial. Ampicillin also appears in the bile and undergoes enterohepatic circulation. Among the penicillins, ampicillin is associated with the highest incidence of skin rash (9%), which typically appears 7 to 10 days after initiation of therapy. Many of these rashes are due to protein impurities in the commercial preparation of the drug and do not represent true allergic reactions.

Amoxicillin

Amoxicillin is chemically identical to ampicillin except for an –OH substituent instead of an –H on the side chain. Its spectrum of activity is identical to that of ampicillin, but it is more efficiently absorbed from the gastrointestinal tract than ampicillin, and effective concentrations are present in the circulation for twice as long.

Extended-Spectrum Carboxypenicillins (Third-Generation Penicillins)

Carbenicillin

Carbenicillin (α -carboxybenzylpenicillin) results from the change from an amino to carboxy substituent on the side chain of ampicillin. The principal advantage of carbenicillin is its effectiveness in the treatment of infections caused by *Pseudomonas aeruginosa* and certain *Proteus* strains that are resistant to ampicillin. This antimicrobial is penicillinase susceptible and therefore ineffective against most strains of *S aureus*.

Carbenicillin is not absorbed from the gastrointestinal tract; therefore, it must be administered parenterally. The elimination half-time is approximately 1 hour and is prolonged to approximately 2 hours when there is hepatic or renal dysfunction. Approximately 85% of the unchanged drug is recovered in urine over 9 hours. Probenecid, by delaying renal excretion of the drug, increases the plasma concentration of carbenicillin by approximately 50%.

The sodium load administered with a large dose of carbenicillin (30–40 g) is considerable because greater than 10% of carbenicillin is sodium (about 5 mEq/g). Congestive heart failure may develop in susceptible patients in response to this acute drug-produced sodium load. Hypokalemia and metabolic alkalosis may occur because of obligatory excretion of potassium with the large amount of nonreabsorbable carbenicillin. Carbenicillin interferes with normal platelet aggregation such that bleeding time is prolonged but platelet count remains normal.

Extended-Spectrum Acylaminopenicillins (Fourth-Generation Penicillins)

The acylaminopenicillins (mezlocillin, piperacillin, azlocillin) have the broadest spectrum of activity of all the penicillins. Like the carboxypenicillins, the acylaminopenicillins are derivatives of ampicillin. These drugs are ineffective against penicillinase-producing strains of *S aureus*. The acylaminopenicillins have lower sodium content than the carboxypenicillins, but otherwise, the side effects are similar. Clinical studies have not demonstrated that these antimicrobials are superior to the carboxypenicillins.

Penicillin β -Lactamase Inhibitor Combinations

Clavulanic acid, sulbactam, and tazobactam are β -lactam compounds that have little intrinsic antimicrobial activity. However, these compounds bind irreversibly to the β -lactamase enzymes, which are produced by many bacteria, thus inactivating these enzymes and rendering the organisms sensitive to β -lactamase–susceptible penicillins. Clavulanic acid is available with oral amoxicillin, and parenteral ampicillin preparations have been combined with sulbactam. Likewise, parenteral piperacillin preparations have been combined with tazobactam.

Cephalosporins

Cephalosporins, like the penicillins, are bactericidal antimicrobials that inhibit bacterial cell wall synthesis and have a low intrinsic toxicity. These antimicrobials are derived from 7-aminocephalosporanic acid. Resistance to the cephalosporins, as to the penicillins, may be due to an inability of the antimicrobial to penetrate to its site of action. Bacteria can also produce cephalosporinases (β -lactamases), which disrupt the β -lactam structure of cephalosporins and thus inhibit their antimicrobial activity. Like the newer penicillins, the new cephalosporins have an extraordinarily broad spectrum of antimicrobial action but are expensive.

Individual cephalosporins differ significantly with respect to the extent of absorption after oral ingestion, severity of pain produced by IM injection, and protein binding. The IV administration of any of the cephalosporins can cause thrombophlebitis. Diacetyl metabolites of cephalosporins can occur and are associated with decreased antimicrobial activity.

A positive Coombs reaction frequently occurs in patients who receive large doses of cephalosporins. Hemolysis, however, is rarely associated with this response. Nephrotoxicity owing to cephalosporins, with

the exception of cephaloridine, is less frequent than after administration of aminoglycosides or polymyxins.

The incidence of allergic reactions in patients being treated with cephalosporins ranges from 1% to 10%. The majority of the allergic reactions consist of cutaneous manifestations, which occur 24 hours after drug exposure. Life-threatening anaphylaxis is estimated to occur in 0.02% of treated patients.⁵² Because the cephalosporins share immunologic cross-reactivity, patients who are allergic to one cephalosporin are likely to be allergic to others. The possibility of cross-reactivity between cephalosporins and penicillins seems to be very infrequent, and cephalosporins are often selected as alternative antimicrobials in patients with a history of penicillin allergy.^{34,52}

Cephalosporins and Allergy to Penicillins

Hypersensitivity is the most common adverse reaction to β -lactam antimicrobials. Allergic reactions were previously noted in 1% to 10% of patients treated with penicillins, making these antimicrobials the most allergenic of all drugs.⁵³ In reality, the overall cross-reactivity is approximately 1% when using first-generation cephalosporins or cephalosporins with similar R1 side chains as β -lactam antimicrobials due to improved manufacturing processes with less contamination. The use of third- or fourth-generation cephalosporins or cephalosporins with dissimilar side chains carries an almost negligible risk of cross allergy.^{34,55} Most often, the allergic response is a delayed reaction characterized by a maculopapular rash and/or fever. Less often but more serious is immediate hypersensitivity that is mediated by IgE antibodies. Manifestations of immediate hypersensitivity may include laryngeal edema, bronchospasm, and cardiovascular collapse. Allergic reactions may occur in the absence of previous known exposure to any of the penicillins. This may reflect prior unrecognized exposure to penicillin, presumably in ingested foods. Allergic reactions can occur with any dose or route of administration, although severe anaphylactic reactions are more often associated with parenteral than with oral administration. Some patients who experience cutaneous reactions may continue to receive the offending penicillin or receive the same penicillin in the future without experiencing a similar response.

The penicillin molecule itself is probably unable to form a complete antigen, but instead, the ring structure of penicillin is opened to form a hapten metabolite, penicilloyl. Approximately 95% of patients allergic to penicillin form this penicilloyl-protein conjugate (the major antigenic determinant); the remaining allergic patients form 6-aminopenicillic acid and benzylpenamalidic acid (minor antigenic determinants). Skin testing with a polyvalent skin test antigen, penicilloyl-polylysine, makes it possible to detect most patients who would develop a life-threatening allergic reaction if treated with a penicillin antimicrobial. Nevertheless, minor antigenic determinants that would not be detected by skin testing may produce severe allergic reactions.

Cross-reactivity

The presence of a common nucleus (β -lactam ring) in the structure of all penicillins means that allergy to one penicillin increases the likelihood of an allergic reaction to another penicillin. Furthermore, there would seem to be the potential for cross-reactivity between penicillins and cephalosporins as they both share a common β -lactam ring. However, actual cross-reactivity is rare.^{34,52}

Classification

Cephalosporins are classified as first-, second-, and third-generation because of their antimicrobial spectrum. In general, activity against gram-positive cocci decreases, and activity against gram-negative cocci increases from the first- to third-generation cephalosporins. First-generation cephalosporins are inexpensive, exhibit low toxicity, and are as active as second- and third-generation cephalosporins against staphylococci and nonenterococcal streptococci. For these reasons, first-generation cephalosporins have been commonly selected for antimicrobial prophylaxis in patients undergoing cardiovascular, orthopedic, biliary, pelvic, and intra-abdominal surgery (see “[Antimicrobial Prophylaxis for Surgical Procedures](#)” section). All cephalosporins can penetrate into joints and can readily cross the placenta.

First-Generation Cephalosporins

Cephalothin is the prototype of first-generation cephalosporins. Like most other cephalosporins, cephalothin is excreted largely unaltered by the kidneys, emphasizing the need to decrease the dose in the presence of renal dysfunction. Oral absorption is poor and IM injection is painful, accounting for its common administration by the IV route. Although cephalothin is present in many tissues and fluids, it does not enter the cerebrospinal fluid in significant amounts and is not recommended for treatment of meningitis. Cefazolin has essentially the same antimicrobial spectrum as cephalothin but has the advantage of achieving higher blood levels, presumably due to slower renal elimination. In this regard, cefazolin is viewed as the drug of choice for antimicrobial prophylaxis for many surgeries. This drug is well tolerated after IM or IV injection.

Second-Generation Cephalosporins

Cefoxitin and cefuroxime are examples of second-generation cephalosporins with extended activity against gram-negative bacteria. Cefoxitin is resistant to cephalosporinases produced by gram-negative bacteria. Cefuroxime is effective against *H influenzae* and is the only second-generation cephalosporin effective in the treatment of meningitis. Both drugs are excreted predominantly unchanged by the kidneys.

Third-Generation Cephalosporins

Third-generation cephalosporins have an enhanced ability to resist hydrolysis by the β -lactamases of many gram-negative bacilli including *E coli*, *Klebsiella*, *Proteus*, and *H influenzae*. Unlike older cephalosporins, the third-generation cephalosporins achieve therapeutic levels in the cerebrospinal fluid and can be used to treat meningitis. The third-generation cephalosporins seem to have the same relatively low toxicities as the older cephalosporins.

Cefotaxime was the first third-generation cephalosporin and has been effective in a broad range of infections, including meningitis caused by gram-negative bacilli other than *Pseudomonas*. The elimination half-time of this antimicrobial is approximately 1 hour, with clearance via the kidneys and hepatic metabolism. An adjustment in dosage or dosing interval is indicated in patients with renal dysfunction who are being treated with this drug. Approximately 30% of cefotaxime is excreted as a desacetyl derivative that has antibacterial activity and is synergistic with the parent compound. Ceftriaxone has the longest elimination half-time of any third-generation cephalosporin and is highly effective against gram-negative bacilli, especially *Neisseria* and *Haemophilus*. Cefixime is an orally effective third-generation cephalosporin that is as active as other cephalosporins against pneumococci, group A streptococci, and *H influenzae* but less active against *S aureus* and not active against anaerobes such as *Pseudomonas*. The spectrum of activity of cefixime and a single daily dose make it attractive for upper respiratory tract infections, but less expensive alternatives are available.

Fourth-Generation Cephalosporins

Fourth-generation cephalosporins are structurally related to the third-generation cephalosporins but possess an extra ammonium group that allows for enhanced activity against gram-negative bacteria. Cefepime is currently the only fourth-generation cephalosporin available in the United States. Its counterpart cefpirome is available overseas. Both have excellent activity against gram-positive bacteria such as methicillin-susceptible staphylococci and penicillin-resistant pneumococci. They are predominantly excreted unchanged in the urine.

Next (Fifth) Generation Cephalosporins

The fifth-generation cephalosporins such as ceftaroline and ceftobiprole are active against MRSA and gram-positive bacteria while retaining the activity of the later generation cephalosporins.

Other β -Lactam Antimicrobials

Aztreonam

Aztreonam is a monobactam antimicrobial that lacks the thiazolidine ring present in penicillins and the dihydrothiazine ring found in cephalosporins. The antimicrobial activity of this drug is limited to gram-negative bacteria. Aztreonam is not absorbed from the gastrointestinal tract, but therapeutic blood levels are achieved after IM or IV administration in most body tissues and fluids, including cerebrospinal fluid. The

elimination half-time is about 1.5 hours, and clearance is principally by glomerular filtration. Neither nephrotoxicity nor bleeding disorders have been reported. A unique advantage is the absence of any cross-reactivity between aztreonam and circulating antibodies of penicillin- or cephalosporin-allergic patients.⁵⁶ Because aztreonam combines the activity of the aminoglycosides with the low toxicity of the β -lactam antimicrobials, it can replace aminoglycosides in the treatment of many gram-negative infections. A potential disadvantage of aztreonam is the development of enterococcal superinfections. This antimicrobial is significantly more expensive than aminoglycosides.

Aminoglycoside Antimicrobials

Aminoglycosides are poorly lipid-soluble antimicrobials that are rapidly bactericidal for aerobic gram-negative bacteria. As would be predicted with the poor lipid solubility of these drugs, less than 1% of an orally administered aminoglycoside is absorbed into the systemic circulation. Aminoglycosides have a volume of distribution similar to the extracellular fluid volume and undergo extensive renal excretion due almost exclusively to glomerular filtration. There is a linear relationship between the plasma creatinine concentration and the elimination half-time of aminoglycosides. In the presence of normal renal function, the elimination half-time of aminoglycosides is 2 to 3 hours and is prolonged 20- to 40-fold in the presence of renal failure. Determination of the plasma concentration of aminoglycosides is an essential guide to the safe administration of these antimicrobials in the setting of renal dysfunction. The role of aminoglycosides is influenced by their toxicity (see “[Side Effects](#)” section) and cost-effectiveness relative to other antibiotics with broad gram-negative coverage.

Streptomycin was the first parenterally administered antimicrobial that was active against many gram-negative bacilli and *Mycobacterium tuberculosis*. Current use of this drug is limited because of the rapid emergence of resistant organisms, the frequent occurrence of vestibular damage during prolonged treatment, and the availability of less toxic antimicrobials.

Gentamicin is active against *P aeruginosa* as well as the gram-negative bacilli. Gentamicin penetrates pleural, ascitic, and synovial fluids in the presence of inflammation. Monitoring plasma concentrations of gentamicin is the best approach for recognizing potentially toxic levels ($>9 \mu\text{g/mL}$). If plasma concentrations of gentamicin cannot be monitored, the dose can be adjusted based on the plasma creatinine concentration.

Amikacin is a semisynthetic derivative of kanamycin that has the advantage of not being associated with the development of resistance. The principal use of amikacin is in the treatment of infections caused by gentamicin- or tobramycin-resistant gram-negative bacilli. Unlike other aminoglycosides, this drug should not be administered in combination with penicillin, which may result in antagonism of the bactericidal actions of penicillin against some strains of *Enterococcus faecalis*. The incidence of nephrotoxicity and ototoxicity is similar to that produced by gentamicin.

Neomycin is commonly used for topical application to treat infections of the skin (as after burn injury), cornea, and mucous membranes. Allergic reactions occur in 6% to 8% of patients treated with topical neomycin. Oral neomycin does not undergo systemic absorption and is thus administered to decrease bacterial flora in the intestine before gastrointestinal surgery and as an adjunct to the therapy of hepatic coma (decreases blood ammonia concentrations).

Side Effects

The side effects of aminoglycosides that limit their clinical usefulness include ototoxicity, nephrotoxicity, skeletal muscle weakness, and potentiation of nondepolarizing neuromuscular-blocking drugs. These side effects parallel the plasma concentration of the aminoglycoside, emphasizing the need to decrease the dose of these drugs in patients with renal dysfunction.

Ototoxicity

Ototoxicity manifests as vestibular dysfunction, auditory dysfunction, or both and parallels the accumulation of aminoglycosides in the perilymph of the inner ear. There is drug-induced destruction of vestibular or cochlear sensory hairs that is dose-dependent and most likely occurs with chronic therapy, especially in elderly patients, in whom renal dysfunction is more likely. Furosemide, mannitol, and probably other

diuretics seem to accentuate the ototoxic effects of aminoglycosides. Vestibular toxicity manifests as nystagmus, vertigo, nausea, and the acute onset of Ménière syndrome. Auditory dysfunction manifests as tinnitus or a sensation of pressure or fullness in the ears. Deafness may develop suddenly.

Nephrotoxicity

Aminoglycosides accumulate in the renal cortex and can produce acute tubular necrosis that initially manifests as an inability to concentrate urine and the appearance of proteinuria and red blood cell casts. These changes are usually reversible if the drug is discontinued. Neomycin is the most nephrotoxic of the aminoglycosides and therefore is not administered by the parenteral route.

Skeletal Muscle Weakness

Skeletal muscle weakness can occur with the intrapleural or intraperitoneal institution of large doses of aminoglycosides. This effect is most likely because of the ability of aminoglycosides to inhibit the prejunctional release of acetylcholine while also decreasing postsynaptic sensitivity to the neurotransmitter. An IV administration of calcium overcomes the effect of aminoglycosides at the neuromuscular junction. Patients with myasthenia gravis are uniquely susceptible to skeletal muscle weakness if treated with an aminoglycoside. Administration of a single dose of an aminoglycoside is unlikely to produce skeletal muscle weakness in an otherwise healthy patient.

Macrolides

Macrolides are stable in the presence of acidic gastric fluid, and as a result, these antimicrobials are well absorbed from the gastrointestinal tract. Structurally, these antimicrobials are characterized by 14 to 16 carbon atoms joined together in a complex, central molecule that is linked to various side chains.

Erythromycin

Erythromycin has a spectrum of activity, which includes most gram-positive bacteria, *Streptococcus pneumoniae*, *S aureus*, *Moraxella catarrhalis*, *H influenzae*, *Mycoplasma*, *Chlamydia pneumoniae*, and *Corynebacterium diphtheriae*. In patients who cannot tolerate penicillins or cephalosporins, erythromycin or clindamycin is an effective alternative for the treatment of streptococcal pharyngitis, bronchitis, and pneumonia. Unfortunately, *S aureus* is now developing that has increased resistance to clindamycin in both pediatric and adult populations.⁵⁷ Gastrointestinal intolerance is the most common side effect, which severely limits its use. The IV preparations are available for treatment of severe infections, but prolonged use by this route of administration is limited by the common occurrence of thrombophlebitis at the injection site and development of tinnitus or hearing loss in many patients. Severe nausea and vomiting may accompany infusion of erythromycin. Erythromycin is excreted largely in bile and only to a minor degree in urine. The dosage need not be altered in the presence of renal failure.

Effects on QTc

Oral erythromycin prolongs cardiac repolarization and is associated with reports of torsades de pointes.⁵⁸ Because erythromycin is extensively metabolized by cytochrome P-450 3A (CYP3A) isozymes, commonly used medications that inhibit the effects of CYP3A may increase plasma erythromycin concentrations thus increasing the risk of ventricular dysrhythmias and sudden death. The concurrent use of erythromycin and strong inhibitors of CYP3A such as ketoconazole is not recommended in mixed infection.

Azithromycin

Azithromycin resembles erythromycin in its antimicrobial spectrum, but an extraordinarily prolonged elimination half-time (68 hours) permits once-a-day dosing for 5 days (500 mg on day 1 and 250 mg on days 2-5). Tissue levels of azithromycin can be expected to remain at therapeutic levels for 4 to 7 days after a 5-day treatment course. Unlike clarithromycin, bioavailability of azithromycin is decreased by food such that the drug should be administered 1 hour before or 2 hours after meals.

Clindamycin

Clindamycin resembles erythromycin in antimicrobial activity, but it is more active against many anaerobes. Because severe pseudomembranous colitis can be a complication of clindamycin therapy, this drug should be used only to treat infections that cannot be adequately treated by less toxic antimicrobials. Significant diarrhea in patients treated with clindamycin is an indication to discontinue this drug and initiate evaluation for pseudomembranous colitis. However, clindamycin is indicated in the treatment of or prophylaxis for serious infections caused by susceptible anaerobes, particularly those originating in the gastrointestinal tract and female genital tract.

Only about 10% of administered clindamycin is excreted in an active form in urine; the remainder is changed into inactive metabolites. In patients with renal dysfunction, the elimination half-time of clindamycin is only slightly prolonged, and little change in dosage is required. In patients with severe liver disease, the dose of clindamycin may need to be decreased.

Side Effects

Clindamycin produces prejunctional and postjunctional effects at the neuromuscular junction, and these effects cannot be readily antagonized with calcium or anticholinesterase drugs. Large doses of clindamycin can induce profound and long-lasting neuromuscular blockade in the absence of nondepolarizing muscle relaxants and after full recovery from the effects of succinylcholine has occurred.⁵⁹ Skin rashes occur in about 10% of patients treated with clindamycin.

Vancomycin

Vancomycin is a bactericidal glycopeptide antimicrobial that impairs cell wall synthesis of gram-positive bacteria. The oral route of administration is used only for the treatment of staphylococcal enterocolitis and antimicrobial-associated pseudomembranous enterocolitis, taking advantage of the fact that vancomycin is poorly absorbed from the gastrointestinal tract. Vancomycin is administered IV for the treatment of severe staphylococcal infections or streptococcal or enterococcal endocarditis in patients who are allergic to penicillins or cephalosporins. Concomitant administration of an aminoglycoside is often necessary when vancomycin is used in the treatment of enterococcal endocarditis. Vancomycin is the drug of choice in the treatment of infections caused by MRSA. Vancomycin can be useful in the therapy of prosthetic heart valve endocarditis caused by *S epidermidis*. In this setting, vancomycin is often administered in combination with gentamicin or rifampin. Vancomycin is also used for prophylaxis against endocarditis in penicillin- and cephalosporin-allergic patients who have valvular heart disease and are undergoing dental procedures.

When vancomycin is administered IV, the recommendation is to infuse the calculated dose (10-15 mg/kg) over 60 minutes to minimize the occurrence of drug-induced histamine release and hypotension. As such, it can be begun 2 hours prior to surgery for prophylaxis. Infusion over 60 minutes produces sustained plasma concentrations for up to 12 hours. Vancomycin is principally excreted by the kidneys, with 90% of a dose being recovered unchanged in urine. The elimination half-time is approximately 6 hours and may be greatly prolonged (as long as 9 days) in the presence of renal failure. Determination of plasma vancomycin peak levels is an important guide to dosage (15-20 µg/mL is considered ideal) when this antimicrobial must be administered in the presence of renal dysfunction.⁶⁰

Side Effects

Rapid infusion (<30 minutes) of vancomycin has been associated with profound hypotension and even cardiac arrest.⁶¹⁻⁶⁴ Hypotension is often accompanied by signs of histamine release characterized by intense facial and truncal erythema (“red man syndrome”). The red man syndrome may occur even with slow infusion of vancomycin and is not always associated with hypotension.⁶⁵ Cardiovascular side effects most likely reflect nonimmunologic histamine release induced by vancomycin.⁶⁶ Although drug-induced histamine release initially causes increases in myocardial contractility, this effect is promptly followed by venodilation, a sudden decrease in left ventricular filling, and decreased contractility. Histamine produces hypotension in humans by directly dilating peripheral blood vessels. Direct myocardial depression produced by vancomycin manifesting as an unexpected decrease in heart rate does not seem to be important in causing hypotension in

humans.⁶⁶ Vancomycin may also produce allergic reactions characterized as anaphylactoid with associated hypotension, erythema, and occasionally bronchospasm.⁶⁴ Plasma tryptase concentrations are not increased following vancomycin-induced anaphylactoid reactions, thus permitting a method to distinguish anaphylactic from anaphylactoid reactions.⁶⁷ Arterial hypoxemia manifesting as an unexpected decrease in the oxygen saturation (SpO_2) may occur in association with vancomycin administration, perhaps reflecting drug-induced vasodilation in the lungs leading to an increase in ventilation to perfusion mismatching.⁶⁸ Oral H₁ (diphenhydramine 1 mg/kg) and H₂ (cimetidine 4 mg/kg) receptor antagonists administered 1 hour before induction of anesthesia decreased histamine-related side effects of rapid vancomycin infusion (1 g over 10 minutes).⁶⁹ In ambulatory anesthesia settings, as for orthopedic procedures, the time available for vancomycin administration before surgical incision or tourniquet inflation is often limited and may result in inadequate levels of antibiotic in blood and tissues if vancomycin cannot be administered more rapidly than 10 to 15 mg/kg over 60 minutes.

Ototoxicity is likely when persistent high plasma concentrations (>30 µg/mL) are present. The incidence of nephrotoxicity in association with vancomycin treatment is low. Particular attention to ototoxicity and nephrotoxicity is required when vancomycin is administered with an aminoglycoside. The administration of vancomycin to a patient recovering from succinylcholine-induced neuromuscular blockade has resulted in a return of neuromuscular blockade.⁷⁰

Linezolid

Linezolid, the first oxazolidinone antibiotic approved by the U.S. Food and Drug Administration, has a unique mechanism of action. It selectively binds to the 50S ribosomal unit and inhibits the synthesis of bacterial proteins. This unique mechanism prevents cross-resistance with other antibiotic agents.

Linezolid is used in the treatment of gram-positive bacteria such as skin and soft tissue infections caused by methicillin-sensitive and MRSA, vancomycin-resistant enterococci, hospital-acquired pneumonia caused by *S aureus*, and community-acquired pneumonia caused by *S pneumoniae*. Although the spectrum of activity is similar to vancomycin, linezolid has 100% oral bioavailability and lower incidences of red man syndrome, pruritus, and rash.^{71,72}

Side Effects

Linezolid appears to be relatively safe in short-term use. Nausea is typically the major side effect with case reports of hypoglycemia occurring within the first week of treatment. Long-term use, however, has been associated with bone marrow suppression, particularly thrombocytopenia, peripheral and ocular neuropathy, and lactic acidosis. Due to its nonspecific inhibition of monoamine oxidase, linezolid can cause serotonin toxicity when combined with serotonin reuptake inhibitors.⁷²

Bacitracins

Bacitracins are a group of polypeptide antibiotics effective against a variety of gram-positive bacteria. Use of these antimicrobials is limited to topical application in ophthalmologic and dermatologic ointments. Despite a perception that topical application of bacitracin rarely results in allergic reactions, there are reports of anaphylactic reactions following bacitracin nasal packing and mediastinal irrigation.^{73,74} Established topical uses of bacitracin include treatment of furunculosis, carbuncle, impetigo, suppurative conjunctivitis, and infected corneal ulcer.

Metronidazole

Metronidazole is bactericidal against most anaerobic gram-negative bacilli and *Clostridium* species. If administered orally, the drug is well absorbed and widely distributed in body tissues, including the CNS. As such, this antimicrobial has been useful in treating a variety of CNS, bone and joint infections, abdominal and pelvic sepsis, and endocarditis. In the past, orally administered metronidazole was used for treating pseudomembranous colitis secondary to *Clostridium difficile* infection (CDI). As of 2018, either vancomycin or fidaxomicin (a new macrocyclic antibiotic) is recommended over oral metronidazole for an initial episode

of CDI. In settings where access to vancomycin or fidaxomicin is limited, metronidazole may be used for an initial episode of nonsevere CDI.⁷⁵ An IV metronidazole is still a useful part of preoperative prophylactic regimens for elective colorectal surgery.

Side effects of metronidazole include dry mouth (metallic taste) and nausea. Concurrent ingestion of alcohol may cause a reaction similar to that produced when alcohol is ingested by patients taking disulfiram. Neuropathy and pancreatitis are infrequent.

Fluoroquinolones

The fluoroquinolones are broad-spectrum antimicrobials that are bactericidal against most enteric gram-negative bacilli and some gram-positive bacteria.⁷⁶ They are rapidly absorbed from the gastrointestinal tract, and penetration into body fluids and tissues is excellent. Their elimination half-time is prolonged (3-8 hours), and the principal route of excretion is via the kidneys, including glomerular filtration and renal tubular secretion. The dose of the fluoroquinolones should be decreased in the presence of renal dysfunction. Side effects are minimal, with mild gastrointestinal disturbances (nausea, vomiting) and CNS disturbances (dizziness, insomnia) occurring in less than 10% of treated patients. Fluoroquinolones have been useful clinically in the treatment of genitourinary and gastrointestinal infections, but soft tissue and bone infections have not responded to these drugs. Fluoroquinolones are bactericidal against most mycobacteria and are useful as part of multidrug regimens.^{77,78} Fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture that is enhanced in patients older than 60 years of age, taking corticosteroid drugs, and in patients with kidney, heart, or lung transplants. In addition, fluoroquinolones may exacerbate muscle weakness in patients with myasthenia gravis.

Ciprofloxacin

Ciprofloxacin is highly effective in the treatment of urinary and genital tract infections, including prostatitis, and gastrointestinal infections. The major advantage of ciprofloxacin is its greatly enhanced serum concentration and its availability as an IV preparation. Because of high blood levels and good tissue penetration, ciprofloxacin has been useful in the treatment of a variety of systemic infections, including upper and lower respiratory tract infections, skin and soft tissue infections, and bone and joint infections. Most strains of *M tuberculosis* are susceptible to ciprofloxacin.

Moxifloxacin

Moxifloxacin is long acting for the treatment of acute bacterial sinusitis, acute bacterial exacerbation of chronic bronchitis, community-acquired pneumonia, skin infections, and complicated intra-abdominal infections. Because of serious adverse effects including peripheral neuropathy, syndrome of inappropriate secretion of antidiuretic hormone, tendonitis, acute liver failure, QTc prolongation, toxic epidermal necrolysis, psychotic reactions, and Stevens-Johnson syndrome, use is recommended only when less toxic options are not available.

Antiseptic and Disinfectant Prophylaxis for Surgical Procedures

Contamination of the surgical site is a requirement for surgical site infection. Decontamination of the skin with antiseptic preparations reduces the burden of skin flora and, in more recent randomized prospective studies, reduces the incidence of surgical site infection.⁷⁹ Centers for Disease Control and Prevention guidelines recommend showering or bathing with an antiseptic solution before surgery and the clinical practice guidelines from the National Institute for Health and Care Excellence recommend bathing or showering with soap, use of an iodine-impregnated drape, and immediate preparation with an antiseptic solution. Neither set of guidelines puts forth a preference of type of antiseptic solution. The main types of disinfectants are alcohols, chlorhexidine, and iodine-containing preparations, which can be used alone or in combination.

Topical Antiseptics

Alcohols

Alcohols are applied topically to decrease local cutaneous bacterial flora (quick drying and antisepsis) before penetration of the skin with needles. Their antiseptic action can be enhanced by prior mechanical cleansing of the skin with water and a detergent and gentle rubbing with sterile gauze during application.

Ethyl alcohol is an antiseptic of low potency but moderate efficacy, being bactericidal to many bacteria. On the skin, 70% ethyl alcohol kills nearly 90% of the cutaneous bacteria within 2 minutes, provided the area is kept moist. Greater than a 75% decrease in cutaneous bacterial count is unlikely with a single wipe of an ethyl alcohol-soaked sponge followed by evaporation of the residual solution. Isopropyl alcohol has a slightly greater bactericidal activity than ethyl alcohol. Alcohols reduce bacterial contamination and are not fungicidal or virucidal.

Fire Risks

It is important to recognize that alcohol-based preparations are flammable until all the liquid has evaporated.^{80,81} Alcohol-based surgical solutions can create a fire hazard (flash fire) especially if the solution is allowed to pool (eg, in the umbilicus) or the patient is draped before the solution is completely dry resulting in trapped alcohol vapors being channeled to the surgical site where a heat source may be used. Sterile towels may be used to absorb excess alcohol-based solutions. Safety checklists, sometimes called “Time Out” protocols, have been developed to assure compliance with preoperative preparation. The degree of fire hazard incurred due to skin preparation and the time required before surgical draping is often part of the protocol.

Coronavirus Disease 2019 Pandemic

During the coronavirus disease 2019 pandemic, alcohol-based hand rubs have been used to decrease contact transmission of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in hospitals. In suspension tests, SARS-CoV-2 was inactivated by ethyl alcohol and isopropyl alcohol at 30%, 40%, and 60% in 30 seconds.⁸² The SARS-CoV-2, in addition to other viruses such as Middle East respiratory syndrome coronavirus and endemic human coronaviruses, can persist on inanimate surfaces like metal, glass, or plastic for up to 9 days. However, these viruses can be inactivated by surface disinfectants including 62% to 71% ethanol, 0.5% hydrogen peroxide, and 0.1% sodium hypochlorite. Other biocidal agents such as 0.05% to 0.2% benzalkonium chloride and 0.02% chlorhexidine digluconate are less effective.⁸³

Chlorhexidine

Chlorhexidine is a colorless chlorophenol biguanide solution that disrupts cell membranes of the bacterial cells and is effective against both gram-positive and gram-negative bacteria. It persists on the skin to provide continued antibacterial protection. As a hand wash or surgical scrub, 2% chlorhexidine causes a greater initial decrease in the number of normal cutaneous bacteria than does povidone-iodine or hexachlorophene, and it has a persistent effect equal to or greater than that of hexachlorophene. Chlorhexidine is mainly used for the preoperative reduction of cutaneous flora for the surgeon and patient. It is also used to treat superficial infections caused by gram-positive bacteria and to disinfect wounds. As an antiseptic, chlorhexidine is rapid acting, has considerable residual adherence to the skin, has a low potential for producing contact sensitivity and photosensitivity, and is poorly absorbed even after many daily hand washings. Chlorhexidine solutions in an alcohol base are not appropriate for instillation into the eye (corneal injury) or middle ear (deafness).

Iodine

Iodine is a rapid-acting antiseptic that, in the absence of organic material, kills bacteria, viruses, and spores. For example, on the skin, 1% tincture of iodine will kill 90% of the bacteria in 90 seconds, whereas a 5% solution achieves this response in 60 seconds. In the presence of organic matter, some iodine is bound covalently, diminishing the immediate but not eventual effect. Nevertheless, commercial preparations contain iodine in such excess that minimal organic matter does not adversely influence immediate efficacy. The local toxicity of iodine is low, with cutaneous burns occurring only with concentrations of greater than 7%. In rare instances, an individual may be allergic to iodine and react to topical application. An allergic reaction usually manifests as fever and generalized skin eruption.

The most important use of iodine is disinfection of the skin. For this use, it is best used in the form of a tincture of iodine because the alcohol vehicle facilitates spreading and skin penetration. Iodine may also be used in the treatment of wounds and abrasions. Applied to abraded tissue, 0.5% to 1.0% iodine aqueous solutions are less irritating than the tinctures.

Iodophors

An iodophor is a loose complex of elemental iodine with an organic carrier that not only increases the solubility of iodine but also provides a reservoir for sustained release. The most widely used iodophor is povidone-iodine, in which the carrier molecule is polyvinylpyrrolidone. A 10% solution contains 1% available iodine, but the free iodine concentration is less than 1 ppm. This is sufficiently low that little, if any, staining of the skin occurs. Because of the low concentrations, the immediate bactericidal action is only moderate compared with that of iodine solutions.

Clinical Uses

The iodophors have a broad antimicrobial spectrum and are widely used as hand washes, including surgical scrubs; preparation of the skin before surgery or needle puncture; and treatment of minor cuts, abrasions, and burns. A standard surgical scrub with 10% povidone-iodine solutions (Betadine) will decrease the usual cutaneous bacterial population by greater than 90%, with a return to normal in about 6 to 8 hours. Compared with povidone-iodine, a disinfectant that contains an iodophor in isopropyl alcohol (DuraPrep) is more effective than povidone-iodine in decreasing the number of positive skin cultures immediately after disinfection as well as in bacterial regrowth and colonization of epidural catheters.

Corneal Toxicity

Chemical burns to the cornea may follow exposure (accidental splashes) to a variety of disinfectant solutions (chlorhexidine, hexachlorophene, iodine, alcohol, detergents containing iodine-based solutions). Povidone-iodine solution without detergent appears to be least toxic to the cornea, depending on concentration.⁸⁴

Preference for Chlorhexidine or Iodine for Skin Disinfection

Central vascular catheters are a common site of hospital-acquired infection. The superiority of chlorhexidine compared to iodine-based solutions has been examined in several studies. A meta-analysis of eight studies concluded that the incidence of bloodstream infections was significantly less when central vascular lines were inserted after skin preparation with chlorhexidine gluconate compared to povidone-iodine.⁸⁵ Similarly, chlorhexidine lowers the incidence of surgical site infections when used as a skin preparation prior to clean-contaminated abdominal surgeries as compared to povidone-iodine.^{86,87} In contrast, no difference was detected in catheter colonization when skin was prepared with iodine or chlorhexidine before epidural catheter insertion.⁸⁸ An iodophor in isopropyl alcohol solution was found to be superior to povidone-iodine, decreasing the number of positive skin cultures immediately after disinfection as well as in bacterial regrowth and colonization of epidural catheters⁸⁹ and chlorhexidine-impregnated split dressing may reduce colonization of epidural catheters.⁹⁰ However, concerns have been raised about potential neurotoxicity of chlorhexidine, which is inadvertently introduced into the neuraxial space.⁹¹

Quaternary Ammonium Compounds

Quaternary ammonium compounds are bactericidal in vitro to a wide variety of gram-positive and gram-negative bacteria. Many fungi and viruses are also susceptible. The *M tuberculosis*, however, is relatively resistant. Alcohol enhances the germicidal activity of quaternary ammonium compounds so that tinctures are more effective than aqueous solutions. The major site of action of quaternary ammonium compounds appears to be the cell membrane, where these solutions cause a change in permeability.

Benzalkonium and cetylpyridinium (mouthwash) are examples of quaternary ammonium compounds. These compounds may be used preoperatively to decrease the number of microorganisms on intact skin. There is a rapid onset of action, but the availability of more efficacious solutions has decreased their frequency of use. Quaternary ammonium compounds have been widely used for the sterilization of

instruments. Endoscopes and other instruments made of polyethylene or polypropylene, however, absorb quaternary ammonium compounds, which may decrease the concentration of the active ingredient to below a bactericidal concentration.

Hexachlorophene

Hexachlorophene (pHisoHex) is a polychlorinated bisphenol that exhibits bacteriostatic activity against gram-positive but not gram-negative organisms. Immediately after a hand scrub with hexachlorophene, the cutaneous bacterial population may be decreased by only 30% to 50% compared with greater than 90% following use of an iodophor. Nevertheless, 60 minutes later, the bacterial population surviving a hexachlorophene scrub will have decreased further to about 4%, whereas with the iodophor scrub, the bacterial population will have recovered to about 16% of normal.

Because most of the potentially pathogenic bacteria on the skin are gram-positive, 3% hexachlorophene is commonly used by physicians and nurses to decrease the spread of contaminants from caregivers' hands. This antiseptic is also used to cleanse the skin of patients scheduled for certain surgical procedures. Hexachlorophene may be absorbed through intact skin in sufficient amounts to produce neurotoxic effects, including cerebral irritability.

Methods for Sterilization of Instruments

The Centers for Disease Control and Prevention offer guidelines for disinfection and sterilization in health care facilities.⁹² Having a central processing department to ensure quality control is recommended; however, multiple methods are required throughout the hospital.

Formaldehyde

Formaldehyde is a volatile, wide-spectrum disinfectant that kills bacteria, fungi, and viruses by precipitating proteins. A 0.5% concentration requires 6 to 12 hours to kill bacteria and 2 to 4 days to kill spores. A 2% to 8% concentration is used to disinfect inanimate objects such as surgical instruments. Formaldehyde can be toxic, allergenic, and was named a known carcinogen by the U.S. National Toxicology Program in 2011. Most exposure is through volatilization and use under with fume hoods is recommended.

Glutaraldehyde

Glutaraldehyde is superior to formaldehyde as a disinfectant because it is rapidly effective against all microorganisms, including viruses and spores. This disinfectant also possesses tuberculocidal activity. Glutaraldehyde is less volatile than formaldehyde and hence causes minimal odor and irritant fumes. A period of 10 hours is necessary to sterilize dried spores, whereas an acid-stabilized solution kills dried spores in 20 minutes. Neither alkaline nor acidic solutions are damaging to most surgical instruments and endoscopes. As a sterilizing solution for endoscopes, glutaraldehyde is superior to iodophors and hexachlorophene.

Pasteurization

Pasteurization (hot water disinfection) is a process that destroys microorganisms in a liquid medium by application of heat. Pasteurizing water temperatures in the range of 55°C to 75°C will destroy all vegetative bacteria of significance in human disease as well as many fungi and viruses. Pasteurization kills bacteria by coagulating cell proteins, and water acts as a very effective medium for transferring the heat required to destroy organisms. This is the rationale for maximizing direct water contact with surfaces to be disinfected. Water temperatures of greater than 75°C may cause some plastic parts to deform. Equipment (respiratory therapy breathing circuits, anesthesia breathing circuits) should be submerged in water at 68°C for a minimum of 30 minutes. With respect to breathing circuits, pasteurization is effective against gram-negative rods, *M tuberculosis*, and most fungi and viruses. Pasteurization may be a cost-effective alternative to potentially toxic disinfecting solutions such as glutaraldehyde and formaldehyde.

Cresol

Cresol is bactericidal against common pathogenic organisms including *M tuberculosis*. It is widely used for disinfecting inanimate objects. Cresol should not be used to disinfect materials that can absorb this solution because burns could result from subsequent tissue contact.

Silver Nitrate

Silver nitrate is used as a caustic, antiseptic, and astringent. A solid form is used for cauterizing wounds and removing granulation tissue. It is conveniently dispensed in pencils that should be moistened before use. Solutions of silver nitrate are strongly bactericidal, especially for gonococci, accounting for its frequent use as prophylaxis for ophthalmia neonatorum.

Silver sulfadiazine or nitrate is used in the treatment of burns. With this use, hypochloremia may occur, reflecting the combination of silver ions with chloride. Hyponatremia also may result because the sodium ions are attracted by chloride ions into the exudate. Furthermore, absorbed nitrate can cause methemoglobinemia.

Ethylene Oxide

Ethylene oxide is a readily diffusible gas that is noncorrosive and antimicrobial to all organisms at room temperature. This gaseous alkylating material is widely used as an alternative to heat sterilization. It reacts with chloride and water to produce two additional active germicides, ethylene chlorohydrin and ethylene glycol. Special sterilizing chambers are required because the gas must remain in contact with the objects for several hours. Adequate airing of sterilized materials, such as tracheal tubes, is essential to ensure removal of residual ethylene oxide and thus minimize tissue irritation. Ethylene oxide sensitization has been described in children with spina bifida experiencing preoperative anaphylactic reactions, always in association with latex sensitization.⁹³

Chemotherapeutic Drugs*

Updated by: Ami K. Patel • Richard D. Urman • James P. Rathmell

Chemotherapy is a term that was coined to refer to a broad range of chemicals (drugs) aimed at treating cancer by eradicating malignant cells anywhere in the body.¹ Conventional wisdom is that the effectiveness of chemotherapy requires that there be complete destruction (total cell kill) of all cancer cells because a single surviving cell with the ability to divide can give rise to sufficient progeny to ultimately kill the host. The role of the immune system in identifying and eliminating foreign tumor cells has gained increasing recognition, and harnessing our intrinsic immune surveillance system has become more and more a part of contemporary investigations of cancer and its treatment.² The use of several chemotherapeutic drugs (also called **antineoplastic drugs**) concurrently or in a planned sequence is commonly done in efforts to eradicate even small residual tumor cell populations that have survived treatment with a single or previous agent. In practice, combination chemotherapy regimens typically use the largest tolerated doses of each chemotherapeutic drug. Drugs that work via different mechanisms and that do not share similar toxic effects are often combined. Using a combination of agents that have different mechanisms also decreases the chances that drug-resistant tumor cell populations will emerge. Chemotherapeutic drugs used in combination are usually administered over short periods at specific treatment intervals rather than as continuous therapy. This approach is based on the empiric observation that normal cells usually recover more rapidly from a pulse of maximal chemotherapy than do malignant cells. Furthermore, immunosuppression is less profound with intermittent administration of chemotherapy. With rare exceptions, the optimal dose of chemotherapeutic drugs requires repetitive dosing because even if all cells in a tumor are sensitive to a drug, a single dose of the drug is not usually sufficient to kill the typically hundreds of millions of cells that are present in patients with cancer.

Malignant cells are often characterized by rapid division and synthesis of DNA. Most conventional chemotherapeutic drugs exert their antineoplastic effects on cells that are actively undergoing division (mitosis) or DNA synthesis. Many chemotherapeutic drugs act only at specific phases of the cell cycle (**Figure 42.1**).¹ The biology of the cancer being treated and the cell cycle specificity of agents affect how drugs are scheduled and combined for maximal effect. Slow-growing malignant cells with a slow rate of division, like carcinoma of the lung and colon, are often unresponsive or at best partially responsive to conventional chemotherapy. Conversely, rapidly dividing normal cells, like the cells found in the bone marrow, gastrointestinal mucosa, skin, and hair follicles, are more vulnerable to the toxic effects of chemotherapeutic drugs. Thus, it is predictable that clinical manifestations of toxicity caused by chemotherapeutic drugs often include myelosuppression (leukopenia, thrombocytopenia, or anemia), nausea, vomiting, diarrhea, mucosal ulceration, dermatitis, and alopecia because these represent activity at normal rapidly dividing cells. Myelosuppression is the dose-limiting factor for many chemotherapeutic drugs and is the most common toxicity that leads to temporary or permanent withdrawal of therapy. Drug-induced myelosuppression is usually reversible with discontinuation of the chemotherapeutic agent, supportive care with blood and platelet transfusions, and growth factor therapy as needed. Although rare, prolonged marrow failure may require intensive treatment with immunosuppression and consideration of bone marrow transplantation in certain instances.³

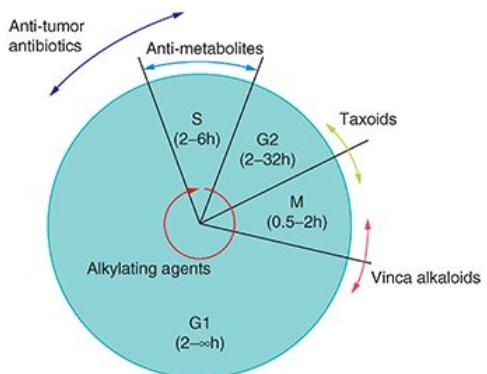

FIGURE 42.1 Cell cycle specificity of chemotherapy agents. The cell cycle is divided into a number of phases: G1 (gap 1; cells increase in size and prepare for DNA synthesis), S (synthesis; DNA replication occurs), G2 (gap 2; cells continue to grow and prepare for mitosis), and M (mitosis; cellular growth stops, and preparation for cell division takes place), each of which can vary in length according to the type of cell and the growth rate of the cell. The activity of different classes of certain chemotherapy agents (antibiotics, antimetabolites, taxoids, vinca alkaloids) is optimal in different phases of the cell cycle, whereas alkylating agents are relatively non–phase-specific. *Reprinted from Dickens E, Ahmed S. Principles of cancer treatment by chemotherapy. Surgery (Oxford). 2018;36(3):134-138. Copyright © 2017 Elsevier. With permission.*

Drug Resistance

Resistance to chemotherapeutic drugs often occurs and has many causes.⁴ Some chemotherapy agents lead to induction of drug-metabolizing enzymes in the liver, other tissues, or tumor cells, accelerating drug conversion to nontoxic metabolites. Many solid tumors grow so rapidly that portions of the tumor are poorly vascularized, preventing therapeutic concentrations from reaching many target cells. In poorly perfused areas of some tumors, cells remain resistant to chemotherapeutic drugs because of relative hypoxia. Indeed, hypoxia causes resistance to both radiation and most chemotherapeutic drugs (with the exception of malignancies susceptible to treatment with the mitomycins).

As in the treatment of infections, multiple drug resistance describes the clinical circumstance in which a tumor is no longer susceptible to several chemotherapeutic drugs. For a number of agents, P-glycoprotein spans the plasma membrane and acts to pump chemotherapeutic drugs (anthracyclines, vinca alkaloids, and taxanes but not alkylating drugs, platinating drugs, and antimetabolites) to the extracellular space such that an effective toxic intracellular concentration is not reached. In addition to P-glycoprotein, there is an additional family of multidrug resistance proteins that are located on plasma membranes and endoplasmic reticulum of some tumor cell types, which confer drug resistance via an adenosine triphosphate (ATP)-dependent decrease in cellular drug accumulation (with the exception of malignancies susceptible to treatment with the taxanes). Collectively, P-glycoprotein and the multidrug resistance proteins are members of the ATP-binding cassette (ABC) class of transporter proteins that protect normal tissues from a variety of toxicants and are overexpressed in some tumor cells. The breast cancer resistance protein (also known as the **ATP-binding cassette subfamily G member 2** or **ABCG₂ protein** or the **mitoxantrone resistance-associated protein**) is a specific example of an ABC protein that confers tumor resistance to certain chemotherapeutic agents via active transport of the offending agent out of cells expressing this transporter.

Topoisomerases, enzymes that regulate the overwinding or underwinding of DNA during replication, are the targets for many chemotherapeutic drugs. Resistance to chemotherapeutic drugs can also occur through mutations in the drug-binding domain of the target enzyme. Resistance to the drug methotrexate may reflect mutations in the drug target, the enzyme dihydrofolate reductase, resulting in its overexpression. Dihydrofolate reductase converts dihydrofolate into tetrahydrofolate and is required for the de novo synthesis of purines and thymidylic acid, which are important for cell growth and proliferation. Another potential mechanism of resistance includes decreased transport of methotrexate into the cell through the reduced folate

carrier. Resistance to alkylating drugs occurs through overexpression of drug-neutralizing substances and metabolizing proteins.

Classification

Chemotherapeutic drugs are classified according to their mechanism of action ([Table 42.1](#))¹; adverse effects associated with these drugs are generally similar among drugs with similar mechanisms of action ([Table](#)

[42.2](#)).^{5–7} Knowledge of drug-induced adverse effects and evaluation of appropriate laboratory tests (hemoglobin, platelet count, white blood cell count, coagulation profile, arterial blood gases, blood glucose, plasma electrolytes, liver and renal function tests, electrocardiogram [ECG], and radiograph of the chest) are useful in the preoperative evaluation of patients being treated with specific chemotherapeutic drugs.

Immunosuppression makes these patients susceptible to iatrogenic infections, making asepsis and the use of appropriate prophylactic antibiotics critical. A history of severe vomiting or diarrhea may be associated with electrolyte disturbances and decreased intravascular fluid volume. The existence of mucositis makes placement of pharyngeal airways, laryngeal mask airways, and esophageal catheters questionable. The response to inhaled and injected anesthetic drugs may be altered by drug-induced cardiac, hepatic, or renal dysfunction and induction of hepatic enzymes. The response to older nondepolarizing neuromuscular-blocking drugs may be altered by impaired renal function. Theoretically, the effects of succinylcholine may be prolonged if plasma cholinesterase activity is decreased by chemotherapeutic drugs. Additionally, many chemotherapeutic drugs are neurotoxic and result in chemotherapy-induced peripheral neuropathy (CIPN), which can profoundly affect the quality of life of patients. Prevention and pain management are therefore very important in preventing and managing CIPN as oncologic outcomes can be adversely affected by required dose modifications and/or premature discontinuation of chemotherapy secondary to CIPN. The incidence of CIPN is highest with use of platinum drugs, taxanes, vinca alkaloids, and bortezomib. It is often managed with duloxetine.

TABLE 42.1

Biochemical classification of chemotherapy drugs^a

Drug class	Mechanism of action	Examples
Alkylating agents	Impair cell function by forming covalent bonds on important molecules in proteins, DNA, and RNA; classified by their chemical structure and mechanism of covalent bonding	Cisplatin, carboplatin, chlorambucil, cyclophosphamide, ifosfamide
Antimetabolites	Structural analogues of naturally occurring metabolites involved in DNA and RNA synthesis. They either substitute for a metabolite that is normally incorporated into DNA or RNA or compete for the catalytic site of a key enzyme.	5-Fluorouracil, methotrexate, pemetrexed, mercaptopurine, gemcitabine
Antitumor antibiotics	Intercalate DNA at specific sequences, creating free radicals, which cause strand breakage. Anthracyclines are products of the fungus having <i>Streptomyces</i> ; also inhibit mechanism of action of topoisomerase I and II; required for the uncoiling of DNA during replication	Bleomycin, anthracyclines (doxorubicin, epirubicin)
Topoisomerase inhibitors	Topoisomerases are enzymes that control the 3-D structure of DNA. Topoisomerase I and topoisomerase II are enzymes responsible for the uncoiling of DNA during replication.	Topoisomerase I— irinotecan, topotecan Topoisomerase II— etoposide
Tubulin-binding drugs	Vinca alkaloids bind to tubulin and prevent the formation of the microtubule, which is important not only during mitosis but also for cell shape, intracellular transport, and axonal function.	Vinca alkaloids— vincristine, vinorelbine

	Taxoids prevent the disassembly of the microtubules, thereby inhibiting normal function.	Taxoids—docetaxel, paclitaxel
Signal transduction modifiers	Hormonal treatment of cancer results in a disruption of the normal growth factor receptor interactions, which lead to cell proliferation and is effective in cancer cells where mutations have resulted in uncontrolled cell proliferation utilizing activated signaling pathways. Monoclonal antibodies bind to specific antigens on tumor cells and thereby modify cell proliferation. Aromatase inhibitors work by inhibiting the action of the enzyme aromatase, which converts androgens into estrogens.	Antiestrogens— tamoxifen, toremifene, raloxifene Antiandrogens— flutamide, bicalutamide, nilutamide Monoclonal antibodies— rituximab, trastuzumab, etc Aromatase inhibitors — aminoglutethimide, anastrazole, letrozole Gonadotropin-releasing drugs— leuprolide, buserelin Progestins— megestrol acetate

TABLE 42.2

Chemotherapeutic drugs, therapeutic uses, and associated side effects^a

Group and class	Therapeutic uses	Side effects (other than nausea and vomiting)
Alkylating agents		
Nitrogen mustards Mechlorethamine	Hodgkin disease Non-Hodgkin lymphoma	Myelosuppression Mucositis Alopecia
Cyclophosphamide	Acute lymphocytic leukemia Chronic lymphocytic leukemia Lymphomas Myeloma Neuroblastoma Breast, ovarian, cervical, and testicular cancer Lung cancer Wilms tumor Sarcoma	Myelosuppression Mucositis Alopecia Hemorrhagic cystitis Skin pigmentation Seizures Renal failure Cardiac failure Inappropriate secretion of vasopressin (ADH)
Melphalan	Myeloma Breast cancer	Myelosuppression
Chlorambucil	Hodgkin disease Non-Hodgkin lymphoma	Myelosuppression Secondary leukemias

Macroglobulinemia		
Ethyleneimine		
Hexamethylmelamine	Ovarian cancer	Myelosuppression Myelosuppression Alopecia Skin pigmentation Renal failure Mucositis Intracranial hemorrhage Seizure Hepatic dysfunction Cytomegalovirus infection Pneumonia
Thiotepa	Bladder, breast, and ovarian cancer	
Alkyl sulfonates		
Busulfan	Acute myelogenous leukemia Chronic myelogenous leukemia	Myelosuppression Thrombocytopenia
Nitrosoureas		
Carmustine (BCNU)	Hodgkin disease Non-Hodgkin lymphoma Astrocytoma Myeloma Melanoma	Myelosuppression Hepatitis Interstitial pulmonary fibrosis Renal failure Flushing
Lomustine (CCNU)	Hodgkin disease Non-Hodgkin lymphoma Astrocytoma Small cell lung cancer	Myelosuppression
Semustine (methyl-CCNU)	Colon cancer	Myelosuppression
Streptozotocin	Insulinoma Carcinoid tumor	Myelosuppression Hepatitis Renal failure
Triazenes		
Dacarbazine (DTIC)	Hodgkin disease Melanoma Sarcomas	Myelosuppression Flu-like syndrome
Temozolamide	Astrocytoma Melanoma	Hepatic toxicity Hyperglycemia Anemia Thrombocytopenia Lymphocytopenia
Bioreductive alkylating drugs		
Mitomycin-C	Head and neck, breast, lung, gastric, colon, rectal, and cervical cancer	Myelosuppression Mucositis Cardiac failure Interstitial fibrosis Hemolytic uremic syndrome
Platinum compounds		
Cisplatin	Head and neck, thyroid, lung, ovarian, endometrial, cervical, and testicular cancer	Myelosuppression Peripheral neuropathy Allergic reactions

	Neuroblastoma Osteogenic sarcoma	Renal toxicity Electrolyte abnormalities (hypocalcemia, hypomagnesemia, hypophosphatemia)
Carboplatin	As for cisplatin	Myelosuppression
Oxaliplatin	Colon cancer	Myelosuppression Peripheral neuropathy
Antimetabolites		
Folate analogues		
Methotrexate	Head and neck, breast, and lung cancer Acute lymphocytic leukemia Non-Hodgkin lymphoma Osteogenic sarcoma	Myelosuppression Mucositis Pneumonitis Hepatic fibrosis
Pyrimidine analogues		
Fluorouracil	Head and neck, breast, gastric, pancreatic, bladder, ovarian, cervical, and prostate cancer Hepatoma	Myelosuppression Mucositis Alopecia Pigmentation Chest pain
Cytarabine	Acute lymphocytic leukemia Acute myeloid leukemia Non-Hodgkin lymphoma	Myelosuppression Mucositis Hepatitis
Gemcitabine	Breast, lung, pancreatic, and bladder cancer	Myelosuppression Flu-like syndrome
Purine analogues		
Mercaptopurine	Acute lymphocytic leukemia Acute myeloid leukemia Chronic myeloid leukemia	Myelosuppression Anorexia Jaundice
Thioguanine	As for mercaptopurine	Myelosuppression Anorexia
Fludarabine	Chronic lymphocytic leukemia Non-Hodgkin lymphoma	Myelosuppression Optic neuritis Peripheral neuropathy Seizures Coma Depletion of CD4 cells
Pentostatin	Chronic lymphocytic leukemia Cutaneous T-cell lymphoma Hairy cell leukemia	Myelosuppression Depletion of T cells Hepatitis
Cladribine	Chronic lymphocytic leukemia Cutaneous T-cell lymphoma Hairy cell leukemia Waldenström macroglobulinemia	Myelosuppression Tumor lysis syndrome Asthenia
Hydroxyurea	Chronic myeloid leukemia Polycythemia vera Thrombocytopenia Melanoma	Myelosuppression Dermatologic changes
Topoisomerase inhibitors		

Anthracyclines		
Doxorubicin	Hodgkin disease Non-Hodgkin lymphoma Acute lymphocytic leukemia Neuroblastoma Thyroid, breast, lung, and gastric cancer	Myelosuppression Cardiomyopathy Mucositis
Daunorubicin	Acute myeloid leukemia Acute lymphocytic leukemia	
Idarubicin	As for daunorubicin	
Epirubicin	Hodgkin disease Non-Hodgkin lymphoma Acute lymphocytic leukemia Breast, lung, gastric, and bladder cancer	Myelosuppression Cardiomyopathy Alopecia Phlebitis
Anthracenediones		
Mitoxantrone	Acute myeloid leukemia Breast cancer	Myelosuppression Mucositis
Epipodophyllotoxins		
Etoposide	Hodgkin disease Non-Hodgkin lymphoma Acute myeloid leukemia Kaposi sarcoma Breast, lung, and testicular cancer	Myelosuppression Systemic hypotension Hepatitis Mucositis
Teniposide	Acute lymphocytic leukemia (children) Acute myeloid leukemia (children)	Myelosuppression Systemic hypotension
Dactinomycin	Wilms tumor Rhabdomyosarcoma Choriocarcinoma Kaposi sarcoma Ewing sarcoma Testicular cancer	Myelosuppression Mucositis Cheilitis Glossitis Alopecia Cutaneous erythema
Camptothecins		
Irinotecan	Colon cancer Ovarian cancer	Myelosuppression Alopecia
Topotecan	Lung cancer Ovarian cancer	As for irinotecan
Antitumor antibiotics		
Antibiotic		
Bleomycin	Hodgkin disease Non-Hodgkin lymphoma Head and neck cancer Testicular cancer	Interstitial pulmonary fibrosis Allergic reactions Skin pigmentation
Tubulin-binding drugs		
Vinca alkaloids		
Vinblastine	Hodgkin disease Non-Hodgkin lymphoma Breast cancer Testicular cancer	Myelosuppression Peripheral neuropathy

Vincristine	Hodgkin disease Non-Hodgkin lymphoma Small cell lung cancer Neuroblastoma Wilms tumor Rhabdomyosarcoma Acute lymphocytic leukemia	Myelosuppression Peripheral neuropathy
Vinorelbine	Breast cancer Lung cancer	Myelosuppression Peripheral neuropathy
Taxanes		
Paclitaxel	Breast, lung, bladder, and ovarian cancer	Myelosuppression Peripheral neuropathy Allergic reactions Alopecia totalis
Docetaxel	Breast, lung, bladder, and ovarian cancer	Myelosuppression Peripheral neuropathy Allergic reactions Alopecia totalis Cardiac dysrhythmias Capillary leakage
Signal transduction modulators		
Antiestrogens		
Tamoxifen	Breast cancer	Venous thrombosis Weight gain Amenorrhea Hypercalcemia Endometrial cancer Hot flashes
Toremifene	Breast cancer	Venous thrombosis Hot flashes
Raloxifene	Breast cancer	Venous thrombosis Hot flashes
Antiandrogens		
Flutamide	Prostate cancer	Gynecomastia Hot flashes
Bicalutamide	Prostate cancer	Gynecomastia Hot flashes
Nilutamide	Prostate cancer	Gynecomastia Hot flashes Delayed visual adaptation to dark
Monoclonal antibodies		
Trastuzumab	Breast cancer	Fever and chills Cardiomyopathy Rash Infusion reaction
Pertuzumab	Breast cancer	Fever and chills Cardiomyopathy Rash Infusion reaction

Bevacizumab	Cervical cancer Colorectal cancer Glioblastoma Hepatocellular cancer Non–small cell lung cancer Ovarian cancer Renal cell cancer	Hypertension Myelosuppression Postoperative wound complication Venous thromboembolism Gastrointestinal perforation Hemorrhage Non-GI fistulae development Congestive heart failure Posterior reversible encephalopathy syndrome (PRES)
Alemtuzumab	B-cell chronic lymphocytic leukemia	Myelosuppression Rash Fever Cytomegalovirus disease/viremia
Rituximab	Chronic lymphocytic leukemia Non-Hodgkin lymphoma	Infusion-related chills, rash, and fever Non-infusion-related myalgias, angioedema, bronchospasm, cardiac dysrhythmias Myelosuppression
Obinutuzumab	Chronic lymphocytic leukemia Follicular lymphoma	Infusion reaction Myelosuppression
Polatuzumab vedotin	Refractory diffuse large B-cell lymphoma	Infusion reaction Myelosuppression
Daratumumab	Multiple myeloma	Infusion reaction Myelosuppression
Other targeted therapies		
Imatinib	Philadelphia chromosome–positive CLL Philadelphia chromosome–positive ALL Gastrointestinal stromal tumors Myelodysplastic/myeloproliferative disease with PDGF receptor gene rearrangements	Peripheral edema Liver function abnormalities Rash Myelosuppression
Venetoclax	Chronic lymphocytic leukemia (CLL) Small lymphocytic lymphoma (SLL) Acute myelogenous leukemia (AML)	Tumor lysis syndrome Neutropenia
Sorafenib	Hepatocellular cancer Renal cell cancer Thyroid carcinoma	Diarrhea Hand-foot syndrome Stomatitis Cardiotoxicity
Sunitinib	Gastrointestinal stromal tumor Pancreatic neuroendocrine tumors Renal cell cancer	Diarrhea Hand-foot syndrome Stomatitis Myocardial infarction
Vaccines		
Sipuleucel-T	Prostate cancer	Severe infusion-related reaction

		Fevers Chills Fatigue Back pain Myalgias Citrate toxicity
Aromatase inhibitors		
Aminoglutethimide	Breast cancer	Orthostatic hypotension Glucocorticoid deficiency Cutaneous rash
Anastrazole	Breast cancer	Asthenia Headache Hot flashes
Letrozole	Breast cancer	Headache Heartburn
Gonadotropin-releasing drugs		
Leuprolide	Breast cancer Prostate cancer	Impotence Hot flashes Pain at sites of bony metastases (tumor flare)
Buserelin	Breast cancer	As for leuprolide
Progestin		
Megestrol acetate	Breast cancer Prostate cancer Endometrial cancer	Weight gain Peripheral edema Venous thromboembolism
Immunomodulatory drugs		
Thalidomide	Multiple myeloma	Somnolence Peripheral neuropathy Myelosuppression Venous thromboembolism Teratogenicity
Lenalidomide	Multiple myeloma	Somnolence Peripheral neuropathy Myelosuppression Venous thromboembolism Teratogenicity
Pomalidomide	Multiple myeloma	Somnolence Peripheral neuropathy Myelosuppression Venous thromboembolism Teratogenicity

Abbreviations: 3-D, three-dimensional; ADH, antidiuretic hormone; ALL, acute lymphoblastic leukemia; BCNU, bischloroethylnitrosourea; CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea; CLL, chronic lymphocytic leukemia; DTIC, dimethyl triazeno imidazole carboxamide; PDGF, platelet-derived growth factor.

^aAdapted from Rubin EH, Hait WN. Principles of cancer treatment. *Sci Am Med*. 2003;12(IV):1-17.

Toxicities

Chemotherapeutic drugs typically target proteins or nucleic acids, which are common to malignant and nonmalignant cells and thus possess a narrow therapeutic index. Therefore, using the standard definition of

therapeutic index (the dose that causes toxicity divided by the minimum effective dose) is not useful because these agents all produce significant, even life-threatening toxicities at doses, which may not reach levels that are high enough to eradicate cancer (therapeutic index <1). Furthermore, chemotherapeutic drugs are usually administered at maximum tolerated doses. Although toxicities may be unique for specific drugs, many toxicities are shared (nausea and vomiting, myelosuppression, mucositis, alopecia) (see [Table 42.2](#)).⁵ Nausea and vomiting result from local gastrointestinal effects as well as activation of the chemoreceptor trigger zone in the CNS. Patients who have a history of chemotherapy-induced nausea and vomiting are not necessarily prone to postoperative nausea and vomiting. Interestingly, there is only weak positive association between the two but patients who have a history of tolerating emetogenic chemotherapy regimens are unlikely to develop postoperative nausea and vomiting.⁸ Development of serotonin antagonists as effective antiemetics in addition to combination antiemetic regimens has facilitated the tolerance of emetogenic chemotherapeutic drugs. Mucositis and diarrhea are common gastrointestinal toxicities that reflect the high proliferative rate of gastrointestinal tissues, which makes these tissues more susceptible to the cytotoxic effects of certain chemotherapeutic drugs. Myelosuppression and alopecia reflect similar chemotherapeutic drug effects on highly proliferative tissues. Chemotherapeutic drugs that damage DNA (alkylating drugs, topoisomerases) are associated with secondary malignancies.

Alkylating Agents

Alkylating drugs include nitrogen mustards, alkyl sulfonates, nitrosoureas, and triazenes. These chemotherapeutic drugs form covalent alkyl bonds with nucleic acid bases, resulting in intrastrand or interstrand DNA cross-links, which are toxic to cells undergoing division. By altering the structure of DNA, these drugs inhibit DNA replication and transcription. The DNA damage produced by alkylating chemotherapeutic drugs is more likely to kill malignant cells than nonmalignant cells because rates of proliferation are greater for the cancer cells. Acquired resistance to alkylating drugs is a common occurrence and largely due to decreased cell membrane permeability to the drugs and increased production of nucleophilic substances that can compete with target DNA for alkylation.

Side Effects

Bone marrow suppression is the most important dose-limiting factor in the clinical use of alkylating drugs, especially busulfan. Cessation of mitosis is evident within 6 to 8 hours. Lymphocytopenia is usually present within 24 hours. Variable degrees of depression of platelet and erythrocyte counts may occur. Hemolytic anemia is predictably present.

Treatment with alkylating drugs is often associated with gonadal dysfunction, including oligospermia and amenorrhea. Hemorrhagic cystitis can result from irritation by the acrolein metabolite of cyclophosphamide or ifosfamide. Gastrointestinal mucosa is sensitive to the effects of alkylating drugs, manifesting as mitotic arrest, cellular hypertrophy, and desquamation of the epithelium. Damage to hair follicles, often leading to alopecia, is a common side effect. Increased skin pigmentation is frequent. All alkylating drugs are powerful central nervous system (CNS) stimulants, manifesting most often as nausea and vomiting. Skeletal muscle weakness and seizures may be present. Pneumonitis and pulmonary fibrosis are potential adverse effects of alkylating drugs. Symptomatic patients may demonstrate a decreased pulmonary diffusing capacity. Inhibition of plasma cholinesterase activity may be present for as long as 2 to 3 weeks after administration of chemotherapy regimens that include an alkylating agent and can lead to prolonged skeletal muscle paralysis after administration of succinylcholine.^{9,10}

Rapid drug-induced destruction of malignant cells can produce increased purine and pyrimidine breakdown, leading to uric acid-induced nephropathy. To minimize the likelihood of this complication, it is recommended that adequate fluid intake, alkalinization of the urine, and administration of allopurinol be established before drug treatment.

Nitrogen Mustards

The most commonly used nitrogen mustards are mechlorethamine, cyclophosphamide, melphalan, and chlorambucil.

Mechlorethamine

Mechlorethamine is a rapidly acting nitrogen mustard administered intravenously (IV) to minimize local tissue irritation. This drug must be freshly prepared before each administration. Mechlorethamine and other nitrogen mustards are intensely powerful vesicants, requiring that gloves be worn by personnel handling the drug. A course of therapy with mechlorethamine consists of the injection of a total dose of 6 mg/m^2 as a single dose on day 1 every 4 weeks for a total of two cycles for favorable/early-stage Hodgkin disease versus a total of three cycles for unfavorable/advanced stage Hodgkin disease. The drug undergoes rapid chemical transformation in tissues such that active drug is no longer present after a few minutes. For this reason, it is possible to prevent tissue toxicity from the drug by isolating the blood supply to that tissue. Alternatively, it is theoretically possible to localize the action of mechlorethamine in a specific tissue by injecting the drug into the arterial blood supply to the tissue.

Clinical Uses

Mechlorethamine produces beneficial effects in the treatment of Hodgkin disease and, less predictably, in other lymphomas. The drug is most often used in combination with vincristine (Oncovin), procarbazine, and prednisone (MOPP regimen) for the treatment of Hodgkin disease.

Side Effects

The major side effects of mechlorethamine include nausea, vomiting, and myelosuppression. Leukopenia and thrombocytopenia constitute the principal limitation on the amount of drug that can be given. Herpes zoster is a type of skin lesion frequently associated with nitrogen mustard therapy. Latent viral infections may be unmasked by treatment with mechlorethamine. Thrombophlebitis is a potential complication, and extravasation of the drug results in severe local tissue reactions, with brawny and tender induration that may persist for prolonged periods.

Cyclophosphamide

Cyclophosphamide is well absorbed after oral administration and is subsequently activated in the liver to aldophosphamide for transport to target tissues. Parenteral administration is also effective. Target cells are able to convert aldophosphamide to the highly cytotoxic metabolites, phosphoramide, and acrolein that then alkylate DNA. Maximal plasma concentrations of cyclophosphamide are achieved about 1 hour after oral administration, and the elimination half-life ranges from 3 to 12 hours. Urinary elimination accounts for approximately 15% to 25% of this drug in an unchanged form.

Clinical Uses

Cyclophosphamide is one of the most frequently used chemotherapeutic drugs because it is effective in the treatment of a wide range of cancers and inflammatory diseases. Its versatility is improved because of its effectiveness after oral as well as parenteral administration. Given in combination with other drugs, favorable responses have been shown in patients with Hodgkin disease, lymphosarcoma, Burkitt lymphoma, and acute lymphoblastic leukemia of childhood. In combination with doxorubicin and paclitaxel, cyclophosphamide is often used as neoadjuvant chemotherapy in the treatment of locally advanced breast cancer.

Cyclophosphamide is also used in combination with methotrexate and fluorouracil as adjuvant therapy after surgical resection of breast cancer when involvement of axillary lymph nodes is identified by pathology. This combination can also be used palliatively to treat heavily pretreated metastatic breast cancer.

Cyclophosphamide has potent immunosuppressive properties, leading to its use in nonneoplastic disorders associated with altered immune reactivity, including Wegener granulomatosis and rheumatoid arthritis.

Side Effects

Hypersensitivity reactions and fibrosing pneumonitis have been noted in patients treated with cyclophosphamide; the incidence is less than 1% and symptoms may develop months to years after initiation of the drug. Large doses of cyclophosphamide are associated with a high incidence of pericarditis and pericardial effusion, which in some cases progress to cardiac tamponade.¹¹ Smaller numbers of treated

patients develop hemorrhagic myocarditis with symptoms of congestive heart failure, which may not occur for as long as 2 weeks after the last dose of drug.

Cyclophosphamide differs from other nitrogen mustards in that significant degrees of thrombocytopenia are less common but alopecia is more frequent. Nausea and vomiting occur with equal frequency regardless of the route of administration. Mucosal ulcerations, increased skin pigmentation, and hepatotoxicity are possible side effects. Sterile hemorrhagic cystitis occurs in 5% to 10% of patients, presumably reflecting chemical irritation produced by reactive metabolites of cyclophosphamide. Dysuria and hematuria are indications to discontinue the drug. Inappropriate secretion of arginine vasopressin hormone has been observed in patients receiving cyclophosphamide, usually with doses of greater than 50 mg/kg. It is important to consider the possibility of water intoxication because these patients are usually being hydrated to minimize the likelihood that hemorrhagic cystitis will develop. Extravasation of the drug does not produce local reactions, and thrombophlebitis does not complicate IV administration.

Melphalan

Melphalan is a phenylalanine derivative of nitrogen mustard with a range of activity similar to other alkylating drugs. It is not a vesicant. Oral absorption is excellent, resulting in drug concentrations similar to those achieved by the IV route of administration. The elimination half-life is approximately 1.5 hours, and up to 10% of the drug is eliminated unchanged in urine.

Side Effects

The side effects of melphalan are primarily hematologic and are similar to those of other alkylating drugs. It is usually necessary to maintain a significant degree of bone marrow depression (leukocyte count 3,000-5,000 cells/mm³) to achieve optimal therapeutic effects. Pulmonary fibrosis is possible. Nausea and vomiting are not common side effects of melphalan. Alopecia does not occur, and changes in renal or hepatic function are possible.

Chlorambucil

Chlorambucil is the aromatic derivative of mechlorethamine. Oral absorption is adequate. The drug has an elimination half-life of approximately 1.5 hours and is almost completely metabolized. Chlorambucil is the slowest acting nitrogen mustard in clinical use. It is used to treat chronic lymphocytic leukemia and in primary (Waldenström) macroglobulinemia. A marked increase in the incidence of leukemia and other tumors has been noted with the use of this drug for the treatment of polycythemia vera.

Side Effects

Cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other alkylating drugs. Its myelosuppressive action is usually moderate, gradual, and rapidly reversible. Pulmonary fibrosis is possible. Nausea and vomiting are frequent. A CNS stimulation can occur but has been observed only with large doses. Hepatotoxicity may rarely occur.

Alkyl Sulfonates

Busulfan is a cell cycle–nonspecific alkylating antineoplastic agent in the class of alkyl sulfonates. Busulfan is well absorbed after oral administration. Intravenous administration is also effective. Almost the entire drug is eliminated by the kidneys as methane sulfonic acid. Busulfan produces remissions in up to 90% of patients with chronic myelogenous leukemia. The drug is of no value in the treatment of acute leukemia.

Side Effects

Busulfan can produce progressive pulmonary fibrosis in up to 4% of patients. The prognosis after appearance of clinical symptoms is poor, with a median survival of 5 months.¹² Enhanced toxicity with administration of supplemental oxygen has not been noted. Myelosuppression and thrombocytopenia are important side effects of busulfan. Nausea, vomiting, and diarrhea occur. Hyperuricemia resulting from extensive purine catabolism

accompanying the rapid cellular destruction and renal damage from precipitation of urates have been noted. Allopurinol is recommended to minimize renal complications.

Nitrosoureas

The nitrosoureas are mustard gas-related compounds used as an alkylating agent in chemotherapy. Nitrosoureas, represented by carmustine, lomustine, semustine, and streptozocin, possess a wide spectrum of activity for human malignancies including intracranial tumors, melanomas, and gastrointestinal and hematologic malignancies. The high lipid solubility allows passage across the blood-brain barrier and therefore efficacy in the treatment of meningeal leukemias and brain tumors. These drugs act by carboxylation and alkylation of nucleic acids as well as cross-linking strands of DNA and RNA. With the exception of streptozocin, the clinical use of nitrosoureas is limited by profound drug-induced myelosuppression.

Carmustine

Carmustine is the nitrosourea in widest clinical use. It is capable of inhibiting synthesis of both RNA and DNA. Although oral absorption is rapid, the drug is injected intravenously because tissue uptake and metabolism occur quickly. Local burning may accompany infusion. Carmustine disappears from plasma in 5 to 15 minutes. Because of its ability to rapidly cross the blood-brain barrier, carmustine is used to treat meningeal leukemia and primary as well as metastatic brain tumors.

Side Effects

Carmustine has been associated with interstitial pneumonitis and fibrosis much like bleomycin.¹³ The incidence of pulmonary toxicity is in the range of 20% to 30%, with a mortality in those affected of 24% to 90%. The cumulative dose is the major risk factor, with 50% of patients exhibiting toxicity at doses above the range of 1,200 to 1,500 mg/m². A unique side effect of carmustine is a delayed onset (after approximately 6 weeks of treatment) of leukopenia and thrombocytopenia. Active metabolites may be responsible for this toxicity. The CNS toxicity, nausea and vomiting, flushing of the skin and conjunctiva, nephrotoxicity, and hepatotoxicity have been reported.

Lomustine and Semustine

Lomustine and its methylated analogue semustine possess similar clinical toxicity to carmustine, including delayed bone marrow suppression manifesting as leukopenia and thrombocytopenia. Lomustine appears to be more effective than carmustine in the treatment of Hodgkin disease.

Streptozocin

Streptozocin has a methylnitrosourea moiety attached to the number 2 carbon atom of glucose. It has a unique affinity for β cells of the islets of Langerhans and has proved useful in the treatment of human pancreatic islet cell carcinoma and malignant carcinoid. In animals, the drug is used to produce experimental diabetes mellitus.

Side Effects

Approximately 70% of patients receiving this drug develop hepatic or renal toxicity. Renal toxicity may manifest as tubular damage and progress to renal failure and death. Hyperglycemia can occur as a result of selective destruction of pancreatic β cells and resultant hypoinsulinism.¹⁴ Myelosuppression is not produced by this drug.

Mitomycin

Mitomycin is the prototypical alkylating agent and is of value in the palliative treatment of gastric adenocarcinoma in combination with fluorouracil and doxorubicin. The drug is administered IV and is widely distributed in tissues but does not readily enter the CNS. Metabolism is in the liver, with less than 10% of mitomycin excreted unchanged in bile or urine.

Side Effects

Myelosuppression is a prominent side effect of mitomycin and is characterized by severe leukopenia and thrombocytopenia, which may be delayed in appearance. Mitomycin is capable of inducing pulmonary fibrosis, with an incidence ranging between 3% and 12%.¹⁴ Like bleomycin, mitomycin appears to act synergistically to induce pulmonary fibrosis with thoracic radiation and oxygen therapy, suggesting the need to limit exposure of treated patients to hyperoxia. Nausea, vomiting, gastrointestinal mucositis, and alopecia are recognized toxic effects. Glomerular damage resulting in renal failure is a rare but well-recognized complication.

Platinating Drugs

Cisplatin

Although cisplatin is frequently designated as an alkylating agent, it has no alkyl group and cannot carry out alkylating reactions. It is correctly classified as alkylating-like. Cisplatin contains a platinum atom, two amines, and two chlorides, which result in chemotherapeutic effects resembling DNA alkylating drugs by cross-linking adjacent or opposing guanine bases to disrupt DNA. The drug must be administered IV because oral ingestion is ineffective. High concentrations of cisplatin are found in the kidneys, liver, intestines, and testes, but there is poor penetration into the CNS. Cisplatin and its analogue carboplatin are components of the treatment of many nonhematologic malignancies, including lung, bladder, testicular, and ovarian cancer.

Side Effects

Renal toxicity is prominent and becomes the dose-limiting toxic effect of cisplatin. Decreased glomerular filtration rate and renal tubular dysfunction produced by cisplatin may begin as early as 3 to 5 days after initiating treatment with this drug. Along with increasing blood urea nitrogen and plasma creatinine concentrations, proteinuria, and hyperuricemia, there is a magnesium-wasting defect in as many as 50% of patients manifesting as some degree of cisplatin-induced renal dysfunction. Acute tubular necrosis may progress to acute renal failure, necessitating hemodialysis. Hydration and diuresis induced with mannitol and furosemide may protect against the development of renal toxicity by dilution of the tubular urinary concentration of cisplatin. The hypomagnesemia that is associated with cisplatin's renal tubular injury may predispose to cardiac dysrhythmias and decrease the dose requirements for neuromuscular-blocking drugs.

Ototoxicity caused by cisplatin is manifested by tinnitus and hearing loss in the high-frequency range. Cisplatin is considered highly emetogenic, with marked nausea and vomiting occurring in almost all patients who do not receive antiemetics, although prophylactic antinausea regimens can be highly effective. Mild to moderate myelosuppression may develop, with transient leukopenia and thrombocytopenia. Peripheral sensory neuropathies, paresthesias, and loss of vibratory and position sense are common findings. Most neuropathies are reversible, although symptoms may persist for months. Hyperuricemia, seizures, and cardiac dysrhythmias have been observed. Allergic reactions characterized by facial edema, bronchoconstriction, tachycardia, and hypotension may occur minutes after injection of the drug.

Antimetabolites

Nucleic acid synthesis inhibitors (antimetabolites) include folate analogues, pyrimidine analogues, and purine analogues. These drugs are particularly effective in destroying cells during the S phase of the cell cycle, which is when DNA is synthesized. Selective effects on cancer cells are due to greater rates of DNA replication in cancer cells than normal cells. Nevertheless, side effects (myelosuppression and mucositis) reflect effects on proliferating but nonmalignant cells.

Folate Analogues

Methotrexate

Methotrexate is a poorly lipid-soluble folate analogue that is effective in the treatment of different hematologic and nonhematologic cancers and is classified as an antimetabolite (folic acid antagonist). This drug inhibits dihydrofolate reductase, which is the enzyme that uses reduced folate as a methyl donor in the

synthesis of pyrimidine and purine nucleosides. Inhibition of dihydrofolate reductase by methotrexate prevents the formation of tetrahydrofolic acid and causes disruption of cellular metabolism by producing an acute intracellular deficiency of folate enzymes. As a result, 1-carbon transfer reactions necessary for the eventual synthesis of DNA and RNA cease.

Methotrexate is readily absorbed after oral administration. Significant metabolism of methotrexate does not occur, with more than 50% of the drug appearing unchanged in urine. Renal excretion reflects glomerular filtration and tubular secretion. Toxic concentrations of methotrexate may occur in patients with renal insufficiency. Methotrexate remains in tissues for weeks, suggesting binding of the drug to dihydrofolate reductase.

Clinical Uses

Methotrexate is widely used in the treatment of malignant and some nonmalignant disorders. It is a useful drug in the treatment of acute lymphoblastic leukemia in children but not adults. Choriocarcinoma is effectively treated with this drug. Improvement in the clinical manifestations of psoriasis in patients reflects the effect of methotrexate on rapidly dividing epidermal cells characteristic of this disease. This drug may also be useful in the treatment of rheumatoid arthritis.

Methotrexate is poorly transported across the blood-brain barrier, and neoplastic cells that have entered the CNS probably are not affected by the usual plasma concentrations of the drug. Intrathecal injection is used to treat cerebral involvement with either leukemia, lymphoma, or choriocarcinoma.

Acquired resistance to methotrexate develops as a result of (1) impaired transport of methotrexate into cells, (2) production of altered forms of dihydrofolate reductase that have decreased affinity for the drug, and (3) increased concentrations of intracellular dihydrofolate reductase.

Side Effects

The most important side effects of methotrexate occur in the gastrointestinal tract and bone marrow. Leukopenia and thrombocytopenia reflect bone marrow depression. Ulcerative stomatitis and diarrhea are frequent side effects and require interruption of treatment. Hemorrhagic enteritis and death from intestinal perforation may occur. Pulmonary toxicity may take the form of fulminant noncardiogenic pulmonary edema, or a more progressive inflammation, with interstitial infiltrates and pleural effusions.¹⁵ The incidence of pulmonary toxicity attributed to methotrexate is in the range of 8%, but its frequent use in combination with other chemotherapeutic drugs makes this number uncertain.¹⁶ Methotrexate is associated with renal toxicity, with an incidence approaching 10% in higher doses.¹⁷ Renal insufficiency may be prevented by hydration and urinary alkalinization. Short-term or intermittent therapy with methotrexate results in increases in liver transaminase enzymes. Hepatic dysfunction is usually reversible but may sometimes lead to cirrhosis. It may be useful to measure liver function tests preoperatively in patients who have recently received methotrexate. Encephalopathic syndromes may accompany intrathecal or IV administration of methotrexate and may be transient or permanent.¹⁸ Additionally, alopecia and dermatitis are associated with administration of methotrexate. Folic acid antagonists also interfere with embryogenesis, emphasizing the risk in administering these drugs to pregnant patients. Normal cells can be protected from lethal damage by folate antagonists with sequential administration of folinic acid (leucovorin), thymidine, or both. This approach has been termed the **rescue technique**.

Pyrimidine Analogues

Pyrimidine analogues have in common the ability to prevent the biosynthesis of pyrimidine nucleotides or to mimic these natural metabolites to such an extent that they interfere with vital cellular activities such as the synthesis and functioning of nucleic acids. Examples of antimetabolite chemotherapeutic drugs that function as pyrimidine analogues are fluorouracil and cytarabine.

Fluorouracil

Fluorouracil blocks production of thymine nucleotides by inhibiting thymidylate synthase. This chemotherapeutic drug lacks significant inhibitory activity on cells and must be converted enzymatically to a

5'-monophosphate nucleotide. Administration of fluorouracil is usually by IV injection because absorption after oral ingestion is unpredictable and incomplete. Metabolic degradation occurs primarily in the liver, with an important metabolite being urea. Only approximately 5% to 20% of fluorouracil appears unchanged in urine. Fluorouracil readily enters the cerebrospinal fluid, with therapeutic concentrations being present within 30 minutes after IV administration.

Clinical Uses

Fluorouracil may be of palliative value in certain types of carcinoma, particularly of the breast and gastrointestinal tract. It can also be used as part of neoadjuvant or adjuvant chemotherapy regimens in the treatment of gastrointestinal malignancies and breast cancer. The drug is often used for the topical treatment of premalignant keratoses of the skin and superficial basal cell carcinomas.

Side Effects

Side effects caused by fluorouracil are difficult to anticipate because of their delayed appearance. Fluorouracil-induced myocardial ischemia is a rare cardiac toxicity that may lead to myocardial infarction up to 1 week after treatment.¹⁹ The incidence of this side effect is low in patients without underlying heart disease but may increase to 4.5% of treated patients with preexisting coronary artery disease. Stomatitis manifesting as a white patchy membrane that ulcerates and becomes necrotic is an early sign of toxicity and warns of the possibility that similar lesions may be developing in the esophagus and gastrointestinal tract. Myelosuppression, most frequently manifesting as leukopenia between 9 and 14 days of therapy, is a serious side effect. Thrombocytopenia and anemia may complicate treatment with fluorouracil. Loss of hair progressing to total alopecia, nail changes, dermatitis, and increased pigmentation and atrophy of the skin may occur. Hand-foot syndrome has also been associated with fluorouracil. Neurologic manifestations, including an acute cerebellar syndrome (ataxia), have been reported.

Capecitabine

Capecitabine is an orally administered drug that is metabolized to fluorouracil by thymidine phosphorylase after absorption from the gastrointestinal tract. Because there is more activity of thymidine phosphorylase in cancer cells (especially breast cancer) than in normal cells, capecitabine has the potential to be more selective than fluorouracil.

Pemetrexed

Pemetrexed is a folate antagonist that is effective in the treatment of mesothelioma and lung cancer. This drug inhibits multiple enzymes involved in the folate pathway, including thymidylate synthase and dihydrofolate reductase.

Cytarabine

Cytarabine (cytosine arabinoside), like other pyrimidine antimetabolites, must be activated by conversion to the 5'-monophosphate nucleotide before inhibition of DNA synthesis can occur. Both natural and acquired resistance to cytarabine develops, reflecting the activity of cytidine deaminase, an enzyme capable of converting cytarabine to the inactive metabolite arabinosyl uracil.

Clinical Uses

In addition to its chemotherapeutic activity, particularly in acute leukemia in children and adults, cytarabine has potent immunosuppressive properties. The drug is particularly useful in chemotherapy of acute granulocytic leukemia in adults. Intravenous administration of cytarabine is recommended because oral absorption is poor and unpredictable.

Side Effects

Cytarabine is a potent myelosuppressive drug capable of producing severe leukopenia, thrombocytopenia, and anemia. Cerebellar toxicity and ataxia can occur at high doses. Other side effects include gastrointestinal

disturbances, stomatitis, and hepatic dysfunction. Thrombophlebitis at the site of infusion is common. Alternatively, the drug may be given subcutaneously.

Gemcitabine

Gemcitabine resembles cytarabine structurally; yet, gemcitabine is active in several nonhematologic cancers, whereas cytarabine is not effective. Gemcitabine is also used in solid organ carcinomas, such as of the pancreas, breast, and lung. This most likely reflects unique effects of this chemotherapeutic drug on DNA and RNA metabolism. Common side effects associated with use of gemcitabine include bone marrow suppression, flu-like symptoms, fever, fatigue, mild nausea/vomiting, and diarrhea.

Purine Analogues

Antimetabolite chemotherapeutic drugs that function as purine analogues include mercaptopurine, azathioprine, thioguanine, pentostatin (2'-deoxycoformycin), and cladribine (2-chlorodeoxyadenosine). Mercaptopurine and thioguanine are analogues of the natural purines hypoxanthine and guanine, respectively.

Mercaptopurine

Mercaptopurine is incorporated into DNA or RNA strands and works by either blocking further strand synthesis or causes structural alterations that damage DNA. This drug is useful in the treatment of acute leukemia in children. Oral absorption is prompt, and gastrointestinal epithelium is not damaged. The elimination half-life is brief (about 90 minutes) due to rapid tissue uptake, renal excretion, and hepatic metabolism. One pathway of metabolism is methylation and subsequent oxidation of the methylated derivatives. A second pathway involves the enzyme xanthine oxidase, which oxidizes mercaptopurine to 6-thiouric acid. Allopurinol, as an inhibitor of xanthine oxidase, prevents conversion of mercaptopurine to 6-thiouric acid and thus increases the exposure of cells to mercaptopurine. The dose of mercaptopurine is decreased by about one-third when the drug is combined with allopurinol.

Side Effects

The principal side effect of mercaptopurine is a gradual development of bone marrow depression manifesting as thrombocytopenia, granulocytopenia, or anemia several weeks after initiation of therapy. Anorexia, nausea, and vomiting are common side effects; stomatitis and diarrhea rarely occur. Jaundice occurs in approximately one-third of patients and is associated with bile stasis and occasional hepatic necrosis. Hyperuricemia and hyperuricosuria may occur during treatment with mercaptopurine due to destruction of cells. This effect may require the use of allopurinol.

Thioguanine

Thioguanine is of particular value in the treatment of acute myelogenous leukemia, especially if given with cytarabine. After oral administration, thioguanine appears in the urine as a methylated metabolite and inorganic sulfate. Minimal amounts of 6-thiouric acid are formed, suggesting that deamination is not important in the metabolic inactivation of thioguanine. For this reason, thioguanine may be administered concurrently with allopurinol without a decrease in dosage, unlike mercaptopurine. Toxic manifestations of thioguanine treatment include bone marrow depression and, occasionally, gastrointestinal effects.

Pentostatin and Cladribine

Pentostatin and cladribine are purine analogues that have clinical activity against a variety of indolent lymphoid tumors, with the most dramatic effects occurring in patients with hairy cell leukemia.²⁰ These drugs act by irreversibly binding to adenosine deaminase (pentostatin) or by chemical modification of enzyme substrate, rendering it resistant to the action of adenosine deaminase (cladribine). Patients with acute leukemia and cells with high levels of adenosine deaminase activity are most likely to respond to these drugs. Fever, which is likely due to cytokines, is a side effect of treatment with cladribine. Both drugs are capable of producing immunosuppression. The recovery from immunosuppression seems to be more rapid after treatment with cladribine than after treatment with pentostatin, perhaps because of the shorter duration of

administration of the former. As a result, cladribine has emerged as the treatment of choice for hairy cell leukemia because of its minimal toxicity and its ability to induce a complete and sustained response with a single course of therapy.

Hydroxyurea

Hydroxyurea acts on the enzyme ribonucleoside diphosphate reductase to interfere with the synthesis of DNA. Oral absorption is excellent, and approximately 80% of the drug appears in the urine within 12 hours after oral or IV administration. The primary use of hydroxyurea is in the treatment of chronic myelogenous leukemia. It can also be used in the treatment of locally advanced squamous cell carcinomas of the head and neck excluding lip cancer in combination with chemoradiation.

Side Effects

Myelosuppression manifesting as leukopenia, megaloblastic anemia, and occasionally thrombocytopenia is the major side effect produced by hydroxyurea. Nausea and vomiting can also occur but are less frequent. Hyperpigmentation of the skin, stomatitis, and alopecia occur infrequently.

Topoisomerase Inhibitors

Topoisomerases are enzymes that correct alterations in DNA, which occur during replication and transcription. Certain chemotherapeutic drugs inhibit either topoisomerase I or topoisomerase II. Because cancer cells possess more topoisomerase activity than normal cells, there is more drug-induced DNA damage and resultant cell death. Toxicity reflects effects of inhibition of topoisomerase enzymes on normal proliferating tissues (myelosuppression, mucositis). Topoisomerase II inhibitors that include doxorubicin, daunorubicin, etoposide, and teniposide are part of most combination chemotherapy treatment regimens. Topoisomerase I inhibitors include topotecan and irinotecan. These drugs exhibit a broad spectrum of chemotherapeutic activity being useful in the treatment of leukemia and lung, colon, and ovarian cancer.

Doxorubicin and Daunorubicin

Doxorubicin and daunorubicin are anthracycline antibiotics that are natural products of certain soil fungi. Structurally, they contain a tetracycline ring attached to the sugar daunosamine by a glycosidic linkage. These drugs act by directly binding to DNA called *intercalation*, resulting in changes in the DNA helix that interfere with the ability of nucleic acids to serve as a template during replication in addition to disrupting DNA repair through topoisomerase II inhibition. These drugs also cause disruptive effects on cellular membranes. Drug-induced free radicals can overwhelm the heart's antioxidant defenses, leading to the oxidation of critical cardiac proteins and membrane components (unsaturated free fatty acids), leading to cardiotoxicity.²¹ Laboratory studies demonstrate that each subsequent dose of doxorubicin appears to diminish the heart's ability to withstand subsequent oxidant stress. Evidence also suggests that free radicals have a role in the protective effect of free radical scavengers.

Daunorubicin and doxorubicin are administered IV, with care taken to prevent extravasation because local vesicant action may result. There is rapid clearance from the plasma into the heart, kidneys, lungs, and liver. These drugs do not cross the blood-brain barrier to any significant extent. The urine may become red for 1 to 2 days after administration of these drugs.

Daunorubicin is metabolized primarily to deoxydaunorubicinol aglycone and daunorubicinol, whereas doxorubicin is excreted unchanged and as metabolites, including adriamycinol in the urine. Ultimately, approximately 40% of daunorubicin and doxorubicin are metabolized. Clinical toxicity may result in patients with hepatic dysfunction.

Clinical Uses

Daunorubicin is used primarily in the treatment of acute lymphocytic and myelocytic leukemia. Doxorubicin, which differs from daunorubicin only by a single hydroxyl group on the number 14 carbon atom, is also effective against a wide range of solid tumors. For example, doxorubicin is one of the most active single

drugs for treating many cancers including adenocarcinoma of the breast, carcinoma of the bladder, bronchogenic carcinoma, metastatic thyroid carcinoma, small cell carcinoma, and osteogenic carcinoma.

Resistance is observed to the anthracycline antibiotics, as with other chemotherapeutic drugs. Furthermore, cross-tolerance occurs between daunorubicin and doxorubicin. Cross-resistance also occurs between these antibiotics and the vinca alkaloids, suggesting that an alteration of cellular permeability is involved.

Side Effects

Cardiomyopathy and myelosuppression are side effects of the chemotherapeutic antibiotics. Leukopenia typically manifests during the second week of therapy. Thrombocytopenia and anemia occur but are usually less pronounced. Stomatitis, gastrointestinal disturbances, and alopecia are common side effects.

Cardiomyopathy

Cardiomyopathy is a unique dose related and often irreversible side effect of the anthracycline antibiotics. Increased plasma concentrations of troponin T reflect drug-induced injury to myocardial cells. Congestive heart failure develops in less than 3% of patients with a cumulative dose of doxorubicin of less than 400 mg/m², rising to 18% at 700 mg/m² (**Figure 42.2**).²² Prior mediastinal radiation or previous treatment with cyclophosphamide increases the subsequent risk of cardiomyopathy in response to administration of an anthracycline antibiotic. Marked impairment of left ventricular function for as long as 3 years after discontinuing doxorubicin has been observed. Previous treatment with anthracycline antibiotics may enhance myocardial depressant effects of anesthetic drugs even in patients with normal resting cardiac function.²³ Acute left ventricular failure 2 months after cessation of treatment with doxorubicin has been described during general anesthesia.²⁴

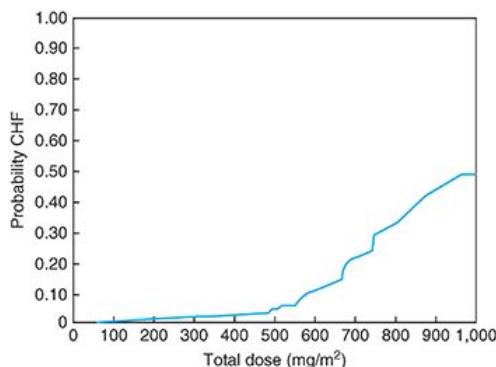

FIGURE 42.2 The probability of developing doxorubicin-induced congestive heart failure (CHF) versus the total cumulative dose of doxorubicin. *From Von Hoff DD, Layard MW, Basa P, et al. Risk factors for doxorubicin-induced congestive heart failure. Ann Intern Med. 1979;91(5):710-717. Copyright © 1979 American College of Physicians. All Rights Reserved. Reprinted with the permission of American College of Physicians, Inc.*

Two types of cardiomyopathies may occur.²¹ An acute form of cardiomyopathy occurs in approximately 10% of patients and is characterized by relatively benign changes on the ECG that include nonspecific ST-T changes and decreased QRS voltage. Other cardiac changes include premature ventricular contractions, supraventricular tachydysrhythmias, cardiac conduction abnormalities, and left axis deviation. These abnormalities occur during therapy at all dose levels and, except for decreased QRS voltage on the ECG, resolve 1 to 2 months after discontinuation of therapy. There is an associated acute reversible decrease in the ejection fraction within 24 hours after a single dose.

The second form of cardiomyopathy is characterized by the insidious onset of symptoms such as dry nonproductive cough, suggesting bronchitis, followed by rapidly progressive heart failure that is unresponsive to inotropic drugs and mechanical ventricular assistance.² This severe form of cardiomyopathy

occurs in almost 2% of treated patients and is fatal approximately 3 weeks after the onset of symptoms in nearly 60% of affected patients. Predictive tests to permit early recognition of impending cardiomyopathy are not available, although diminution in QRS voltage on the ECG is consistent with the diffuse character of the myocardial damage. Increased plasma concentrations of cardiac enzymes occur late in the course of cardiac failure and are of limited value in achieving an early diagnosis. Systolic time intervals and echocardiograms have been used to detect cardiotoxicity before the occurrence of clinically significant damage. Dexrazoxane is a free radical scavenger that protects the heart from doxorubicin-associated damage.²⁵

Dactinomycin

Dactinomycin (actinomycin D) is an antibiotic with chemotherapeutic activity resulting from its ability to bind to DNA, especially in rapidly proliferating cells. As a result of this binding, the function of RNA polymerase and thus the transcription of the DNA molecule are blocked. After IV injection, dactinomycin rapidly leaves the circulation. In animals, approximately 50% of an injected dose is excreted unchanged in bile and 10% in urine. Approximately 30% is excreted in the urine and feces within 1 week in humans. There is no evidence that the drug undergoes metabolism. Dactinomycin does not cross the blood–brain barrier in amounts sufficient to produce a pharmacologic effect.

Clinical Uses

The most important clinical use of dactinomycin is the treatment of Wilms tumor in children, rhabdomyosarcoma, and Ewing sarcoma. It may be effective in some women with methotrexate-resistant gestational trophoblastic neoplasia. Occasionally, this drug is used to inhibit immunologic responses associated with organ transplantation.

Side Effects

The toxic effects of dactinomycin include the early onset of nausea and vomiting, often followed by myelosuppression manifesting as pancytopenia 1 to 7 days after completion of therapy. Pancytopenia may be preceded by thrombocytopenia as the first manifestation of bone marrow suppression. Glossitis, ulcerations of the oral mucosa, diarrhea, alopecia, and cutaneous erythema are commonly associated with dactinomycin therapy. Extravasation of the drug results in tissue necrosis.

Bleomycin

Bleomycins are water-soluble glycopeptides that differ from one another (there are more than 200 congeners) in their terminal amine moiety. The terminal amine is coupled through an amide linkage to a carboxylic acid. Bleomycin possesses a tripeptide component that binds DNA and a metal-binding region. In the presence of oxygen and either iron or copper, bleomycin produces free radicals, which create DNA breaks.

Bleomycin is administered IV, and high concentrations occur in the skin and lungs. The drug accumulates in tumors, suggesting the presence of a lower level of inactivating enzyme. Bleomycin is eliminated primarily by renal excretion, with approximately 50% of the dose cleared within 4 hours and 70% by 24 hours.²⁶ Therefore, excessive concentrations of drug occur if usual doses are administered to patients with impaired renal function.

Clinical Uses

Bleomycin is effective in the treatment of testicular carcinoma, particularly if administered in combination with vinblastine, as well as Hodgkin lymphoma. It can also be used to treat squamous cell carcinomas of the head, neck, esophagus, skin, and genitourinary tract with palliative intent.

Side Effects

The most common side effects of bleomycin are mucocutaneous reactions including stomatitis, alopecia, pruritus, erythema, and hyperpigmentation, which occur in approximately 45% of patients. In contrast to other chemotherapeutic drugs, bleomycin causes minimal myelosuppression. Unexplained exacerbations of rheumatoid arthritis have occurred.

Patients with lymphomas who are receiving bleomycin may develop an acute reaction characterized by hyperthermia, hypotension, and hypoventilation. The likely mechanism is the release of an endogenous pyrogen, presumably from destroyed tumor cells. An initial small test dose of bleomycin is recommended to minimize the occurrence of this syndrome.

Pulmonary Toxicity

The most serious side effect of bleomycin is dose-related pulmonary toxicity ([Figure 42.3](#)).¹² Indeed, bleomycin is concentrated preferentially in the lungs and is inactivated by a hydrolase enzyme, which is relatively deficient in lung tissue. Initially, bleomycin produces pulmonary capillary endothelial damage, progressing to alveolar epithelial injury with necrosis of type 1 and proliferation of type 2 alveolar cells. Interstitial fibrosis develops and may progress to involve the entire lung. It is estimated that some form of pulmonary toxicity (most often pulmonary fibrosis) occurs in 4% of patients treated with bleomycin. Fatal pulmonary toxicity has occurred with bleomycin doses as low as 100 mg but more often in the presence of other risk factors ([Table 42.3](#)).

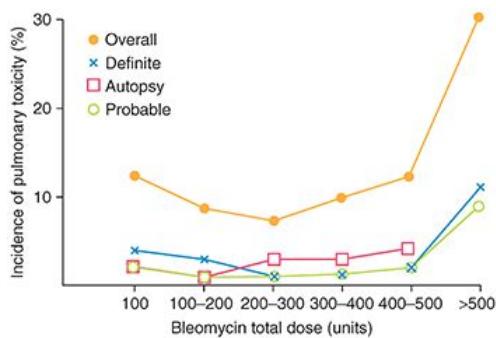

FIGURE 42.3 The relationship between the total dose of bleomycin and the incidence of pulmonary toxicity. *Reprinted from Ginsberg SJ, Comis RL. The pulmonary toxicity of antineoplastic agents. Semin Oncol. 1982;9(1):34-51. Copyright © 1982 Elsevier. With permission.*

TABLE 42.3

Risk factors for development of chemotherapy-induced pulmonary toxicity

Total drug dose

Age

Concurrent or prior chest radiation

Oxygen therapy

Combination chemotherapy

Preexisting pulmonary disease

Genetic predisposition

Cigarette smoking

The first signs of pulmonary toxicity are cough, dyspnea, and basilar rales, which progress in one of two directions. A mild form of pulmonary toxicity is characterized by exertional dyspnea and a normal resting PaO_2 . A more severe form of arterial hypoxemia at rest is associated with radiographic findings of interstitial pneumonitis and fibrosis. Lesions are found more frequently in lower lobes and subpleural areas, and radiographs of the chest often reveal basilar and perihilar infiltrates. The alveolar-arterial gradient for oxygen is increased, and pulmonary diffusion capacity may be decreased. Pulmonary function studies have been of no greater value than clinical signs in detecting the onset of pulmonary toxicity.

Early reports of postoperative respiratory failure in bleomycin-treated patients suggested that either arterial hyperoxia or excessive crystalloid administration played a role in the exacerbation of pulmonary

fibrosis.^{27–29} One speculation is that acutely increased inhaled concentrations of oxygen facilitate production of superoxide and other free radicals in the presence of bleomycin. For this reason, it has been recommended that inhaled oxygen concentrations be maintained below 30% in bleomycin-treated patients. Animal model literature confirms that the continuous administration of inspired oxygen concentrations of greater than 30% immediately after exposure to bleomycin increases pulmonary damage.³⁰ Nevertheless, it is unlikely that patients will present to the operating room immediately after treatment with bleomycin. A more practical question is whether hyperoxia for short periods of time several days after treatment is a risk factor for bleomycin-induced pulmonary damage.³¹ In this regard, animal studies have confirmed that delayed exposure to supplemental oxygen after bleomycin treatment is not harmful.³² Nevertheless, there are case reports of respiratory failure with inspired oxygen concentrations greater than 30% in patients last exposed to bleomycin up to 6 to 12 months before hyperoxia. Patients with prior exposure to bleomycin but with no risk factors appear to be at a minimum risk from hyperoxia. In contrast, those patients with one or more major risk factors (preexisting pulmonary damage from bleomycin, which is more likely if the total dose is >450 mg; renal dysfunction, which slows clearance of the drug from the lungs; and/or prior exposure to bleomycin within a 1- to 2-month period) may be at higher risk for the development of bleomycin-induced hyperoxic pulmonary injury in the operating room. It may be prudent to maintain these patients on the minimum inspired oxygen concentration that can be used safely intraoperatively to provide oxygen saturations of greater than 90% by pulse oximetry.³¹ The value of corticosteroids as pretreatment in patients with risk factors and in whom greater than 30% oxygen may be needed; for example, operations requiring cardiopulmonary bypass, has not been confirmed by controlled studies. The role of excessive crystalloid administration has not received the same scrutiny as increased delivered oxygen concentrations. A consideration in this regard is replacement of fluids with colloids rather than crystalloids to decrease or prevent pulmonary interstitial edema in bleomycin-treated patients undergoing surgery. Accumulation of interstitial fluid may reflect impaired lymphatic function caused by bleomycin-induced fibrotic changes in the lungs. In the future, bleomycin may be replaced with phleomycin, an analogue of bleomycin that has lower pulmonary toxicity and a broader effectiveness against multiple types of tumors.³³

Tubulin-Binding Drugs

Microtubules are subcellular structures that are essential for normal function of cells. They form the architecture to maintain cell shape, organize the location of organelles, and mediate intracellular transport and secretion, neurotransmission, axonemal flow, and cell motility.³⁴ Vinca alkaloids and taxanes are examples of antimitotic chemotherapeutic drugs that disrupt the normal function of microtubules. Vinca alkaloids bind to depolymerized microtubules and inhibit microtubule formation. Taxanes bind to polymerized microtubules and inhibit their breakdown. The result of these interactions is the failure of the cell to undergo normal mitosis leading to cell death.

Vinca Alkaloids

Vinca alkaloids represent the active medicinal ingredients from the pink periwinkle plant and include vincristine, vinblastine, vinorelbine, and vindesine. Vincristine is highly effective against Hodgkin disease, non-Hodgkin lymphoma, and pediatric solid tumors; yet, it has little activity against adult solid tumors. Vinorelbine, in contrast, is active against breast and lung cancer. Vinblastine is most often used in the treatment of testicular cancer and non-Hodgkin lymphoma.

Side Effects

Myelosuppression manifesting as leukopenia, thrombocytopenia, and anemia are the most prominent side effects of vinca alkaloids, appearing 7 to 10 days after initiation of treatment. Vincristine is less likely than vinblastine and vinorelbine to cause bone marrow depression.

Symmetric peripheral sensory-motor neuropathy often occurs during administration of therapeutic doses of vincristine and may become the dose-limiting side effect.^{35,36} Clinical manifestations may include several aspects of peripheral nerve function with areflexia (loss of Achilles tendon reflex) being the earliest finding. Paresthesias in the hands and feet, weakness and atrophy of the extremities, and skeletal muscle pain make

use of the hands and feet difficult (ataxia). Tremors frequently develop, whereas neuropathic pain and foot drop are common. Autonomic neuropathy with orthostatic hypotension, bowel motility dysfunction, and cranial nerve involvement (laryngeal nerve paralysis with hoarseness, weakness of the extraocular muscles) are present in about 10% of treated patients.³⁷ The CNS effects (confusion, insomnia, seizures, hallucinations) due to vincristine are rare, presumably because of poor penetration of the blood–brain barrier by the drug. The peripheral neuropathy is mainly axonal, but demyelination may also occur as demonstrated by measurement of somatosensory evoked potentials.³⁶ Vincristine-induced peripheral neuropathy is said to be reversible after discontinuing the drug, although this may require months, and in some patients, the resolution may be incomplete.³⁵ There is limited evidence that suggests that neuraxial anesthesia and peripheral nerve blocks can be safely and effectively used in patients with preexisting peripheral neuropathy without significant risk of worsening of the neuropathy. The concentration of local anesthetic should be reduced, epinephrine should be avoided, and a nerve localization technique that minimizes the likelihood of intraneuronal injection should be used in efforts to minimize the risk of worsening the neuropathy.³⁸ Neuropathies do worsen during the perioperative period in a small number of patients whether general or regional anesthesia is used. Thus, a careful risk-benefit assessment and informed decision making along with each individual patient is essential.

The syndrome of hyponatremia associated with high urinary sodium and inappropriate secretion of arginine vasopressin hormone has occasionally been observed during vincristine therapy. An effect on the autonomic nervous system can cause paralytic ileus and abdominal pain, which commonly develops during vinblastine therapy. Urinary retention, tenderness of the parotid glands, dryness of the mouth, and sinus tachycardia are other occasionally experienced manifestations of altered autonomic nervous system activity. Transient mental depression is most likely to occur on the second or third day of treatment with vinblastine. Alopecia appears to occur more frequently with vincristine than with vinblastine. Vinorelbine may cause chest pain, bronchospasm, dyspnea, and pulmonary infiltrations.

Taxanes

Paclitaxel (active extract from the Pacific yew tree) and docetaxel (more water-soluble semisynthetic derivative) share a broad spectrum of similar chemotherapeutic activity against breast, lung, ovarian, and bladder cancer.³⁹ Both drugs are also active against lymphoid malignancies. Taxanes block the function of the mitotic apparatus by impeding the normal function of microtubules. Unlike vinca alkaloids, which affect the rates of tubulin polymerization, the taxanes inhibit microtubule depolymerization in a dose-dependent manner. The microtubules formed in the presence of taxanes are extraordinarily stable and dysfunctional, thereby causing the death of the cell by disrupting the normal microtubule dynamics required for cell division.

Taxanes are rapidly cleared from the plasma despite extensive binding to proteins. The volume of distribution is large, suggesting binding to cellular proteins, possibly tubulin. Renal clearance accounts for a small proportion (<10%) of total clearance. Hepatic metabolism, biliary excretion, fecal elimination, or extensive tissue binding appears to be responsible for most of the plasma clearance.

Side Effects

Taxanes are associated with myelosuppression, peripheral neuropathy, and alopecia. Severe neurotoxicity precludes the administration of high doses of taxanes. The peripheral neuropathy is characterized by sensory symptoms such as numbness and paresthesia in a glove-and-stockinet distribution. Patients may also experience transient taxane-associated arthralgias and myalgias for several days following treatment. Cardiac effects, including dysrhythmias, myocardial ischemia, and transient asymptomatic bradycardia may be more common with paclitaxel than docetaxel. Docetaxel seems to have unique vascular permeability properties, which may result in peripheral edema, pleural effusion, and ascites. Fluid retention produced by docetaxel is dose-dependent and may be decreased by pretreatment with dexamethasone. Docetaxel also produces skin toxicities including an erythematous maculopapular rash on the forearms and hands. Hypersensitivity reactions (flushing, bronchospasm, dyspnea, systemic hypotension) caused by direct release of histamine or other chemical mediators may occur in 25% to 30% of patients treated with taxanes.³⁹

Estramustine

Estramustine exerts its chemotherapeutic effects by inhibition of microtubule assembly and depolymerization. This drug also binds to an estramustine-binding protein in prostate tissue explaining the possible usefulness of this drug as part of combination therapy of hormone-refractory prostate cancer. Although it increased the prostate-specific antigen response rate in these patients, it did not improve overall survival or grade 3 or 4 toxicity.⁴⁰

Signal Transduction Modulators

Signal transduction modulators (hormones) that may be useful in the treatment of neoplastic disease include antiestrogens, antiandrogens, aromatase inhibitors, gonadotropin-releasing drugs, and progestin. Normal cell division results from the interaction of growth factors with specific receptors. This interaction initiates a series of enzyme reactions (signal transduction), culminating in activation of nuclear transcription factors that produce cell proliferation molecules. Mutations in cancer cells result in uncontrolled cell proliferation using activated signaling pathways. Hormonal treatment of cancer disrupts growth factor receptor interactions.

Progestins

Progestational drugs are useful in the management of patients with endometrial carcinoma. Progestins act by reducing the production of hormones that stimulate the neoplastic endometrium.

Estrogens and Androgens

Malignant changes in the breast and prostate often depend on hormones for their continued growth. For example, prostatic cancer is stimulated by androgens, whereas orchectomy or estrogens (diethylstilbestrol) slow the growth of the tumor cells. Eventually, prostatic tumors become insensitive to the lack of androgen or the presence of estrogens, presumably because of the survival of progressively undifferentiated cells that favor the emergence of cell types that no longer depend on androgens for their growth.

Malignant tissues that are responsive to estrogens contain receptors for the hormone, whereas malignant tissues lacking these receptors are unlikely to respond to hormonal manipulation. The onset of action of hormone therapy is slow, requiring 8 to 12 weeks.

Hypercalcemia may be associated with androgen or estrogen therapy, requiring adequate hydration in an attempt to facilitate renal excretion of calcium. Plasma calcium concentrations should be determined in patients receiving treatment with these hormones.

Antiestrogens

Antiestrogens, such as tamoxifen, are useful in the treatment of breast cancer that expresses estrogen or progesterone receptors. The estrogen receptor resides in the cytosol and, upon occupation by estradiol, is transported to the nucleus, where it activates genes (including those genes that encode proliferation molecules) containing estrogen-response elements. Tamoxifen binds to estrogen receptors and disrupts receptor interactions with estrogen in some but not all estrogen-responsive tissues. For example, tamoxifen is antiestrogenic in breast and ovarian tissue but is estrogenic in the uterus, liver, and bone. As a result, tamoxifen is effective in the prevention and treatment of breast cancer but produces undesired estrogen side effects including deep vein thrombosis (<1% of patients), endometrial cancer (about 0.3% of patients), and early menopausal symptoms (hot flashes). In addition, tamoxifen lowers plasma cholesterol concentrations and increases bone density.

The response to tamoxifen is proportional to the degree of expression of estrogen receptors in breast tumors. Tamoxifen is of little benefit in women with breast cancer that does not express hormone receptors. After surgical removal of the primary breast tumor, adjuvant treatment of women with tumors that are hormone receptor-positive decreases the odds of recurrence by more than 30%. Other antiestrogens that may have greater selectivity for breast estrogen receptors include raloxifene, toremifene, and fulvestrant.

Antiandrogens

Antiandrogens such as flutamide, bicalutamide, and nilutamide are competitive antagonists of the interactions between androstenedione and androgen receptors. Flutamide is a nonsteroidal antiandrogenic that possesses pure antiandrogenic activity when metabolized to its hydroxylated derivative. Administered with other drugs that decrease androgen production, flutamide is an effective treatment for hormone-dependent prostate cancer. Androgenic blockade results in feminizing side effects in men, including gynecomastia, hot flashes, and loss of facial hair. Skeletal muscle weakness and development of osteoporosis reflect a male menopause-like state. Flutamide can induce methemoglobinemia.⁴¹ Pulse oximetry readings in the presence of methemoglobinemia can overestimate the hemoglobin saturation levels. At levels of methemoglobinemia of greater than 35%, the pulse oximetry readings tend to approach a minimal level of 85%.⁴²

Aromatase Inhibitors

Aromatase is an enzyme complex consisting of two proteins: aromatase cytochrome P450 (CYP19) and nicotinamide adenine dinucleotide phosphate cytochrome P450 reductase. Inhibition of aromatase blocks the conversion of androgens to estrone in peripheral tissues including breast tissue. The high affinity of the aromatase inhibitors anastrozole and letrozole for CYP19 results in intense inhibition of estrogen effects on responsive receptors. Inhibition of aromatase is an effective treatment for postmenopausal women with breast cancer, in which the greatest source of estrone comes from conversion of androstenedione to estrone in liver, skeletal muscles, and fat. Exemestane is a steroidal aromatase inhibitor that binds to the enzyme complex and promotes enzyme degradation.

A partial medical hypophysectomy is produced by luteinizing hormone-releasing hormone agonists, such as leuprolide, buserelin, and goserelin, which inhibit secretion of follicle-stimulating hormone and luteinizing hormone by downregulating receptors that respond to these hormones. The result is insignificant plasma concentrations of sex hormones and palliation of breast and prostate cancer.

Monoclonal Antibodies

Numerous antibody-based therapies for treatment of cancer have emerged and are commonly used. This class of drugs includes the monoclonal antibodies trastuzumab, pertuzumab, bevacizumab, alemtuzumab, rituximab, obinutuzumab, polatuzumab vedotin, daratumumab, etc., which target specific antigen sites on cancer cells.⁴³ The mechanisms of action of these agents are specific and varied depending on the target. Common side effects include infusion reactions and cytopenias.

Trastuzumab is a monoclonal antibody that binds to the human epidermal growth factor receptor 2 (HER2) protein. It mediates antibody-dependent cellular cytotoxicity by inhibiting proliferation of cells that overexpress the HER2 protein. Similarly, pertuzumab is a recombinant humanized monoclonal antibody that targets the extracellular HER2 dimerization domain. It thereby inhibits HER2 dimerization and blocks HER downstream signaling, which halts cell growth and initiates apoptosis. Because pertuzumab binds to a different HER2 epitope than trastuzumab, they are often used in combination to synergistically inhibit HER2 signaling more completely. Both are used to treat HER2+ breast cancers.⁴⁴ Bevacizumab is a recombinant, humanized monoclonal antibody which binds to and neutralizes vascular endothelial growth factor by which it prevents its association with endothelial receptors fms-like tyrosine kinase 1 and kinase insert domain receptor. This results in inhibition of angiogenesis and thereby halts microvascular growth and subsequently growth of all tissues including malignant tissue. Bevacizumab is currently used in the treatment of many solid tumors including cervical cancer, colorectal cancer, glioblastoma, hepatocellular cancer, non-small cell lung cancer, ovarian cancer, and renal cell cancer. Additionally, it is often discontinued several weeks prior to surgery because it can result in postoperative wound healing complications.

Alemtuzumab targets CD52, which is a nonmodulating antigen present on the surface of B and T lymphocytes, most monocytes, macrophages, natural killer cells, and a subpopulation of granulocytes. Antibody-dependent lysis of cells occurs after it binds to CD52. It is used to treat B-cell chronic lymphocytic leukemia. Common side effects include myelosuppression, rash, fever, and cytomegalovirus disease/viremia. More commonly, rituximab is used to treat leukemias and lymphomas. Rituximab binds to a specific protein (CD20) that is expressed on the cell surface of B cells; the rituximab-CD20 complex appears to improve the effectiveness of natural killer cells in killing these diseased cells. Obinutuzumab is a glycoengineered type II

anti-CD20 monoclonal antibody used in the treatment of chronic lymphocytic leukemia and follicular lymphoma. It binds to the CD20 antigen expressed on the surface of pre-B- and mature B-lymphocytes, which activates complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity, and antibody-dependent cellular phagocytosis that all result in cell death.⁴⁵ Polatuzumab vedotin is an antibody drug conjugate directed at CD79b, a B-cell specific cell surface protein commonly expressed in mature B-cell lymphomas.⁴⁶ This complex is internalized within the cell and produces monomethyl auristatin E, a microtubule-disrupting agent that induces cell cycle arrest in the G2/M phase and apoptosis. It is used to treat relapsed/refractory diffuse large B-cell lymphoma. Finally, daratumumab is a newer monoclonal antibody that binds to the CD38 glycoprotein found on hematopoietic cells and leads to cell death. It is commonly used in the treatment of multiple myeloma and amyloidosis. Common side effects of these drugs include infusion reactions and myelosuppression.

Other Targeted Therapies

Many targeted therapies continue to emerge and are employed in the treatment of various cancers. A few of the most notable are discussed in the following text. Imatinib is a tyrosine kinase inhibitor that binds to the extracellular domain of a specific tyrosine kinase (BCR-ABL) and inhibits this enzyme, which is responsible for cell proliferation in Philadelphia chromosome–positive chronic myelocytic leukemia. Major side effects include peripheral edema, liver function abnormalities, rash, and myelosuppression. Venetoclax is another targeted therapy that selectively inhibits the antiapoptotic protein BCL-2. BCL-2 is overexpressed in chronic lymphocytic leukemia cells and acute myeloid leukemia cells. Venetoclax binds to BCL-2 and restores the apoptotic process by displacing proapoptotic proteins. The major side effects of venetoclax are tumor lysis syndrome and neutropenia.

Sorafenib is a multikinase inhibitor that targets intracellular Raf kinases (CRAF, BRAF, and mutant BRAF) and cell surface kinase receptors (VEGFR1, VEGFR2, VEGFR3, platelet-derived growth factor receptor β [PDGFR- β], cKIT, FMS-like tyrosine kinase 3, rearranged during transfection [RET], and RET/PTC [papillary histotype]) to inhibit tumor growth and angiogenesis, whereas sunitinib does the same by inhibiting multiple receptor tyrosine kinases including platelet-derived growth factors (PDGFR α and PDGFR β), vascular endothelial growth factors (VEGFR1, VEGFR2, and VEGFR3), fms-like tyrosine kinase 3, colony-stimulating factor type 1 receptor, and glial cell line–derived neurotrophic factor (GDNF), which signals through activation of RET tyrosine kinase. Major side effects include diarrhea, hand-foot syndrome, stomatitis, and cardiotoxicity. Myocardial infarction is more of a concern with use of sunitinib.

Vaccines

Two types of vaccines aimed at preventing infection related to subsequent development of cancer have been approved by the U.S. Food and Drug Administration: vaccines against the hepatitis B virus, which can cause liver cancer, and vaccines against specific human papillomaviruses, which are responsible for the majority of cases of cervical cancer. Vaccines are also being developed that may include genetic manipulation of cancer cells to make them more antigenic and thus susceptible to immune responses. For example, virus-derived proteins expressed by virus-infected cancer cells can serve as promising sources of markers for vaccines to target. The U.S. Food and Drug Administration has approved one therapeutic cancer vaccine (sipuleucel-T) for certain men with metastatic castrate-resistant prostate cancer that is asymptomatic or minimally symptomatic. Sipuleucel-T is a cellular immunotherapy consisting of extracting autologous peripheral blood mononuclear cells (PBMCs) by leukapheresis (primarily dendritic cells that serve as antigen-presenting cells). The patient's PBMCs are then cultured (activated) with a recombinant human protein (PAP-GM-CSF) consisting of prostatic acid phosphatase linked to granulocyte-macrophage colony-stimulating factor. Prostatic acid phosphatase is a protein produced at abnormally high levels and overexpressed by prostate cancer cells. The patient's PBMCs are then reinjected into the patient every 2 weeks for a total of three times, stimulating T-cell immune response against prostate cancer cells. Side effects include severe infusion-related reaction, fevers, chills, fatigue, back pain, myalgias, and citrate toxicity.^{47,48}

Immunomodulatory Drugs

Immunomodulatory drugs are a novel class of orally available antineoplastic agents that are used to treat multiple myeloma. This class of drugs includes thalidomide, lenalidomide, and pomalidomide. Thalidomide is a first-generation immunomodulatory drug, whereas lenalidomide and pomalidomide are second-generation immunomodulatory drugs. They contain an imide group and work by producing antiproliferative, antiangiogenic, and immunomodulatory effects. Notable side effects of these drugs include somnolence, peripheral neuropathy, myelosuppression, venous thromboembolism, and teratogenicity.

Cancer Immunotherapies

Cancer immunotherapies is a class of cancer-directed therapy that has recently emerged over the past several years and includes immune checkpoint inhibitors and adoptive cell therapies. It has completely transformed the treatment algorithms for multiple solid tumor and hematologic malignancies due to the potential of these therapies to induce durable responses. Immune checkpoint inhibitors are usually used in the treatment of advanced disease and at times as adjuvant treatment. Immune checkpoint inhibitors bind to immune checkpoint proteins (cytotoxic T-lymphocyte-associated antigen 4 [CTLA-4] and programmed cell death-1 [PD-1]) as well as PD-1 ligands (PD-L1) expressed on multiple tissues including malignant tissues. Through this mechanism, they overcome tumor-mediated inhibition of T-cell function and reprogram T-cells to attack cancer cells and thereby induce antitumor responses. Disinhibition of T-cell function by immune checkpoint inhibitors can lead to a spectrum of inflammatory side effects affecting different organ systems collectively referred to as *immune-related adverse events* (i.e., pneumonitis, colitis, hypophysitis, hepatitis, nephritis, etc.). The exact pathophysiology driving this is not fully understood but is thought to be related to a combination of pathways involving autoreactive T cells, autoantibodies, and cytokines. The mainstay of therapy is typically corticosteroids and other immunosuppressive drugs in addition to temporarily holding or discontinuing further treatment with immune checkpoint inhibitors depending on severity. Duration of treatment may often last for several weeks depending on clinical course. Ipilimumab, nivolumab, pembrolizumab, atezolizumab, and durvalumab are the commonly used immune checkpoint inhibitors ([Table 42.4](#)).⁴⁹

TABLE 42.4

Immune checkpoint inhibitors and their approved indications in oncology practice in the United States^a

Class of agent and agent	Approved tumor types in the United States
CTLA-4 inhibitor	
Ipilimumab ^b	Melanoma ^c
PD-1 inhibitor	
Nivolumab ^b	Melanoma, ^c NSCLC, ^c RCC, ^c Hodgkin lymphoma, ^c UCC, ^c head and neck sqCC, ^c dMMR and MSI-H colorectal cancer, hepatoma
Pembrolizumab	Melanoma, ^c NSCLC, ^c Hodgkin lymphoma, ^c UCC, ^c head and neck sqCC, MSI-H or dMMR solid tumors, gastric and gastroesophageal junction cancers, cervical cancer
PD-L1 inhibitor	
Atezolizumab	UCC, ^c NSCLC ^c
Durvalumab	UCC, NSCLC (as consolidation after chemoradiotherapy for stage III)

Abbreviations: CTLA-4, cytotoxic T-lymphocyte antigen 4; dMMR, mismatch repair deficient; MSI-H, microsatellite instability high; NSCLC, non-small cell lung cancer; PD-1, programmed cell death protein 1; PD-L1, programmed cell death protein ligand 1; RCC, renal cell carcinoma; sqCC, squamous cell carcinoma; UCC, urothelial cancer.

^aData from Nishino M, Hatabu H, Hodi FS. Imaging of cancer immunotherapy: current approaches and future directions. *Radiology*. 2019;290(1):9-22.

^bIpilimumab and nivolumab combination therapy is also approved for metastatic melanoma and advanced RCC and for dMMR and MSI-H colorectal cancer.

^aThe indications have also been approved in the European Union.

Ipilimumab is a recombinant human immunoglobulin G1 monoclonal antibody that targets CTLA-4. Nivolumab is a fully human immunoglobulin G4 monoclonal antibody that selectively inhibits PD-1 activity by binding the PD-1 receptor and blocking PD-1 ligands (PD-L1 and PD-L2) from binding. Similarly, pembrolizumab is a highly selective anti-PD-1 humanized monoclonal antibody that works by using the same mechanism. In contrast, atezolizumab is a humanized monoclonal antibody immune checkpoint inhibitor that binds to PD-L1 to selectively prevent it from interacting with PD-1 and B7.1 (CD80) receptors. This restores antitumor T-cell function, which PD-L1 typically downregulates by binding to PD-1 and B7.1 (CD80) receptors. Similarly, durvalumab is a human immunoglobulin G1 \times monoclonal antibody, which works via the same mechanism. Whereas the combination of ipilimumab/nivolumab is used to treat metastatic melanoma, nivolumab and pembrolizumab are used alone and in conjunction with other cancer-directed therapies to treat a variety of solid tumors and Hodgkin lymphoma. Atezolizumab and durvalumab are typically used in the treatment of urothelial cancer and non–small cell lung cancer ([Tables 42.5](#) and [42.6](#)).

TABLE 42.5

Presentation of immune-related adverse events by organ system^a

Organ system	Presentation	
	Routinely reported events	Rare or infrequently reported events
Dermatologic	Rash (maculopapular, lichenoid), pruritus, vitiligo	Acneiform rash, alopecia, bullous pemphigoid, papulopustular rosacea, psoriasis, Stevens-Johnson syndrome, toxic epidermal necrosis, DRESS, Sweet syndrome
Gastrointestinal	Diarrhea, colitis, lichenoid mucositis	Enteritis, gastritis, pancreatitis
Endocrine	Hypothyroidism, hyperthyroidism, thyroiditis, hypophysitis	Autoimmune type 1 diabetes, primary adrenal insufficiency
Hepatic	Transaminitis, hepatitis	—
Respiratory	Pneumonitis	Pleuritis, sarcoidosis
Rheumatic	Arthralgia, inflammatory arthritis, myalgia	Dermatomyositis, myositis, polymyalgia-like syndrome, Sjögren syndrome, vasculitis
Renal	Increase in serum creatinine, nephritis	—
Ophthalmic	—	Uveitis, conjunctivitis, scleritis, episcleritis, blepharitis, retinitis
Neurologic	Sensorimotor neuropathy	Aseptic meningitis, autonomic neuropathy, encephalitis, facial nerve palsy, Guillain-Barré syndrome, myasthenia gravis, posterior reversible leukoencephalopathy, transverse myelitis
Hematologic	—	Aplastic anemia, hemolytic anemia, idiopathic thrombocytopenia purpura, lymphopenia, hemophilia
Cardiac	—	Cardiomyopathy, myocarditis, pericarditis

Abbreviation: DRESS, drug rash with eosinophilia and systemic symptoms.

TABLE 42.6

Management algorithm for immune-related adverse events by grade^a

Event type	Management considerations
Grade 1	<ul style="list-style-type: none"> Asymptomatic, minimally symptomatic, or radiographic or laboratory change Supportive care or localized therapy (or both) as outpatient Immune checkpoint inhibitor continued Increased monitoring
Grade 2	<ul style="list-style-type: none"> Mild-to-moderate or persistent symptoms Delay immune checkpoint inhibitor if corticosteroids are required.^b Oral corticosteroids (0.5-1 mg/kg)^c and supportive care as outpatient <i>Pneumocystis jiroveci</i> prophylaxis per institutional guideline and clinical judgment if 20 mg or more prednisone daily for more than 1 month; calcium and vitamin D; and prophylaxis for lower gastrointestinal bleed if risk factors are present Taper corticosteroids over at least 2-4 weeks when event reaches grade 1 or less. Increased monitoring; treat as grade 3 if symptoms persist.
Grade 3	<ul style="list-style-type: none"> Moderate-to-severe symptoms Delay immune checkpoint inhibitor; discontinue if risk exceeds benefit. Oral corticosteroids (1-2 mg/kg)^c as outpatient; consider intravenous route and hospitalization if symptoms persist for 48-72 hours, with or without additional immunosuppression^d if no response to intravenous corticosteroids in 48-72 hours. <i>Pneumocystis jiroveci</i> prophylaxis per institutional guideline and clinical judgment if 20 mg or more prednisone daily for more than 1 month; calcium and vitamin D; and prophylaxis for lower gastrointestinal bleed if risk factors are present. Taper corticosteroids over at least 4-6 weeks when event reaches grade 1 or less. Consider organ specialist consultation.
Grade 4	<ul style="list-style-type: none"> Life-threatening symptoms Hospitalization for intravenous corticosteroids (2-4 mg/kg),^c with or without additional immunosuppression^d if no response to intravenous corticosteroids in 48-72 hours. <i>Pneumocystis jiroveci</i> prophylaxis per institutional guideline and clinical judgment if 20 mg or more prednisone daily for more than 1 month; calcium and vitamin D; and prophylaxis for lower gastrointestinal bleed if risk factors are present. Taper corticosteroids over at least 4-8 weeks when event reaches grade 1 or less. Consult with organ specialist. Discontinue immune checkpoint inhibitor.

^aReprinted with permission from Myers G. Immune-related adverse events of immune checkpoint inhibitors: a brief review. *Curr Oncol.* 2018;25(5):342-347. Copyright 2018 Multimed Inc.

^bImmune checkpoint inhibitor can be continued in grade 2 dermatologic or endocrine toxicity.

^cPrednisone equivalent.

^dAntithymocyte globulin, cyclophosphamide, infliximab, intravenous immunoglobulin, mycophenolate mofetil, tacrolimus, vedolizumab.

Adoptive Cellular Therapy

Chimeric Antigen Receptor T Cells

The chimeric antigen receptor (CAR) T cells are autologous T cells that have been genetically engineered to express the intracellular domain of a T-cell receptor fused to the antigen-binding domain of a B-cell receptor. These reprogrammed T cells recognize and attack tumor cells bearing the tumor-specific antigen when reinfused. The CAR T cells are currently used to target CD19, which is the pan B-cell antigen. Two CAR T-cell products are currently available. Tisagenlecleucel has been approved for treatment of refractory B-cell precursor acute lymphoblastic leukemia and diffuse large B-cell lymphoma, whereas axicabtagene ciloleucel has been approved for relapsed diffuse large B-cell lymphoma. Promising studies have shown the potential to

induce durable complete remissions in subsets of patients. Serious and potentially life-threatening side effects of these therapies include cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS). CRS is thought to be due to T-cell activation after engagement of CAR T cells with their targets leading to systemic inflammatory response. This is often characterized by fevers, hypotension, respiratory failure, fatigue, and myalgias. It is generally treated based on grade. Broad-spectrum antibiotics and supportive care are used for low-grade CRS. Tocilizumab (interleukin 6 receptor antagonist) and high-dose steroids are used to manage severe CRS. ICANS, however, typically presents with a diverse range of neurologic symptoms including tremor, dysgraphia, mild expressive aphasia, apraxia, and impaired attention. Expressive aphasia is a specific symptom of ICANS. It is thought that ICANS may be due to diffusion of cytokines into the CNS or trafficking of CAR T cells into the CNS. Treatment usually involves high-dose steroids, and tocilizumab is not particularly effective in treating ICANS but may be administered to treat concurrent severe CRS.⁴⁹

Psychopharmacologic Drugs*

Updated by: Peter J. van Roessel • Carolyn Rodriguez • Pamela Flood

Psychopharmacologic therapeutics comprise a range of medicines targeting diverse aspects of central nervous system neuronal function. They include drugs developed primarily for psychiatric indications as well as those “borrowed” from neurology, anesthesiology, and other fields of medicine. Although traditionally organized by indication (eg, anxiolytics, antidepressants, antipsychotics) or by chemistry (eg, benzodiazepines, tricyclics, phenothiazines), the increasing application of particular medication classes across diagnostic boundaries—and growth in the number and diversity of compounds—has made such classification systems untenable. A recent initiative has thus sought to rationalize and destigmatize nomenclature via reference to the pharmacologic target and presumed mode of action of each drug.^{1,2} This chapter attempts to incorporate this emerging organizational framework into the traditional categories by indication.

The development of relatively safe and effective psychotherapeutic drugs now permits the vast majority of individuals with psychiatric disorders to be treated in ambulatory settings. Medications for adults with depressive mood disorders or anxiety are most typically prescribed by primary care physicians, although those with severe or persistent mental illness are more often treated by psychiatrists. Psychotropic medication use is prevalent and growing: The National Center for Health Statistics reported in 2017 that 12.7% of Americans older than age 12 years had used antidepressant medications in the past month, with markedly higher rates in women, non-Hispanic white Americans, and the elderly.³ Data for antipsychotic medications similarly confirms widespread use, with nearly 24 million prescriptions issued in the United States in 2017 for just the top 6 most commonly prescribed antipsychotic drugs.⁴

It is widely accepted that anesthesia can be safely administered to patients who are using medications for treatment of mental illness.^{5,6} There appears to be growing acceptance that the problem of drug interactions between psychopharmacologic drugs and drugs administered in the perioperative period is less than previously perceived and that past recommendations for discontinuation of antidepressant therapy are not justified. Nevertheless, vigilance for potential drug interactions remains important.⁷ In particular, many psychotropic and anesthetic drugs interact with various receptors for serotonin and are metabolized by common liver enzymes. This is particularly important in elderly patients, who use psychotropic medications at higher rates and who are at particular risk for toxicity. Furthermore, the anesthesiologist needs to understand the pharmacology as well as the expected and potential side effects of the drugs on which their patient is maintained. This chapter provides these important details.

Drugs With Primarily Serotonergic Activity

The majority of drugs classified by indication as “antidepressants” have impacts on either serotonergic neurotransmission or on both serotonergic and noradrenergic neurotransmission.⁸ Considering the wide range of disorders for which these drugs are effective—including diverse manifestations of depressive, anxiety, and chronic pain disorders—the term *antidepressant* has become a misnomer (**Table 43.1**). The broad spectrum of effectiveness of the antidepressant drugs does not imply a common pathophysiology but rather reflects the diverse roles of monoamine neurotransmitters in the human nervous system.

Mechanisms of Action

The precise mechanisms by which the serotonergic drugs work is unknown, but their direct actions serve to increase the amount of serotonin in synapses or to alter serotonin receptor signaling. Nevertheless, the characteristic time course of clinical improvement with these drugs is not explained by these acute effects. Neurobiologically, increases in synaptic serotonin or action at serotonin receptors occur promptly after initiation of antidepressant therapy; yet, clinical improvement typically does not occur for 2 to 4 weeks. Symptomatic improvement has thus been suggested to reflect a number of adaptive changes resulting from chronic exposure to these drugs. Such changes may include the desensitization of serotonin 5-HT_{1A} inhibitory autoreceptors, which at baseline respond to extracellular serotonin by downregulating presynaptic serotonin release and thus constrain serotonin levels, changes in synaptic plasticity of mood and anxiety-relevant neural circuits via drug-mediated effects on neurotrophic signaling pathways, or changes in hippocampal neurogenesis.⁹⁻¹²

Serotonin Receptors

Serotonin signaling is mediated by a large family of serotonin receptors, organized into seven families: six of which signal via excitatory or inhibitory G proteins and one of which (5-HT₃) is a ligand-gated cation channel. Receptors are found throughout tissues of the body, and serotonin signaling regulates a diverse array of processes outside of the central nervous system (CNS), including gastrointestinal motility, genital arousal, vascular tone, hematopoiesis, platelet aggregation, and aspects of the inflammatory response.¹³ In the CNS, serotonergic projections emanate broadly from a small group of neurons in the raphe nuclei of the brainstem—reaching targets throughout the cortex, subcortex, cerebellum, and spinal cord and regulating the release of a broad array of neurotransmitters and peptide hormones. Serotonin thus influences a broad array of social, affective, and cognitive functions including mood, sleep, aggression, appetite, sex, and memory.¹⁴ Although the specific relation of various receptor subtypes to behaviorally relevant circuits and clinical outcomes is poorly understood and beyond the scope of this chapter, a few specific receptors warrant particular mention. As noted earlier, the inhibitory receptor 5-HT_{1A} is of particular relevance to antidepressant responses—both as an autoreceptor regulating serotonergic neuronal activity and also postsynaptically in target tissues relevant to the neurogenic effects of antidepressant treatment.^{9,12} The excitatory 5-HT_{2A} receptor—agonized by the second-generation “atypical” antipsychotic (SGA) drugs and agonized by hallucinogens such as lysergic acid diethylamide and psilocin—localizes to cortical layer 5 and serves to regulate aspects of cognition, attention, and working memory relevant to psychosis; 5-HT_{2A} signaling is further implicated in the most threatening manifestations of serotonin syndrome. Lastly, the 5-HT₃ receptor regulates nausea and vomiting and may be beneficially targeted by psychotropic medications with 5-HT₃ antagonist activity, such as mirtazapine, in addition to the dedicated 5-HT₃ antagonist antiemetic drugs.

Serotonin Reuptake Inhibitors

Considered broadly, the serotonin reuptake inhibitors (SRIs) comprise several classes of medications which bind and inhibit the serotonin transporter protein (SERT), blocking reuptake of serotonin from the synaptic cleft into the presynaptic neuron and thus enhancing serotonergic neurotransmission. They are among the

most widely used medications for treatment of psychiatric conditions. Specific classes of SRIs, the relevant drugs, and general indications are discussed in the following text.

Adverse Effects

Common side effects of SRIs include insomnia, agitation, headache, nausea, and diarrhea ([Table 43.2](#)). However, these side effects are typically transient—arising when SRIs are first introduced or when dosages are increased—and typically remit fully within a week or two of their emergence. One exception to this pattern, however, and a prominent cause of noncompliance with SRI therapy, is drug-induced sexual dysfunction. This typically dose-dependent adverse effect occurs in both men and women and typically manifests as a requirement for greater sexual stimulation in order to attain orgasm, or complete anorgasmia in more severe cases.¹⁵

Treatment-Emergent Suicidality

In September 2004, the U.S. Food and Drug Administration (FDA) recommended a “black box” warning for newer antidepressant drugs—primarily selective serotonin reuptake inhibitors (SSRIs).¹⁶ This controversial warning was based on evidence that suicidal thoughts and behaviors—although not completed suicides—occurred in children and adolescents at higher rates during treatment with SRIs compared to placebo. This warning has been criticized as harmful, in as much as its issuance led to decreased rates of diagnosis and treatment for depressed children and adolescents, and no data has suggested any increase in suicidal behavior in adults taking SRI medications.¹⁷

Serotonin Reuptake Inhibitor Discontinuation Syndrome

Abrupt discontinuation of SRI medications can lead to withdrawal symptoms, and the SRI discontinuation syndrome has received increasing attention as a clinical concern influencing management.^{18,19} Withdrawal symptoms are most commonly associated with SRIs that have short elimination half-lives (eg, paroxetine, venlafaxine, duloxetine), and they rarely emerge during dose decreases but rather develop when medication is fully discontinued—typically 3 to 4 half-lives (2-3 days) after a last dose. Vulnerability to withdrawal effects is higher in patients with longer histories of SRI use. The SRI discontinuation syndrome may be associated with dizziness, flu-like myalgias, pronounced irritability, insomnia, and visual disturbances. Yet the most common and pathognomonic symptom is a type of paresthesia, commonly referred to as “brain zaps” and typically described as recurrent, momentary electrical shock-like sensations in the head. The SRI withdrawal symptoms do not respond to benzodiazepines but do remit rapidly with reintroduction of SRI medication.¹⁸ Although not considered medically dangerous, the constellation of withdrawal symptoms can be intensely distressing for patients and, in acute care settings, may complicate interpretations of clinical condition or response to therapies. As such, in the absence of explicit contraindications, outpatient SRI medications should be continued in acute care settings, particularly for those individuals with long histories of SRI use. When SRI medications must be discontinued, a gradual and “hyperbolic” tapering course is recommended, with large initial decrements followed by increasingly smaller steps as the taper progresses.²⁰

Bleeding Risk

Relevant to acute care and operative settings, SRI-associated bleeding risks have long been a focus of theoretical concern, given serotonin’s role in platelet aggregation. In older adults, SRI use has been associated with increased relative risk (although low absolute risk) of upper gastrointestinal bleeding and intracerebral brain hemorrhage.²¹⁻²³ At the same time, the combination of SRI medications with anticoagulant therapies is common and not specifically contraindicated, with a recent study finding no significant increase in major bleeding events for anticoagulated outpatients taking SSRIs.²⁰ In surgical settings, where understandably data aggregation is challenging given the diversity of surgical contexts in which SRI-related risks have been studied, a recent systematic review has suggested that risks of increased bleeding are real and should be weighed in context against the risks of medication discontinuation, including risks of symptom relapse or discontinuation syndrome.²⁴

Hyponatremia

Clinically significant hyponatremia is another potential complication of SRI medication relevant to acute care settings. Although decreases in serum sodium have been reported as an adverse effect of a number of different psychopharmacologic drugs, most attention has been given to the association between drugs used to treat depression and new-onset hyponatremia. A 2004 prospective longitudinal study of older adults with major depressive disorder who started the SRI paroxetine showed that 12% developed hyponatremia, defined as serum sodium below 135 mEq/L, with a mean time to onset of approximately 9 days after initiating the drug.²⁵ Urine osmolality and serum antidiuretic hormone analysis suggested that hyponatremia after paroxetine was consistent with the syndrome of inappropriate secretion of antidiuretic hormone. Subsequent population-based studies and reviews of case reports suggest that many classes of antidepressant medication can cause hyponatremia but that the risk with SRI medications is clearly higher than that seen with serotonin receptor modulating medications or the tricyclic antidepressant medications.^{26,27} The risk appears higher in women, the elderly, and those with cardiovascular comorbidity. Risk of hyponatremia appears to diminish with time after medication initiation. For chronic users of SRI medication, there appears to be no increased risk of new-onset hyponatremia. Thus, for acute care patients with clinically significant hyponatremia, use and duration of use of SRI antidepressants should be assessed. Recently initiated SRI antidepressants should be considered for discontinuation, and for those patients requiring antidepressant use, a switch to non-SRI medications, such as mirtazapine, may be considered.^{28,29}

Serotonin Syndrome

Serotonin syndrome, attributed to toxic levels of synaptic and extracellular serotonin, is a rare but serious complication of SRI use.^{30–32} It classically presents with the triad of neuromuscular excitability, autonomic nervous system excitability, and mental status changes (**Table 43.3**).^{33–35} Signs of neuromuscular excitability may include hyperreflexia, clonus, myoclonus, opsoclonus, or rigidity; autonomic changes may include diarrhea, tachycardia, hypertension, fever, diaphoresis, flushing, and mydriasis; mental status changes may range from insomnia, agitation, and anxiety through to confusion or coma. In severe cases, life-threatening hyperpyrexia and rigidity may lead to rhabdomyolysis, multiorgan failure, and disseminated intravascular coagulation.

TABLE 43.3

Serotonin syndrome and commonly mistaken diagnoses

Diagnosis	Inciting agent	Time course	Fever	Physical examination
Serotonin syndrome	Serotonergic agonists	<12 hours	>41°C	Mydriasis, drooling, sweating, hyperactive reflexes, agitation, coma
Anticholinergic syndrome	Muscarinic antagonists	<12 hours	<39°C	Mydriasis, dry mouth and skin, normal reflexes, delirium
Neuroleptic malignant syndrome	Dopamine antagonists	1-3 days after dosing	>41°C	Normal pupils, drooling, pallor, lead-pipe rigidity, hyporeflexia, alert mutism, coma
Malignant hyperthermia	Volatile anesthetic and/or succinylcholine	Onset immediate to 24 hours after administration	To 46°C	Normal pupils, mottled sweaty skin, total body rigidity, hyporeflexia, agitation

Adapted from Boyer EW, Shannon M. The serotonin syndrome. *N Engl J Med.* 2005;352(11):1112-1120.

Serotonin syndrome typically results from the combination of different classes of serotonergic medications—characteristically, and most dangerously, the combination of an SRI with a monoamine oxidase inhibitor (MAOI). It rarely results from the use of a single serotonergic medication at therapeutic doses, although a large case series described its occurrence in approximately 15% of SRI overdoses.³⁶ Rigidity and hyperpyrexia—the most severe consequences of serotonin syndrome—appear to reflect excessive stimulation via the 5-HT_{2A} receptor and thus causative agents are generally those drugs that broadly increase extracellular serotonin, including serotonin precursors, stimulants of serotonin release, SRIs, or MAOIs.³⁷

Serotonergic modulators that agonize specific serotonin receptors other than 5-HT_{2A} appear to present low risk. However, a number of nonpsychiatric or nonserotonergic medications may trigger serotonin syndrome in conjunction with SRI or other serotonergic medication use. These include linezolid; methylene blue; lithium; the opioids pethidine, tramadol, fentanyl, and dextromethorphan; stimulants such as amphetamine, methamphetamine, methylphenidate, and phentermine; muscle relaxants including cyclobenzaprine; and recreational drugs including ecstasy. Opioids deserve particular mention: Although many inhibit SERT and thus increase synaptic serotonin levels, additional mechanisms including disinhibition of serotonergic neurons³⁸ or direct engagement with serotonin receptors may underlie serotonin syndrome risk.³⁹ This risk of serotonin syndrome precipitated by opioid drugs was addressed in a 2016 FDA drug safety communication.⁴⁰ Drugs that cause rapid elevations in serum level of SRI medications via pharmacokinetic interactions may also lead to serotonin syndrome, including ciprofloxacin, fluconazole, ritonavir, and erythromycin.

Serotonin syndrome is of particular concern in the recovery room or intensive care unit (ICU) as serotonergic agonists—known or unknown—may have been administered during surgery, reflecting the many serotonergic agonists in common use during anesthesia. Symptoms of serotonin syndrome characteristically develop acutely, within hours after introduction of a causative medication. The rapidity of onset and its association with changes in pharmacotherapy serve to differentiate serotonin syndrome from other entities in differential diagnosis, such as alcohol withdrawal, encephalitis, and neuroleptic malignant syndrome (see [Table 43.3](#)). Prompt recognition is critical to limiting associated morbidity. Primary interventions include discontinuation of serotonergic medications and prompt initiation of supportive care, including benzodiazepines or other neuromuscular sedatives, intravenous (IV) fluids when indicated, and in life-threatening cases, cooling, paralysis, and ventilation. Animal studies and case report literature have suggested the benefit of 5-HT_{2A} antagonist interventions, including cyproheptadine. However, these interventions have not been systematically assessed in clinical trials.⁴¹

Selective Serotonin Reuptake Inhibitors

The paradigmatic class of SRI medication—the SSRIs—includes the drugs fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram, and escitalopram. The SSRIs selectively block neuronal reuptake of serotonin and are among the most widely prescribed psychotropic medications. The SSRIs are first-line pharmacotherapy for the majority of depressive and anxiety disorders, including major depressive disorder, generalized anxiety disorder, panic disorder, social anxiety disorder, posttraumatic stress disorder, and obsessive-compulsive disorder.

Compared with the tricyclic medications (the historical antecedents of the SSRIs as first-line treatment for depressive and anxiety disorders), SSRIs have greatly reduced anticholinergic properties, minimally contribute to postural hypotension, do not cause delayed conduction of cardiac impulses, and do not appear to have a major effect on the seizure threshold. Perhaps the most important advantage of SSRIs compared with the tricyclic medications is their relative safety when taken in overdose.⁴²

Different SSRIs have different side effect profiles, and patients who do not respond to one drug or who fail to tolerate it may do well on a different SSRI.⁴³ Standard practice thus dictates trying more than one SSRI before moving to another class of medication. Although efficacy of the various SSRIs is generally similar, differences within this class of drugs are in anticholinergic effects, elimination half-lives, and propensity for pharmacokinetic interactions. Notably, **fluoxetine** is a potent inhibitor of CYP2D6 and a moderate inhibitor of CYP2B6 and CYP2C9, and it has a markedly longer elimination half-life than other SRI medications, at 3 to 6 days (half-life is prolonged with chronic use, as fluoxetine inhibits its own metabolism). In addition, fluoxetine has an active metabolite, norfluoxetine, with a half-life of up to 16 days, similarly longer with chronic administration. The long half-life of fluoxetine means that its discontinuation is rarely complicated by withdrawal syndromes but also means that a long period of washout (6 weeks) is required before MAOIs or other medications contraindicated with SRIs may be added. **Paroxetine** has a markedly shorter half-life, at 21 hours, and has more significant anticholinergic effects. Use of paroxetine is thus often complicated by anticholinergic adverse effects, and discontinuation is frequently complicated by withdrawal syndrome. **Sertraline** has a half-life of 25 hours and fewer cytochrome P450 (CYP450) enzyme interactions than

fluoxetine, although may be more likely to contribute to dyspepsia and other gastrointestinal symptoms. **Fluvoxamine**, FDA approved solely for obsessive-compulsive disorder, is relatively rarely used given its short half-life (12-22 hours) requiring twice-daily dosing, a higher incidence of gastrointestinal side effects with initiation, and potent inhibition of numerous CYP450 enzymes leading to many clinically significant drug-drug interaction risks. **Citalopram** and its active S-enantiomer **escitalopram** are both widely used and well tolerated, with minimal pharmacokinetic interactions. However, citalopram may cause dose-dependent QT interval prolongation, which can place patients at risk for torsades de pointes.^{44,45} Escitalopram may also prolong the QT interval but possibly to a lesser degree. Thus, citalopram should be used with caution in patients at risk for prolonged QT intervals.

Serotonin-Norepinephrine Reuptake Inhibitors

Many SRI medications have pharmacologic activities in addition to SERT blockade. The serotonin-norepinephrine reuptake inhibitors (SNRIs) inhibit the norepinephrine transporter (NET) as well as SERT and are commonly prescribed as first- or second-line medications for depressive and anxiety disorders. The SNRIs include **venlafaxine**, **desvenlafaxine**, and **duloxetine** as well as **milnacipran** and **levomilnacipran**. Although various analyses have suggested that more noradrenergic medications may have superior efficacy for treatment of depression, any greater benefit of SNRIs is weighed against suggestions of poorer tolerability and concerns related to the potential hemodynamic consequences of increased noradrenergic tone.^{46,47} Although statistically significant elevation of systolic and diastolic blood pressure is observed with SNRI versus SSRI medications, observed blood pressure elevations are generally not clinically significant.⁴⁸ Other suggestions of increased risk relative to benefit for SNRIs include, for venlafaxine at least, elevated overdose-associated risk associated with proconvulsant and cardiac side effects.⁴⁹

Utility in Chronic Pain Syndromes

One symptom domain for which SNRI medications do clearly have superior efficacy over SSRI medications is for chronic pain.^{50,51} Together with the norepinephrine reuptake inhibitor tricyclic medications, SNRIs are commonly used off-label to treat various forms of chronic pain. Duloxetine and milnacipran have FDA-approved indications for the treatment of specific chronic pain syndromes. Although comparative efficacy for chronic pain of SNRIs versus tricyclics or other noradrenergic medications is not established—in part as the variability of pain syndromes studied limits comparison—these medicines are thought to work by increasing engagement of descending pain systems that suppress ascending pain transmission and regulate pain homeostatically.⁵² The emergence of benefit for pain at doses lower than those used for depression—and the more rapid onset of analgesic benefit than antidepressant benefit—suggests that mechanisms of treatment for these two distinct conditions are different.⁵⁰

Tricyclic Serotonin Reuptake Inhibitors

The broad category of SRI medications also includes **clomipramine**, a tricyclic medication with FDA approval for the treatment of obsessive-compulsive disorder, and **imipramine**, a tricyclic medication approved for treatment of depression and childhood enuresis. Clomipramine is a potent inhibitor of SERT, while imipramine potently inhibits both SERT and NET. The major metabolites of both medications, desmethylclomipramine (DCMI) and desipramine, respectively, additionally function as NET inhibitors, and thus, both medicines functionally serve as SNRIs. Like other tricyclic medications, clomipramine and imipramine have significant anticholinergic and antihistaminergic properties as well as greater propensity for related adverse effects, including cardiac dysrhythmia; so drug levels should be obtained as a routine aspect of patient management when doses are increased, new pharmacokinetic interactions are encountered, or toxicity is suspected.

Notably, the major metabolite of clomipramine, DCMI, like other tricyclic compounds, is predominantly noradrenergic. Attention should be paid to clomipramine versus DCMI plasma levels when drugs with inhibition of cytochromes 2D6 or 3A4 are added; yet, 3A4 inhibition via grapefruit juice has also been suggested as a therapeutic adjunct to alter clomipramine to DCMI ratios and increase the relative serotonergic activity of orally administered clomipramine.⁵³

Serotonin Multimodal Drugs

A number of drugs modulate specific serotonin receptors in addition to SERT blockade. These “multimodal” serotonergic drugs include **vortioxetine** and **vilazodone**, both of which are partial agonists at the 5-HT_{1A} receptors in addition to their primary SRI activity. Vortioxetine additionally acts as an antagonist at other serotonin receptors 5-HT₃ and 5-HT₇. The efficacy in major depression and the adverse effect profile of these medications is generally similar to that of the SSRIs, although vortioxetine may have additional benefit for depression-related cognitive impairment.⁵⁴ Vortioxetine notably has a long half-life, at 66 hours, whereas the half-life of vilazodone is approximately 25 hours, similar to that of the nonfluoxetine SSRIs.

Trazodone is another multimodal serotonergic drug, formally indicated for treatment of major depressive disorder but far more widely used at low dose as a safe and nondependency forming hypnotic for insomnia. Although it has some SRI activity, it is distinct from vilazodone and vortioxetine, particularly at low doses, in that its effects are primarily through serotonin receptor modulation, particularly antagonism of 5-HT_{2A} receptors and weaker 5-HT_{1A} partial agonism. Its efficacy as a hypnotic may reflect its 5-HT_{2A} antagonism as well as weak histamine H₁ receptor agonism and potent α₁ antagonism. Anticholinergic activity is minimal. An α₁ antagonism contributes to orthostasis and dry mouth as prominent side effects of the medication as well as the risk of priapism. Trazodone lacks effects on conduction of cardiac impulses but, on rare occasions, has been associated with cardiac dysrhythmias. The half-life of trazodone is relatively brief (3-9 hours). Notably, an active metabolite of the medication, meta-chlorophenylpiperazine, may contribute to false positives on urine tests for 3,4-methylenedioxymethamphetamine (MDMA). Toxicity associated with an overdose is less than what accompanies overdose of tricyclic drugs or MAOIs. Although relatively contraindicated in combination with MAOIs due to risk of serotonin syndrome, given minimal SRI activity at low doses, low-dose trazodone has been used in combination with MAOIs for treatment of MAOI-emergent insomnia in a case series and an open-label study.^{55,56}

Nefazodone is chemically related to trazodone, but with fewer α₁-adrenergic blocking properties. Like trazodone, nefazodone works primarily via 5-HT_{2A} antagonism and 5-HT_{1A} agonism, and it similarly weakly inhibits reuptake of serotonin. Unlike trazodone, nefazodone also weakly inhibits norepinephrine and dopamine reuptake. Despite significant α₁ antagonism, the risk of priapism may be less than that conveyed by trazodone. It has antihistaminergic activity, and thus is significantly sedative, but has minimal anticholinergic activity. The principal side effects are nausea, dry mouth, and sedation. Orthostatic hypotension may occur. Nefazodone-induced inhibition of CYP450 results in elevated plasma concentrations of benzodiazepines, antihistamines, and of protease inhibitors used in the treatment of human immunodeficiency virus infection. Rare cases of serious hepatotoxicity have been reported in association with nefazodone use, and liver enzymes should be monitored after initiation. Combination therapy with an MAOI is not recommended.

Serotonin Agonist

Buspirone is a serotonin agonist indicated for the short-term treatment of generalized anxiety disorder. This drug is a partial agonist at serotonin receptors, particularly 5-HT_{1A}, resulting in decreased serotonin turnover and anxiolytic effects. Downstream effects include elevations in cortical norepinephrine and dopamine, which may be attributable to the α₂-antagonist activity of a major metabolite, 1-(2-pyrimidinyl)piperazine.⁵⁷ As an anxiolytic, buspirone has no direct effects on γ-aminobutyric acid (GABA) receptors and thus no pharmacologic cross-reactivity with benzodiazepines, barbiturates, or alcohol. Buspirone lacks sedative, anticonvulsant, and skeletal muscle-relaxing effects characteristic of benzodiazepines. Absorption from the gastrointestinal tract is 100%, but extensive hepatic first-pass metabolism decreases bioavailability to 4%. The elimination half-time is 2 to 11 hours. Buspirone does not produce dependence and does not appear to be highly toxic if taken in overdose. The principal disadvantage seems to be a slow onset of effect (1-2 weeks), which may be interpreted as ineffectiveness by patients experiencing acute anxiety.

Serotonin and Norepinephrine Multimodal Drugs

Mirtazapine is a tetracyclic drug approved for treatment of major depressive disorder that functions—particularly at higher doses—to increase norepinephrine release through α_2 antagonism. It additionally is a 5-HT_{1A} agonist and antagonizes 5-HT_{2A} and 5-HT_{2C} receptors, activity that may facilitate antidepressant response by increasing cortical norepinephrine and dopamine release.⁵⁸ It is additionally a potent H₁-blocking antihistamine. Mirtazapine's antihistamine activity makes it highly sedating, and together with its 5-HT_{2C} antagonism, highly appetite stimulating. The sedation and weight gain limit its clinical use but make it a helpful drug for those suffering with depression characterized by insomnia and anorexia. Its 5-HT₃ antagonism further renders it an effective antiemetic. It is thus often used for medically ill, depressed patients, for example, those experiencing nausea and anorexia in conjunction with cancer treatment.⁵⁸ Mirtazapine has no appreciable SERT inhibition and no serotonin agonist activity. It thus does not cause sexual or other side effects typical of SRIs, nor is it thought to convey significant risk of serotonin syndrome. Furthermore, it has little anticholinergic activity and relatively low cardiac toxicity in overdose.

Doxepin is a tricyclic norepinephrine and serotonin multimodal drug, approved for treatment of depression and insomnia (at low dose), and yet differs from mirtazapine in that it is a potent SERT and NET inhibitor. It functions as a 5-HT_{1A} agonist and as an antagonist at multiple receptors, including α_1 , 5-HT_{2A}, 5-HT_{2C}, and muscarinic acetylcholine receptors. It is also a highly potent H₁ antihistamine, which contributes to its benefit at low dose as a hypnotic treatment for insomnia and as an antipruritic. **Amitriptyline** is similarly a tricyclic serotonin and norepinephrine multimodal drug, with both SERT and NET inhibition, indicated for major depressive disorder and at lower doses for chronic pain treatment. Amitriptyline additionally acts as an agonist or inverse agonist at 5-HT_{2A} and 5-HT_{2C} receptors as well as more weakly at 5-HT₃, 5-HT₆, and 5-HT₇ receptors. Like doxepin, it also has highly potent H₁ antagonism, resulting in significant sedative effects. The primary metabolite of amitriptyline is nortriptyline, itself an active NET inhibitor approved for treatment of major depressive disorder.

Like other tricyclics, doxepin and amitriptyline have significant anticholinergic side effects and are highly dangerous in overdose. Given potential for toxicity, monitoring of plasma level is essential at antidepressant doses and in the presence of relevant CYP450 inhibitors (2D6 for doxepin; 2C19 and 3A4 for amitriptyline). The mean elimination half-life of doxepin is 17 hours, with a more slowly cleared metabolite, nordoxepine, at 31 hours. Half-life for amitriptyline is variable, from 10 to 50 hours.

Monoamine Oxidase Inhibitors

Classed as serotonin, norepinephrine, and dopamine enzyme inhibitors (**phenelzine**, **isocarboxazid**, **moclobemide**, **selegiline**) or serotonin, norepinephrine, and dopamine multimodal drugs (**tranylcypromine**), the MAOIs constitute a heterogeneous group of drugs, which block the enzyme that metabolizes biogenic amines, increasing the availability of these neurotransmitters in the CNS and peripheral autonomic nervous system. Historically, MAOIs have been one of the most potent psychopharmacologic interventions for depressive disorders, but they are used much less commonly now because their administration is complicated by side effects (hypotension, insomnia), lethality in overdose, and lack of simplicity in dosing. In particular, most patients treated with MAOIs must follow specific diet guidelines because of the potential for pharmacodynamic interactions with dietary tyramine that can result in systemic hypertension ([Table 43.4](#)). However, many patients with major depression who do not respond to other antidepressants improve with MAOIs. Given their historical and ongoing importance in the psychopharmaceutical armamentarium, and unique risk of potentially dangerous drug-drug interactions, they are discussed in detail in the following text as a functional class.

TABLE 43.4

Dietary and drug restrictions in patients treated with monoamine oxidase inhibitors

Prohibited foods

Aged cheese

Cured, smoked, or processed meats

Preserved, salted, or pickled fish
Liver
Fermented soy products, including sauces
Yeast extracts
Fava or other broad beans
Dried or overripe fruits
Red wine, draft or homebrewed beer, some liqueurs
Prohibited drugs
Serotonin reuptake inhibitors (SSRIs, SNRIs, many TCAs)
Cold or allergy medications
Nasal decongestants
Sympathomimetic drugs
Opioids (especially meperidine)

Abbreviations: SNRIs, serotonin-norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Monoamine Oxidase Enzyme System

Monoamine oxidase (MAO) is a flavin-containing enzyme found principally on outer mitochondrial membranes. The enzyme functions via oxidative deamination to inactivate several monoamines, including dopamine, serotonin (5-hydroxytryptamine), norepinephrine, and epinephrine. The MAO is divided into two subtypes (MAO-A and MAO-B) based on different substrate specificities ([Figure 43.1](#)).^{6,7} The MAO-A preferentially deaminates serotonin, norepinephrine, and epinephrine, whereas MAO-B preferentially deaminates phenylethylamine. Platelets contain exclusively MAO-A, and the placenta exclusively MAO-B. About 60% of human brain MAO activity is of the A subtype.

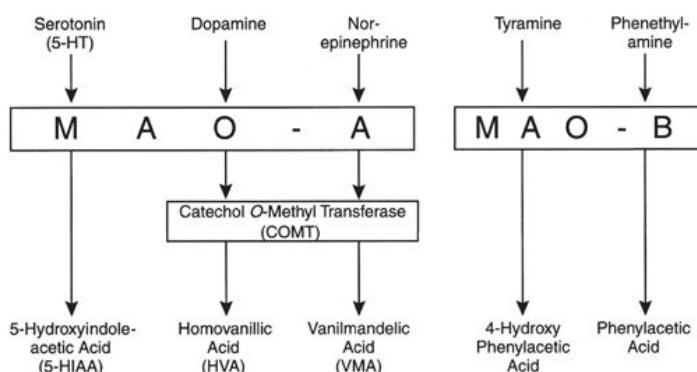

FIGURE 43.1 The two forms of monoamine oxidase enzyme (MAO-A and MAO-B) exhibit substrate selectivity. Reprinted with permission from Michaels I, Serrins M, Shier NQ, et al. Anesthesia for cardiac surgery in patients receiving monoamine oxidase inhibitors. *Anesth Analg*. 1984;63(11):1041-1044. Copyright © 1984 International Anesthesia Research Society.

Mechanisms of Action

The MAOIs act by forming a stable, irreversible complex with MAO enzyme, especially with cerebral neuronal MAO.⁵⁹ As a result, the amount of neurotransmitter (monoamines including serotonin, norepinephrine, and dopamine) available for release from CNS neurons increases. These effects, however, are not limited to the brain, and the concentration of monoamines also increases in the sympathetic nervous system. Because MAOIs cause irreversible enzyme inhibition, their effects are prolonged, as the synthesis of new enzyme is a slow process.

Due to its location in the outer mitochondrial membrane, MAO in neurons is only capable of deaminating substrates that are free within the cytoplasm and are unable to gain access to substrates once they are bound in the storage vesicles. As a result, cytoplasmic concentrations of monoamines are maintained at a low level.

Adverse Effects

The most common serious side effect of MAOIs is orthostatic hypotension, which may be especially prominent in elderly patients. Orthostatic hypotension may reflect accumulation of the false neurotransmitter octopamine in the cytoplasm of postganglionic sympathetic nerve endings. Release of this less potent vasoconstrictor in response to neural impulses is the most likely explanation for orthostatic hypotension as well as the antihypertensive effect that has been associated with chronic MAOI therapy.⁶⁰

Phenelzine has anticholinergic-like side effects and may produce sedation in some patients. Tranylcypromine has no anticholinergic side effects but has mild stimulant effects, which may cause insomnia and may contribute to transient increases in blood pressure commonly observed after dosing. Decreased libido and anorgasmia are serotonergic side effects of MAOIs. Some patients complain of paresthesias, which may respond to pyridoxine therapy. Weight gain is a common side effect of treatment with MAOIs, except for the stimulant-like tranylcypromine, which tends to be an appetite suppressant. Peripheral edema may also be seen with MAOI use. Hepatitis is a rare complication of MAOI therapy. Effects of MAOIs on the electroencephalogram (EEG) are minimal and not seizure-like, which contrasts with tricyclic antidepressants. Also in contrast with tricyclic antidepressants is the failure of MAOIs to produce cardiac dysrhythmias.⁶¹ Although elderly patients may be more susceptible to side effects, the dosage of MAOIs is the same in the elderly as in younger adults. Elderly persons often have higher levels of MAO, and the metabolism of these drugs does not seem to be affected by age.

Dietary Restrictions

The MAO enzyme present in the liver, gastrointestinal tract, kidneys, and lungs seems to perform a protective function in deactivating circulating monoamines. In particular, this enzyme appears to form the initial defense against monoamines absorbed from foods, such as tyramine and β-phenylethanolamine, which would otherwise produce an indirect sympathomimetic response and precipitous hypertension. The MAO-A is found in the gastrointestinal tract and liver, where it acts to metabolize bioactive amines such as tyramine. The MAOIs used in the United States as antidepressants inhibit MAO-A and MAO-B nonselectively. Selegiline, when used to treat Parkinson disease, selectively inhibits MAO-B, and patients do not need to follow a tyramine-free diet. At high doses (30 mg per day), however, even selegiline becomes a nonselective MAOI, making dietary precautions necessary (see [Table 43.4](#)). A form of selegiline has also been developed for transdermal administration in major depressive disorder, with aim to increase CNS levels while minimizing gut exposure. As with oral dosing, following a tyramine-restricted diet is not required with lower doses (6 mg/24 hours) but is required at higher doses (eg, 12 mg/24 hours).

Because patients treated with MAOIs cannot metabolize dietary tyramine and other monoamines, these compounds can enter the systemic circulation and be taken up by sympathetic nervous system nerve endings. This uptake can elicit massive release of endogenous catecholamines and result in a hyperadrenergic crisis characterized by hypertension, hyperpyrexia, and cerebral vascular accident. Therefore, patients taking MAOIs should be instructed to report promptly the onset of serious headache, nausea, vomiting, or chest pain. The precipitous hypertension resembles that which occurs with the release of catecholamines from a pheochromocytoma. In emergency settings, treatment of hypertension is with a peripheral vasodilator, such as nitroprusside. Cardiac dysrhythmias that persist after control of systemic blood pressure are treated with lidocaine or a β-adrenergic antagonist.

Drug Interactions

In addition to interacting with foods, MAOIs can interact adversely with opioids, ephedrine, tricyclic antidepressants, and SSRIs. These interactions can result in hypertensive crises or, most concerning, serotonin syndrome, characterized by CNS excitation, with potential for delirium, seizures, and death. Because MAOIs

are used uncommonly but have significant interactions with sympathomimetics and opioids that are commonly used in anesthesia, it is important for the anesthesiologist to be vigilant to identify them in the patient's medication list.

Opioids and Monoamine Oxidase Inhibitors

Administration of meperidine to a patient treated with MAOIs may result in an excitatory (type I) response (agitation, headache, skeletal muscle rigidity) or a depressive (type II) response characterized by hypotension, depression of ventilation, and coma.⁶² Enhanced serotonin activity in the brain (ie, serotonin syndrome) is presumed to be responsible for excitatory reactions evoked by meperidine. Meperidine is capable of inhibiting neuronal serotonin uptake. Slowed breakdown of meperidine due to *N*-demethylase inhibition by MAOIs is the presumed explanation for hypotension and depression of ventilation. About 20% of MAOI-treated patients experience excitatory reactions in response to meperidine. There is evidence that meperidine toxicity is increased only when both MAO-A and MAO-B are inhibited.⁷ Other opioids that are synthetic phenylpiperidines (fentanyl, sufentanil, alfentanil) have been associated with adverse reactions in patients treated with MAOIs, although the incidence seems to be less than with meperidine.⁶³ Morphine does not inhibit uptake of serotonin, but its opioid effects may be potentiated in the presence of MAOIs.⁶⁴ As noted previously, the FDA has warned about the risk of serotonin syndrome for all opioid medications when administered in conjunction with serotonergic drugs.⁴⁰

Sympathomimetics and Monoamine Oxidase Inhibitors

There is no experimental evidence to support the recommendation that all sympathomimetic drugs be avoided in patients treated with MAOIs. The most consistent observation has been an occasional patient who experienced an exaggerated systemic blood pressure response after the administration of an indirect-acting vasopressor such as ephedrine. The hypertensive response is presumed to reflect an exaggerated release of norepinephrine from neuronal nerve endings. If needed, the use of a direct-acting sympathomimetic (phenylephrine) is preferable to an indirect-acting drug, keeping in mind that receptor hypersensitivity may enhance the systemic blood pressure response to these drugs as well. Regardless of the drug selected, the recommendation is to decrease the dose to about one-third of normal, with additional titration of doses based on cardiovascular responses.⁷

Overdose

Overdose with an MAOI is reflected by signs of excessive sympathetic nervous system activity (tachycardia, hyperthermia, mydriasis), seizures, and coma. Treatment is supportive in addition to gastric lavage. Dantrolene has been suggested as a treatment for skeletal muscle rigidity and associated symptoms of hypermetabolism after an overdose with MAOIs.⁶⁵

Management of Anesthesia

In the past, it was a common recommendation to discontinue MAOIs 2 to 3 weeks before elective surgery based on the concern that life-threatening cardiovascular and CNS instability could occur during anesthesia and surgery when these drugs were present. This policy of drug withdrawal seems to be based more on anecdotes and isolated responses than on controlled scientific studies. Furthermore, discontinuation of effective therapy potentially places patients at risk for their psychiatric disturbances. There is general consensus that anesthesia can be safely administered in most patients being chronically treated with MAOIs.^{7,66-68} When anesthesia is administered to patients treated with MAOIs, it remains prudent to consider certain drug interactions and to avoid certain drugs, particularly meperidine.^{7,59}

Selection of Drugs Used During Anesthesia

The anesthetic technique selected should minimize the possibility of sympathetic nervous system stimulation or drug-induced hypotension. Regional anesthesia as in parturients is acceptable, recognizing that ephedrine should be avoided in the treatment of resulting hypotension.⁶² An advantage of regional anesthesia is

postoperative analgesia such that the need for opioids is negated or minimized. Etomidate and thiopental have been administered to MAOI-treated patients undergoing electroconvulsive therapy without adverse effects. Responses to nondepolarizing neuromuscular-blocking drugs are not altered by MAOIs.

Drugs With Primarily Noradrenergic Activity

Tricyclic and Related Antidepressants

In the decades prior to the approval and clinical implementation of the safer SSRI and SNRI drugs—in the late 1980s and early 1990s—**tricyclic antidepressant medications** were the standard of care for treatment of major depressive disorder. From a neuroscience-based nomenclature perspective, they are primarily norepinephrine reuptake inhibitors (particularly the secondary amines **desipramine** and **nortriptyline**). Yet, they also include drugs with both NET and SERT inhibition, or primary SERT inhibition (the tertiary amines **amitriptyline**, **imipramine**, **clomipramine**), as well as direct action at serotonin receptors, as noted previously. Despite their somewhat divergent functional activity; their shared side effect profile, pharmacology, and toxicities warrants consideration of these medications as a chemical class.

Mechanisms of Action

Tricyclic antidepressants act at several transporters and receptors, but their antidepressant effect is likely produced by blocking the reuptake (uptake) of serotonin and/or norepinephrine at presynaptic terminals, thereby increasing the availability of these neurotransmitters.

As with the more recently developed SRI medications, despite immediate effects of SERT and NET inhibition on increasing synaptic monoamine levels, therapeutic antidepressant effects typically only emerge after 2 to 3 weeks of treatment. It seems likely that potentiation of monoaminergic neurotransmission in the brain is only an early event in a complex cascade of events that eventually results in an antidepressant effect. Indeed, chronic administration of these drugs is associated with (1) decreased sensitivity of postsynaptic β_1 and serotonin 2 receptors and of presynaptic α_2 receptors and (2) increased sensitivity of postsynaptic α_1 receptors. Compared to other SRI drugs, tricyclics tend to be more sedative given their antihistaminergic potency, which may convey particular benefit for depressed patients with prominent insomnia.

Utility in Chronic Pain Syndromes

As with other SNRIs or norepinephrine reuptake inhibitors, tricyclic antidepressants may be useful in the treatment of chronic neuropathic pain and other chronic pain syndromes including fibromyalgia. Although there is no consensus on the mechanism of pain relief, beyond SERT and NET inhibition, potentiation of endogenous opioids in the CNS and antiinflammatory effects may contribute as mechanisms of benefit.⁶⁹ The antiinflammatory action of tricyclics has been shown in neuronal cell culture and may reflect structural similarities of tricyclic antidepressants to local anesthetics and known sodium channel blockade.^{58,70} In major depressive disorder, levels of an inflammatory marker, C-reactive protein, predict relative antidepressant benefit of nortriptyline over an SSRI.⁷¹ Because many chronic pain syndromes include an inflammatory component, it is possible that the clinical efficacy of tricyclic antidepressants in chronic pain patients is due to inhibition of an overactive inflammatory system.⁷² As with depression, the efficacy of tricyclic antidepressants for chronic pain syndromes may be limited by a narrow therapeutic index and tolerability of side effects.

Adverse Effects

Tricyclic antidepressants are highly effective, yet they have been supplanted as first-line drugs in many clinical situations because of their unfavorable side effect profile, largely resulting from their anticholinergic, antiadrenergic, and antihistaminic properties. The side effects of tricyclic antidepressants occur frequently and most commonly manifest as (1) anticholinergic effects, (2) cardiovascular effects, and (3) CNS effects (**Table 43.5**). Individual variation in the incidence and type of side effects may be related to the plasma concentrations of the tricyclic antidepressant and its active metabolites. Fortunately, the therapeutic window

for the treatment of chronic pain encompasses lower doses, and it is possible to measure plasma concentration to guide therapy.

TABLE 43.5

Pharmacologic treatment of tricyclic antidepressant overdose

Symptom	Treatment
Seizures	Diazepam Sodium bicarbonate Phenytoin
Ventricular cardiac dysrhythmias	Sodium bicarbonate Lidocaine Phenytoin
Heart block	Isoproterenol
Hypotension	Crystalloid or colloid solutions Sodium bicarbonate Sympathomimetics Inotropics

Data from Frommer DA, Kulig KW, Marx JA, Rumack B. Tricyclic antidepressant overdose: a review. *JAMA*. 1987;257(4):521-526, with permission.

Anticholinergic Effects

The anticholinergic effects of tricyclic antidepressants are prominent, especially at high doses. Amitriptyline causes the highest incidence of anticholinergic effects (dry mouth, blurred vision, tachycardia, urinary retention, slowed gastric emptying, ileus), whereas desipramine produces the fewest such effects (see [Table 43.5](#)). Anticholinergic delirium may occur in elderly patients even at therapeutic doses of these drugs. Serious anticholinergic toxicity may reflect the results of polypharmacy with more than one anticholinergic drug (eg, a tricyclic plus an over-the-counter preparation to treat diarrhea or insomnia). Elderly patients have greater sensitivity to anticholinergic effects.

Cardiovascular Effects

Orthostatic hypotension and modest increases in heart rate are the most common cardiovascular side effects of tricyclic antidepressants, presumably reflecting NET inhibition. Orthostatic hypotension may be particularly hazardous in elderly patients, who are at increased risk of fractures when they fall. The risk of hypotension during general anesthesia in patients treated with tricyclic antidepressants is low but has been reported.⁷³ Although cardiac dysrhythmia is a known risk of tricyclic overdose, at therapeutic levels, previous suggestions that tricyclic antidepressants increase the risks of cardiac dysrhythmias and sudden death have not been substantiated.⁷⁴ Furthermore, in the absence of severe preexisting cardiac dysfunction, tricyclic antidepressants at therapeutic levels lack adverse effects on left ventricular function and may even possess cardiac antidysrhythmic properties.⁷⁵ Orthostatic hypotension can be particularly problematic after ambulatory anesthesia and should be carefully anticipated on patients taking tricyclic antidepressants.

Tricyclic antidepressants depress conduction of cardiac impulses through the atria and ventricles, manifesting on the electrocardiogram (ECG) as prolongation of the P-R interval, widening of the QRS complex, and flattening or inversion of the T wave. Their quinidine-like properties may reflect slowing of sodium ion flux into cells, resulting in altered repolarization and conduction of cardiac impulses.

Nevertheless, changes on the ECG are probably benign and gradually disappear with continued therapy.⁷⁴

Central Nervous System Effects

Amitriptyline and doxepin produce the greatest degree of sedation. Weakness and fatigue are attributable to CNS effects and may resemble those seen in patients treated with phenothiazine dopamine antagonists. Tricyclic antidepressants—especially maprotiline and clomipramine—lower the seizure threshold, raising the

question of the advisability of administering these drugs to patients with seizure disorders or to those receiving other potentially proconvulsant drugs. Children seem to be especially vulnerable to the seizure-inducing effects of tricyclic antidepressants. Treatment with tricyclic antidepressants may enhance the CNS-stimulating effects of enflurane. Extrapyramidal reactions are rare, although a fine tremor develops in about 10% of patients, especially the elderly. The potential impact on neurologic diseases is important to consider when tricyclic antidepressants are prescribed for pain.

As mentioned earlier, tricyclic antidepressants have a narrow therapeutic index. Because of their cardiac toxicity, tendency to cause seizures, and depressant properties on the CNS, the tricyclic antidepressants may be fatal if taken in an overdose. Therapeutic plasma concentrations (parent drug plus the pharmacologically active demethylated metabolites) vary by drug but are typically in the range of 100 to 300 ng/mL, whereas toxicity is likely at levels greater than 500 ng/mL. Many individual tricyclic drugs have more clearly defined parameters: Plasma levels should not exceed 225 ng/mL when imipramine is administered; plasma levels should not exceed 125 ng/mL when desipramine is administered; the therapeutic range for nortriptyline is 50 to 150 ng/mL. When a patient treated with tricyclic antidepressants presents with signs and symptoms that could be due to mild toxicity, it is important to check a plasma concentration if possible prior to immediately stopping the drug or adding other commonly used serotonergic agonists and reuptake inhibitors. This important information will prevent sudden withdrawal or exacerbation in toxicity. This situation might occur in the ICU in a patient admitted for trauma when considering using a fentanyl infusion or in the chronic pain clinic in the common setting of polypharmacy.

Tolerance

Tolerance to anticholinergic effects (dry mouth, blurred vision, tachycardia) and orthostatic hypotension develops during chronic therapy with tricyclic antidepressants. Conversely, tolerance to desirable effects often fails to develop. As with SRI medications, it is preferable to taper tricyclic antidepressants when discontinuing. A mild withdrawal syndrome characterized by malaise, chills, coryza, and skeletal muscle aching may be attributable to super sensitivity of the cholinergic nervous system. These side effects may be difficult to differentiate from postoperative infection if these drugs are stopped acutely after surgery in the inpatient setting.

Pharmacokinetics

Tricyclic antidepressants are efficiently absorbed from the gastrointestinal tract after oral administration, reflecting high lipid solubility. Peak plasma concentrations occur within 2 to 8 hours after oral administration. Tricyclic antidepressants are strongly bound to plasma and tissue proteins, which, in combination with high lipid solubility, results in a large volume of distribution (up to 50 L/kg) for these drugs. The long elimination half-time (17-30 hours) and wide range of therapeutic plasma concentrations make once-daily dosing intervals effective.

Tricyclic antidepressants are oxidized by microsomal enzymes in the liver with subsequent conjugation with glucuronic acid. Metabolism varies 10- to 30-fold between individual patients and may be slowed in elderly patients, further supporting the critical role of plasma drug level monitoring. The elimination of tricyclic antidepressants occurs over several days, with 1 week or longer required for excretion. Many tricyclic compounds have active metabolites. Imipramine is metabolized to the active compound desipramine. Both these active compounds are inactivated by oxidation of hydroxy metabolites and by conjugation with glucuronic acid. Nortriptyline, which is the pharmacologically active demethylated metabolite of imipramine and amitriptyline, can accumulate to levels that exceed the precursors. Doxepin also appears to be converted to an active metabolite, nordoxepin, by demethylation.

Drug Interactions

The potential for toxicity related to excessive drug levels of the tricyclic medications, individual variation in metabolic rates, and need for drug-level monitoring, as noted in the preceding text, suggest that particular caution be applied with tricyclic drugs. Tricyclic antidepressants are principally metabolized by CYP450 1A2. Drugs commonly used for surgery and anesthesia that inhibit CYP450 1A2 including verapamil and

cimetidine would be likely to increase plasma concentrations. On the contrary, CYP1A2 inducers including rifampin, omeprazole, insulin, barbiturates, and carbamazepine reduce the peak concentrations and duration of action.⁷⁶ Fortunately, it is possible to measure the concentration of tricyclic antidepressants in the blood. This is particularly important in pain medicine where polypharmacy is the norm.

Sympathomimetics

The systemic blood pressure response to the administration of sympathomimetics to patients treated with tricyclic antidepressants is complex and unpredictable. It has been suggested that indirect-acting sympathomimetics may produce exaggerated pressor responses due to an increased amount of norepinephrine available to stimulate postsynaptic adrenergic receptors. Although acute administration of tricyclic antidepressants increases sympathetic nervous system synaptic activity due to norepinephrine reuptake blockade, chronic administration of these drugs may result in decreased sympathetic nervous system transmission due to downregulation of β -adrenergic receptors.^{77,78} It would appear that for patients recently started on tricyclic antidepressants, exaggerated pressor responses should be anticipated whether or not direct-acting or indirect-acting sympathomimetics are administered, although pressor responses may be more pronounced with an indirect-acting drug such as ephedrine. Smaller-than-usual doses of direct-acting sympathomimetics that are titrated to a specific hemodynamic response are recommended. For individuals chronically treated with tricyclic antidepressants (>6 weeks), administration of either a direct-acting or an indirect-acting sympathomimetic is acceptable, although a prudent approach may be to decrease the initial dose of drug to about one-third the usual dose. Conversely, conventional sympathomimetics may not be effective in restoring systemic blood pressure in patients chronically treated with tricyclic antidepressants because adrenergic receptors are either desensitized or catecholamine stores are depleted. In these patients, a potent direct-acting sympathomimetic such as norepinephrine may be the only effective management for hypotension.⁷⁹

Induction of anesthesia may be associated with an increased incidence of cardiac dysrhythmias in patients treated with tricyclic antidepressants. The tricyclic antidepressants are associated with arrhythmogenic activity, which may be a result from the potent blockade of cardiac sodium and potassium channels.⁸⁰

Anticholinergics

Because the anticholinergic side effects of drugs may be additive, the use of centrally active anticholinergic drugs for preoperative medication of patients treated with tricyclic antidepressants could increase the likelihood of postoperative delirium and confusion (central anticholinergic syndrome). Glycopyrrolate would theoretically be less likely to evoke this type of drug interaction in patients being treated with tricyclic antidepressants.

Antihypertensives

Rebound hypertension after abrupt discontinuation of clonidine may be accentuated and prolonged by concomitant tricyclic antidepressant therapy.⁸¹ Conceivably, increased plasma concentrations of catecholamines can persist for longer periods in the presence of tricyclic antidepressants that prevent uptake of norepinephrine back into sympathetic nerve endings.

Opioids

In animals, tricyclic antidepressants augment the analgesic and ventilatory depressant effects of opioids. If these responses also occur in patients, doses of these drugs should be carefully titrated to avoid exaggerated or prolonged depressant effects.

Monoamine Oxidase Inhibitors

The combination of a tricyclic antidepressant with SERT inhibition and an MAOI may result in potentially fatal serotonin syndrome. Although tricyclic medications are relatively contraindicated in combination with

MAOIs, this pairing of medications has been used historically by experts for patients with highly treatment-resistant illness.^{82–84}

Overdose

Tricyclic antidepressant overdose is life-threatening, as the progression from an alert state to unresponsiveness may be rapid.⁸⁵ Intractable myocardial depression or ventricular cardiac dysrhythmias are the most frequent terminal events. Presenting features of tricyclic antidepressant overdose include agitation and seizures followed by coma, depression of ventilation, hypotension, and hypothermia. Patients also present with striking evidence of anticholinergic effects including mydriasis, flushed dry skin, urinary retention, and tachycardia. The QRS complex on the ECG may be prolonged to greater than 100 milliseconds, and such prolongation beyond 100 milliseconds signifies increased likelihood of ventricular dysrhythmias and seizures.⁸⁶ The QRS prolongation in fact provides a better prediction of these events than plasma concentrations of tricyclic antidepressants, which have little predictive value.⁸⁶

The comatose phase of tricyclic antidepressant overdose lasts 24 to 72 hours. Even after this phase passes, the risk of life-threatening cardiac dysrhythmias persists for up to 10 days, necessitating continued monitoring of the ECG.

Treatment of a life-threatening overdose of a tricyclic antidepressant is directed toward management of CNS and cardiac toxicity (see **Table 43.5**).⁸⁵ Coma is frequently severe enough to require invasive airway support. Extrapyramidal effects and organic brain syndrome usually require supportive care only, although judicious use of physostigmine, 0.5 to 2 mg given IV, for treatment of anticholinergic psychosis may be indicated.

Seizures may precede cardiac arrest and should be treated aggressively with a benzodiazepine such as diazepam. After initial suppression of seizure activity, it may be necessary to provide sustained effects with a longer acting drug such as phenytoin. Acidosis associated with seizure activity may abruptly increase the unbound fraction of tricyclic antidepressant in the circulation and increase cardiac dysrhythmia risk. Alkalization of the plasma ($\text{pH} > 7.45$) either by IV administration of sodium bicarbonate or deliberate hyperventilation of the patient's lungs can temporarily reverse drug-induced cardiotoxicity. Lidocaine and phenytoin may be used subsequently to provide sustained suppression of cardiac ventricular dysrhythmias. Atropine is a useful treatment when tricyclic antidepressants dangerously slow atrioventricular or intraventricular conduction of cardiac impulses. Hypotension may be the result of direct tricyclic antidepressant-induced vasodilation, α -adrenergic blockade, or myocardial depression. Patients remaining hypotensive despite intravascular fluid replacement and alkalinization of the plasma may require systemic blood pressure support with sympathomimetics, inotropes, or both.

Gastric lavage may be useful in the early treatment, but this is most safely performed with a cuffed tracheal tube already in place. Activated charcoal significantly absorbs drugs throughout the gastrointestinal tract ("intestinal dialysis"). Conversely, avid protein binding of tricyclic antidepressants negates any therapeutic value of hemodialysis or drug-induced diuresis.

Other Norepinephrine Reuptake Inhibitor Drugs

The tetracyclic medication **maprotiline** is FDA approved for treatment of major depressive disorder and functions primarily like a secondary amine tricyclic with primary activity as an inhibitor of NET. It may, however, have additional effects as an antagonist at 5-HT_{2A} , 5-HT_7 , and α_1 receptors. Maprotiline is a potent antihistamine but differs from the tricyclic medications in that it is less anticholinergic. It is a CYP450 2D6 substrate and is highly protein bound with a mean elimination half-life of 51 hours. Toxicity and potential for interaction with anesthetic interventions (sympathomimetics, antihypertensives) is otherwise similar to that of the tricyclic medications.

Atomoxetine is a potent norepinephrine reuptake inhibitor with FDA approval for attention deficit hyperactivity disorder (ADHD) in children and adults. Although primarily an inhibitor of NET, animal and cell culture model experiments suggest it may also have activity on glutamatergic neurotransmission via *N*-methyl-D-aspartate (NMDA) antagonism.⁸⁷ As an NET inhibitor, it may potentiate the effect of

sympathomimetic drugs. Atomoxetine inhibits human ether-à-go-go-related gene (hERG) ion channel currents and may thus contribute to QT prolongation or predispose to arrhythmia in overdose.⁸⁸ Atomoxetine is a CYP450 2D6 substrate, and metabolism of atomoxetine is highly variable, with estimates of elimination half-life ranging from 4 to 19 hours. Measurement of atomoxetine concentration is not commonly available at clinical laboratories.

Norepinephrine Agonists

Familiar to most clinicians as antihypertensives, the α_2 agonist drugs **clonidine** and **guanfacine** have been usefully repurposed for the treatment of ADHD as non–dependency-forming alternatives or augmentations to the stimulant drugs. Both drugs have received FDA approval in long-acting formulations for treatment of ADHD in pediatric patients. Unlike the stimulants, which convey immediate attentional benefit, treatment effect of the α_2 antagonists may emerge more gradually with consistent use. Clonidine blocks a wide range of α_2 receptors, although guanfacine is highly selective for the α_{2A} receptor; thus, guanfacine may be less likely to cause the asthenic adverse effects of clonidine. Conversely, the broader antiadrenergic effects of clonidine have led to its off-label use for a number of indications, with varying levels of evidentiary support, including as a general anxiolytic, for the symptomatic management of opioid withdrawal, and for management of impulsivity and aggression in traumatic brain injury, borderline personality disorder, and other conditions. As with the cardiovascular use of these drugs, in addition to asthenia and dry mouth, rebound hypertension with abrupt discontinuation is a clinical concern, particularly when combined with β -adrenergic antagonist drugs.

Clonidine is also used in the neuraxis for pain management. A general barrier to use of drugs in the neuraxis is that proper neurotoxicology may not have been established during drug development and many of the drugs used are currently generic.^{89,90} Clonidine has a long history of use in intrathecal pumps for spasticity and analgesia. Its sole FDA indication for neuraxial use is in intrathecal pumps for intractable cancer pain. However, it is commonly used as an adjuvant in epidurals for childbirth and general surgery to facilitate local anesthetic sensory block.^{91,92} Its major dose-limiting side effect is hypotension and bradycardia. The antihypertensive effects of clonidine can be useful in the analgesic management of parturients with preeclampsia. It carries a black box warning for neuraxial use in labor and delivery that states “The risk of hemodynamic instability, especially hypotension and bradycardia, from epidural clonidine may be unacceptable in these patients. However, in a rare obstetrical, postpartum or perioperative patient, potential benefits may outweigh the possible risks.” Clonidine is also a commonly used adjuvant in peripheral nerve blocks, where it prolongs the action of local anesthetics.⁹³

Norepinephrine Dopamine Reuptake Inhibitor

Bupropion is one of the most widely prescribed psychotropic medications, with indications for treatment of major depressive disorder and for smoking cessation. It is also frequently used as a nonstimulant treatment for ADHD. Bupropion is structurally related to amphetamine—although is nondependency forming—and is thought to work via inhibition of dopamine and norepinephrine reuptake. As a first-line alternative to SSRI medications for treatment of depression, bupropion lacks the sexual side effects of serotonergic drugs. Bupropion is however associated with a greater incidence of seizures (about 0.4%) than other antidepressants, and some patients experience stimulant-like effects early in therapy that may exacerbate comorbid anxiety symptoms.⁹⁴ Bupropion has no anticholinergic effects, does not cause postural hypotension, and lacks significant effects on conduction of cardiac impulses. Bupropion is not associated with significant drug interactions. Ataxia and myoclonus have occurred rarely. Bupropion is relatively contraindicated with MAOIs given potential for hypertensive effects, and yet there is no theoretical basis for risk of serotonin syndrome. With a mechanism of action that includes inhibition of norepinephrine reuptake, it is not surprising that it has been evaluated for antineuropathic pain properties. There is some evidence for bupropion’s efficacy in neuropathic pain and inflammatory bowel disease.⁵⁰

Drugs With Primarily Dopaminergic Activity

Dopamine Norepinephrine Multimodal Drugs

Methylphenidate, like bupropion, blocks reuptake of both norepinephrine and dopamine via NET and dopamine transporter (DAT), respectively. Approved for the treatment of ADHD, methylphenidate is also a psychostimulant—increasing release of dopamine and, to a lesser extent, norepinephrine, through presynaptic mechanisms. Unlike related phenylethylamine-derived stimulants, methylphenidate appears to increase dopamine release through increasing presynaptic firing rates.⁹⁵ Common side effects of methylphenidate include appetite loss, nausea, insomnia, and anxiety. Methylphenidate may also exacerbate behavioral tics disorders. Use of the drug is associated with subjective palpitations and with mild increases in heart rate and blood pressure. Whether use of the drug may be associated with arrhythmia risk or cardiac morbidity/mortality risk is a subject of controversy and conflicting data.⁹⁶ Like other stimulant drugs, there is potential for tolerance and abuse, and with sudden discontinuation, withdrawal symptoms including fatigue, subjective cognitive cloudiness, and irritability may present. Overt risks of discontinuation are minimal, however, and holding stimulant medication in acute care settings is reasonable.

Mixed amphetamine salts (levoamphetamine and dextroamphetamine, marketed as Adderall) and **dextroamphetamine** are dopamine and norepinephrine multimodal drugs like methylphenidate that inhibit DAT and NET but also increase presynaptic dopamine release. Unlike methylphenidate, amphetamine blocks vesicular monoamine transporter 2, thus increasing presynaptic cytosolic dopamine and driving reverse transport through DAT. Amphetamines may have greater abuse liability and risk of tolerance/dependency than methylphenidate, and anesthesia providers should be aware of its abuse potential. An inactive prodrug of dextroamphetamine, **lisdexamfetamine**, requires hepatic metabolism for conversion into amphetamine and as such has a slower onset and longer duration of action, both felt to reduce abuse liability and dependency risk. Lisdexamfetamine is approved for both ADHD and binge eating disorder. Adverse effects of these stimulant drugs are similar to those of methylphenidate and include anxiety, insomnia, exacerbation of tics, and stereotypic behaviors as well as palpitations and mild increases in heart rate and blood pressure. The data is limited as to the effect these psychostimulants may have on the anesthetized patient when used at clinical doses, but it is commonly thought that the risk of intraoperative hemodynamic instability and arrhythmias may be increased. A small case study showed that patients who take chronic prescription amphetamines are hemodynamically stable during anesthesia.⁹⁷

Dopamine Reuptake Inhibitor Drugs

Modafinil and its purified enantiomer **armodafinil** are psychostimulant-like drugs that promote wakefulness. They are indicated for narcolepsy, shift-work sleep disorder, and obstructive sleep apnea. Classified as a dopamine reuptake inhibitor, modafinil is considered a highly selective and atypical DAT inhibitor.⁹⁸ Nonetheless, it has a complex pharmacodynamic profile and may further act through indirect promotion of histamine or orexin release.^{99,100} Tolerance and dependency risks are thought to be markedly less than those of amphetamines. Side effects of modafinil may include headache (common), nausea, and anxiety. Rare cases of Stevens-Johnson syndrome and other acute hypersensitivity reactions have been reported, leading to an FDA alert. As a CYP3A4 inducer, modafinil may reduce levels and thus efficacy of oral contraceptives and of opioid medications including fentanyl, oxycodone, and hydrocodone. Modafinil has been explored as an intervention to reduce postanesthesia recovery times in two small randomized studies. Although both studies showed subjective improvement in feelings of alertness and energy, the latter showed no benefit in psychomotor coordination.^{101,102}

Benztropine (also called benzatropine) is primarily anticholinergic, as a selective M₁ muscarinic acetylcholine receptor antagonist, yet also acts as an inhibitor of dopamine reuptake via DAT. However, it lacks the wakefulness promoting effects of modafinil or the reinforcing effects of methylphenidate or cocaine. It is most commonly used in conjunction with D₂ receptor-blocking drugs as a prophylactic for, or antidote to, acute drug-induced extrapyramidal symptoms (EPS). It is FDA approved for treatment of parkinsonism and for acute treatment of extrapyramidal side effects. Although indicated for acute treatment, it is not infrequently prescribed for chronic use, and as such, clinicians should be aware of the potential for additive anticholinergic effects, including urinary retention and delirium.

Dopamine Agonists

The nonergot dopamine D₃ receptor agonist drug **pramipexole** is approved for neurologic indications including Parkinson disease and restless legs syndrome. A number of smaller controlled trials and case report series have suggested the significant effect of pramipexole on depression in both bipolar II disorder and in treatment-resistant unipolar depression.^{103,104} The observation that pramipexole—but not L-dopa or other dopamine-increasing treatments—alleviates depressive symptoms in Parkinson disease has suggested that activity beyond D₃ agonism in the CNS may convey the drug's antidepressant benefit. In particular, pramipexole may have depression-relevant antiinflammatory action, perhaps via D₃ receptors on CD4 cells.¹⁰⁵ Side effects of pramipexole include common titration-rate-limiting nausea and the relatively rare but significant emergence of compulsive hedonic behaviors, including compulsive gambling, shopping, or sexual activity. Given the risks of dopamine agonist withdrawal syndrome, which has been reported for pramipexole use in Parkinson disease, a monitored taper off of pramipexole is recommended.¹⁰⁶ In perioperative context, case reports suggest the benefit of pramipexole for “restless limb” symptoms associated with general anesthesia.¹⁰⁷

Dopamine Antagonists

Dopamine antagonism, particularly at the D₂ receptor, has long been considered the central characteristic of medications used to treat psychosis.¹⁰⁸ The antipsychotic drugs are a chemically diverse group of compounds that are useful in the treatment of schizophrenia, severe bipolar disorder, depression with psychotic features, and certain organic psychoses (Table 43.6). These dopamine antagonist drugs are also used to treat Tourette disorder and certain movement disorders, and, given antiemetic effects of dopamine blockade, they are used for treatment of nausea and vomiting. Use for this latter indication became less common after a black box warning was placed on droperidol related to long QT syndrome. However, recently amisulpride—a D₂/D₃ antagonist that does not cause QT prolongation—has been found to be safe and effective for high-risk patients anesthetized with inhalational anesthetics.^{109–111}

TABLE 43.6

Comparative pharmacology of dopamine antagonist drugs

Category and drug	Sedative potency	Anticholinergic potency	Orthostatic hypotension potency	Extrapyramidal potency

Historically, medications for psychosis have been divided into “first-generation” antipsychotic (FGA) and SGA drugs—the former functioning primarily as dopamine blockers, and the latter adding serotonin antagonism among other actions.

Mechanisms of Action

As a functional class, the efficacy of antipsychotic medications—as well as a number of risks and side effects—largely reflects their shared dopamine antagonist activity. Canonically, dopamine is believed to act via four primary projections in the brain: the mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular pathways.¹¹² Although the antipsychotic efficacy of these medications is believed to come primarily via their modulation of dopamine in the mesolimbic pathway, potent dopamine blockade via the mesocortical pathway may contribute to the negative cognitive and affective symptoms of schizophrenia, blockade of the nigrostriatal pathway underlies extrapyramidal side effects, and blockade of the tuberoinfundibular pathway contributes to endocrine effects of the medications. These risks are discussed in more detail in the following text. Antiemetic benefits of the dopamine antagonist drugs reflect action on dopamine receptors in the chemoreceptor trigger zone of the medulla. All antipsychotic drugs achieve maximum clinical efficacy over a period of weeks—emphasizing the importance of distinguishing the acute receptor antagonist effects of antipsychotic drugs from their chronic effects.

First-Generation Antipsychotics

The FGA drugs, including **chlorpromazine**, **thioridazine**, **perphenazine**, and **fluphenazine** (phenothiazine drugs), as well as **haloperidol**, **loxpipamine**, and **pimozide**, among others, are now infrequently used because the SGA drugs, which include serotonin 5-HT_{2A} antagonism, have been presumed to have greater benefit for the cognitive and affective aspects of psychotic disorders and lower risks of EPS, including tardive dyskinesia.¹¹³ Nonetheless, some FGA drugs remain commonly used in emergency or acute care settings (particularly haloperidol and chlorpromazine), and a landmark study failed to show greater efficacy for SGA drugs than an FGA comparator, perphenazine.¹¹⁴

Pharmacokinetics

The phenothiazine drugs have a high therapeutic index and relatively flat dose-response curve, accounting for the remarkable safety of these drugs over a wide dose range. Even large overdoses are unlikely to cause life-threatening depression of ventilation. These drugs do not produce physical dependence, although abrupt discontinuation may be accompanied by skeletal muscle discomfort. Phenothiazines often display erratic and unpredictable patterns of absorption after oral administration. These drugs are highly lipid soluble and accumulate in well-perfused tissues such as the brain. Passage across the placenta and accumulation of drug in the fetus is possible. Avid binding to protein in plasma and tissues limits the effectiveness of hemodialysis in removing these drugs.

Metabolism

Metabolism of phenothiazines is principally by oxidation in the liver followed by conjugation. Most oxidative metabolites are pharmacologically inactive. Metabolites appear primarily in urine and to a lesser extent in bile. Typical elimination half-lives of these drugs are 10 to 20 hours, permitting once-daily dosing intervals. The elimination half-time may be prolonged in the fetus and in the elderly, who have decreased capacity to metabolize these drugs.

Antiemetic Effects

The antiemetic effects of antipsychotic drugs reflect their interaction with dopaminergic receptors in the chemoreceptor trigger zone of the medulla. These drugs seem most effective in preventing opioid-induced nausea and vomiting. Perphenazine, 5 mg IV, has been shown to be as effective as ondansetron, 4 mg IV, for prevention of postoperative vomiting after gynecologic surgery.¹¹⁵ Unlike these other antiemetics, perphenazine was not associated with side effects such as sedation or hypotension, making this phenothiazine

derivative uncommon but potentially useful as an inexpensive prophylactic antiemetic. At 70 µg/kg IV, perphenazine decreases the incidence of vomiting in children during the first 24 hours after tonsillectomy.^{[116](#)}

Adverse Effects

The use of dopamine antagonist drugs may be complicated by serious side effects. Despite the common occurrence of side effects, however, these drugs have a large margin of safety and overdoses are rarely fatal. The serious side effects described in the following text are typically associated with the FGA medications, yet, with few exceptions, all are possible with the SGA drugs as well.

Extrapyramidal Effects

Acute dystonic reactions occur in approximately 2% of treated patients and are most likely to occur within the first 72 hours of therapy. Dystonic reactions are most common in young men and in patients taking high-potency D₂ antagonist drugs. Acute skeletal muscle rigidity and cramping may develop, usually in the musculature of the neck, tongue, face, and back. Opisthotonus and oculogyric crises may occur. The sudden onset of respiratory distress in a patient on neuroleptics may reflect laryngeal dyskinesia (laryngospasm).^{[117](#)} Acute dystonia responds dramatically to diphenhydramine (25-50 mg IV). Other forms of acute extrapyramidal side effects include drug-induced akathisia, characterized by restlessness, urges to move, and inability to tolerate inactivity, as well as drug-induced parkinsonism, characterized by tremor, masked facies, and skeletal muscle rigidity, especially in elderly patients. Patients with antipsychotic-induced akathisia often appear restless (inability to tolerate inactivity), which may be confused with the underlying psychotic disorder.

With chronic exposure to D₂ antagonist medications, late-appearing (tardive) extrapyramidal effects may emerge, including, most notoriously, tardive dyskinesia. Tardive dyskinesia may occur in 20% of patients who receive D₂ antagonist drugs for greater than 1 year, although it may occur even after only brief exposures to these drugs. Elderly patients and women of all ages seem to be more susceptible to the development of tardive dyskinesia. Manifestations of tardive dyskinesia include abnormal involuntary movements, which may affect the tongue, facial and neck muscles, upper and lower extremities, truncal musculature, and, occasionally, skeletal muscle groups involved in breathing and swallowing. Tardive dyskinesia may be exacerbated by withdrawal of the causative medication and only rarely remits. Compensatory increases in the function of dopamine activity in the basal ganglia may be responsible for the development of tardive dyskinesia. The FDA has recently approved two medication treatments for tardive dyskinesia—deutetrabenazine and valbenazine—both related to tetrabenazine and both of which inhibit the vesicular monoamine transporter 2 and thus decrease synaptic release of dopamine, serotonin, and norepinephrine.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome occurs in 0.2% to 1.0% of all patients treated with antipsychotic drugs.^{[118](#)} The emergence of the syndrome in the setting of dopamine antagonist drugs as well as the onset of the syndrome with abrupt withdrawal of levodopa therapy suggests a role of dopamine receptor blockade in the development of this syndrome. Risk factors for the development of neuroleptic malignant syndrome may include youth, male gender, dehydration, iron deficiency, catatonia, organic brain disease, and intercurrent illness.^{[119](#)} The syndrome typically develops over 24 to 72 hours and is characterized by (1) hyperthermia; (2) generalized hypertonicity of skeletal muscles; (3) instability of the autonomic nervous system manifesting as alterations in systemic blood pressure, tachycardia, and cardiac dysrhythmias; and (4) fluctuating levels of consciousness.^{[120](#)} Autonomic nervous system dysfunction may precede the onset of other symptoms. Increased skeletal muscle tone may so decrease chest wall expansion that it becomes necessary to provide mechanical support of ventilation. Skeletal muscle rigidity may be severe enough to cause myonecrosis leading to increased creatine phosphokinase levels, myoglobinuria, and renal failure. Liver transaminase enzymes are likely to be increased. Mortality may be greater than 5%, with common causes of death being ventilatory failure, cardiac failure and/or dysrhythmias, renal failure, and thromboembolism.^{[118](#)}

Treatment of neuroleptic malignant syndrome is primarily supportive, with emphasis on cessation of the dopamine antagonist treatments (or reinstatement of dopaminergic agonist medication when precipitated by withdrawal of dopamine agonists), ICU monitoring, IV hydration, cooling, and treatment of agitation and CNS arousal with IV benzodiazepines.^{118,119} The administration of the direct-acting muscle relaxant dantrolene and the dopamine agonists bromocriptine or amantadine with dopamine withdrawal is supported by case series and clinical literature but not by controlled trials.¹¹⁸ Electroconvulsive therapy is also applied clinically for treatment of neuroleptic malignant syndrome, although similarly without evidence from controlled trials.¹¹⁹

Malignant hyperthermia associated with anesthesia as well as the central anticholinergic syndrome may mimic the neuroleptic malignant syndrome.¹²⁰ A distinguishing feature is the ability of nondepolarizing muscle relaxants to produce flaccid paralysis in patients experiencing the neuroleptic malignant syndrome but not in those experiencing malignant hyperthermia (see [Table 43.3](#)).¹²¹

Cardiovascular Effects

Prolonged QTc Interval

Not restricted to the FGAs, yet long identified as a risk of their use, prolonged QTc syndrome warrants discussion as a general risk of psychotropic medication in the setting of anesthesia and a particular risk of the dopamine antagonists medications.¹²² Sudden death during treatment with haloperidol has been attributed to drug-induced prolongation of the QTc interval on the ECG.¹²³

Prolonged QTc syndrome is a malfunction of cardiac ion channels resulting in impaired ventricular repolarization that can lead to a characteristic polymorphic ventricular tachycardia known as torsades de pointes.¹²⁴ The single most common cause of the withdrawal or restriction of the use of drugs that are already in clinical use is the prolongation of the QTc interval on the ECG associated with torsades de pointes (polymorphic ventricular tachycardia).^{125,126} This prolongation most often results from delayed ventricular repolarization, a process that is mediated by the efflux of intracellular potassium. The channels responsible for the current are susceptible to blockade by many drugs, producing a suitable environment for the development of torsades de pointes, which may lead to sudden death. Nondrug factors associated with prolongation of the QTc interval include female gender, advanced age, electrolyte disturbances (hypokalemia, hypomagnesemia), congestive heart failure, bradycardia, myocardial ischemia, and congenital long QTc syndrome.

Several classes of noncardiac drugs commonly used in anesthesia (propofol, isoflurane, sevoflurane, succinylcholine, neostigmine, atropine, glycopyrrolate, metoclopramide, methadone macrolide and quinolone antibiotics, SSRIs, 5-HT₃ receptor antagonists, and dopamine antagonist drugs) produce dose-dependent prolongation of the QTc interval on the ECG in some patients.¹²⁵ Although these drugs can provoke torsades de pointes in susceptible patients, the risk of this response in patients with no other risk factors is minimal. Nevertheless, even in low-risk patients, drug interactions can lead to life-threatening torsades de pointes. These drug interactions are characterized by (1) additive or synergistic effects when two drugs capable of prolonging the QTc are administered (haloperidol and amitriptyline) or (2) the simultaneous administration of a drug that interferes with the metabolism of a second drug capable of prolonging the QTc interval (resulting increased plasma concentration of the second drug increases the risk of torsades de pointes). Drugs capable of inhibiting P450 enzyme and thus delaying the metabolism of second drugs capable of prolonging the QTc interval include calcium channel blockers, antifungal drugs, SSRIs, macrolide and quinolone antibiotics, antiretroviral drugs, and amiodarone. It is remarkable that long QT syndrome is not found in most general anesthesia, as propofol for induction, a volatile anesthetic for maintenance, and a 5-HT₃ antagonist for postoperative nausea and vomiting prophylaxis are such common companions. Fortunately, ECG monitoring is a standard during general anesthesia and in the recovery room, and we can be confident that if this were a common occurrence, we would be aware. We can only conclude that the personal predisposing factors cited earlier are an important factor in the occurrence of this potentially lethal arrhythmia.

When considering the effects of drugs on the QTc interval, it is important to recognize that it is difficult to measure this interval with precision.¹²⁷ There is inherent imprecision in identifying the end of the T wave

and variation in the onset of the QRS complex on some ECG leads providing different QTc values, depending on the leads selected for the measurement. Automatic QTc measurement techniques have been found to be less accurate in cardiac patients than in healthy controls. Indeed, calculation of the QTc interval is ambiguous, as there are numerous different formulas and each produces different results.

Drug administration route may also influence risk of dysrhythmia associated with QT prolongation. In 2007, the FDA formally warned against the administration of haloperidol IV—previously common practice for postoperative nausea and vomiting prophylaxis—given concerns for potentially higher risk of sudden cardiac death associated with QT prolongation. The IV administration of FGA drugs is thus discouraged. Intramuscular (IM) administration remains the standard for acute or emergency use of the FGA drugs.

Hypotension

Acute administration of chlorpromazine causes a decrease in systemic blood pressure resulting from (1) depression of vasomotor reflexes mediated by the hypothalamus or brainstem, (2) peripheral α -adrenergic blockade, (3) direct relaxant effects on vascular smooth muscle, and (4) direct cardiac depression. α -Adrenergic blockade produced by chlorpromazine is sufficient to blunt or prevent the pressor effects of epinephrine. Miosis that occurs predictably may also be due to α -adrenergic blockade. Some of the FGA drugs, including pimozide, also potently block calcium channels, which may contribute to their cardiac toxicity, including prolongation of the QTc interval on the ECG. Oral administration of the FGA drugs is associated with less pronounced systemic blood pressure-lowering effects. Indeed, tolerance to the hypotensive effect develops so that after several weeks of therapy, the blood pressure returns toward normal. Nevertheless, some element of orthostatic hypotension may persist for the duration of therapy.

Endocrine Effects

Dopamine antagonist medications increase prolactin levels disrupting the normal dopaminergic inhibition of prolactin secretion. Galactorrhea and gynecomastia may accompany excess prolactin secretion. Amenorrhea is a possible but rare complication of therapy. Decreased secretion of corticosteroids may be due to diminished corticotropin release from the anterior pituitary. Chlorpromazine may impair glucose tolerance and the release of insulin in some patients. Hypothalamic effects may manifest as weight gain and occasionally abnormalities of thermoregulation.

Sedation

Sedation produced by antipsychotic drugs appears to be due to antagonism of α_1 -adrenergic, muscarinic, and histamine (H_1) receptors. With chronic therapy, tolerance develops to the sedative effects produced by these drugs.

Obstructive Jaundice

Obstructive jaundice that is considered to be an allergic reaction occurs rarely 2 to 4 weeks after administration of phenothiazines. Indeed, there is prompt recurrence of jaundice if the offending drug, usually chlorpromazine, is again administered. If jaundice is not observed in the first month of therapy, it is unlikely to occur at a later date.

Hematologic Toxicity

Blood dyscrasias are rare but potentially life-threatening toxicities of the antipsychotic medications. Drug-induced agranulocytosis is most typically associated with the SGA drug clozapine but may occur in response to FGA drugs including chlorpromazine and haloperidol as well as other SGA drugs.¹²⁸ Routine monitoring of white blood cell is indicated, particularly during drug titration and in the early phase of treatment, and suspicion for agranulocytosis should accompany evaluation of fever in patients treated with antipsychotic medications.

Hypothermia

An effect of chlorpromazine on the hypothalamus is most likely responsible for the poikilothermic effect of this drug.

Seizure Threshold

Many antipsychotic drugs decrease the seizure threshold and produce a pattern on the EEG similar to that associated with seizure disorders. Chlorpromazine causes slowing of the EEG pattern, with some increase in burst activity and spiking. Sensory evoked potentials are often decreased in amplitude, and there is an increase in latency. It is unclear whether this can be problematic in their interpretation.

Skeletal Muscle Relaxation

Chlorpromazine causes skeletal muscle relaxation in some types of spastic conditions, presumably by actions on the CNS because the drug is devoid of actions at the neuromuscular junction.

Drug Interactions

The ventilatory depressant effects of opioids are likely to be exaggerated by antipsychotic drugs. Likewise, the miotic and sedative effects of opioids are increased, and the analgesic actions are likely to be potentiated. These drugs may interfere with the actions of exogenously administered dopamine, and the effects of alcohol are enhanced.

Dopamine and Serotonin Antagonist Drugs

The SGA drugs—also described as “atypical” antipsychotics—are thought to have decreased risk of extrapyramidal side effects relative to the FGA drugs. Although “atypicality” is poorly defined, these drugs include prominent antagonism at 5-HT_{2A} and other serotonin receptors in addition to their dopamine antagonist activity.¹²⁸ The SGA drugs come with similar overall risks and adverse effects as the FGA drugs, most notably potential extrapyramidal effects (including tardive dyskinesia and neuroleptic malignant syndrome), although relative risks may be reduced. More pronounced with the SGA drugs, however, are increased metabolic risks, including weight gain, hypercholesterolemia, and insulin resistance. Although pharmacologic mechanisms are unclear, direct impacts on these drugs on mechanisms of glucose homeostasis may convey risks for insulin resistance independent of weight gain.¹²⁹ These metabolic adverse effects conspire with more direct mediators of cardiac risk, including QTc prolongation, such that the SGA drugs are associated with higher rates of cardiovascular morbidity. Increased all-cause mortality in elderly patients using these drugs is a reason their use in management of dementia-related psychosis, in particular, is discouraged.

Despite these limitations, the SGA drugs have proven tolerable and effective in treating a broad range of psychopathology beyond primary psychotic disorders like schizophrenia. This is reflected by an increasingly broad range of FDA indications for individual drugs, including management of manic episodes, depressive episodes, and relapse prevention in bipolar disorder, augmentation treatment of major depressive disorder, management of irritability in autistic disorders, and treatment of Tourette disorder. They are also widely used off-label for treatment-resistant obsessive-compulsive disorder, severe personality disorders, and other conditions.

Clozapine

As an exception to the general model of D₂ antagonist-mediated antipsychotic efficacy, **clozapine** is the most effective of antipsychotic medications—often beneficial when other treatments fail—but has relatively little D₂ antagonist activity.¹³⁰ It also is the only antipsychotic medication that appears not to convey risk of tardive dyskinesia or extrapyramidal side effects.¹³¹ As the class-defining SGA, clozapine includes antagonist actions at 5-HT_{2A}, 5-HT_{2C}, 5-HT₆, and 5-HT₇ receptors. It additionally has potent antimuscarinic activity and α₁ antagonism. More recent literature has suggested that additional activities may contribute to therapeutic benefit, including GABA_B receptor agonism.¹³⁰

Despite its superior efficacy, clozapine is not a first-line medication, in part due to multiple potential medical complications of clozapine use, detailed in the following text. Despite these risks—perhaps because of its benefit for the underlying disorder—clozapine use in schizophrenia is associated with the lowest all-cause mortality of any antipsychotic drug.¹³² Clozapine is additionally the only medication for schizophrenia proven to decrease suicidality.¹³³

The most concerning adverse effect of clozapine is agranulocytosis. Although it occurs in less than 1% of patients; the patients, prescribers, and pharmacies must be registered with a central clozapine Risk Evaluation and Mitigation Strategy program.¹³⁴ In order to have access to the drug, patients must undergo mandatory weekly blood count monitoring for the first 6 months of treatment, and a reduced but ongoing schedule of monitoring thereafter.

Low-grade fever sometimes occurs early in the use of clozapine and sustained mild sinus tachycardia may be observed. More concerning potential cardiac effects include the development of potentially fatal clozapine-associated myocarditis, the basis for recommended testing of C-reactive protein and troponins weekly during clozapine initiation and titration.¹³⁵ Considered rare, this complication may be more likely in inpatient settings where clozapine is more rapidly titrated to therapeutic doses.¹³⁶ Inflammatory processes involving other organs, including hepatitis, nephritis, and pancreatitis, have also been attributed to clozapine.¹³⁷

Excessive salivation, especially during sleep, is a common but paradoxical and poorly explained effect of this strongly anticholinergic drug. Oral rinse with two drops of ophthalmic atropine solution in a glass of water is a potential treatment. Given the pronounced anticholinergic effects of clozapine, systemic anticholinergics should be avoided, and caution is advised when using clozapine in patients at risk for glaucoma, ileus, or urinary retention. These anticholinergic effects are also thought to contribute to clozapine's significant potential for constipation, which may be severe and even life-threatening if not managed assertively. Bowel function should be routinely monitored in individuals using clozapine.

Clozapine has been combined safely with lithium and antidepressant drugs, and the white blood cell count/augmenting effect of lithium may preserve clozapine treatment for patients with borderline low neutrophil counts.

Olanzapine

Olanzapine is structurally and pharmacologically similar to clozapine and similarly is one of the most effective antipsychotic medications, frequently used first line in acute care settings for agitated psychosis or bipolar mania, where it may be administered orally or via IM injection. Like clozapine, it is initially heavily sedating and associated with hypotensive effects; it also conveys among the strongest risks for weight gain and metabolic syndrome. Like other antipsychotic medications, olanzapine may disrupt thermoregulation and leave treated patients more susceptible to heat injury. Its efficacy and tolerability profile is otherwise superior, however.¹³⁰ Olanzapine's propensity for hypotension and its frequent acute care use intramuscularly, in situations where patients may also receive IM or IV benzodiazepines, has led to guidance from its manufacturer warning against coadministration of IM olanzapine and parenteral benzodiazepines due to risk of cardiorespiratory suppression and death.¹³⁸ The post-marketing data supporting this association have been challenged, however, and it has been suggested that this risk may be significant primarily in those patients already intoxicated upon presentation.¹³⁹ Olanzapine has an elimination half-time of 30 to 50 hours, with literature suggesting slower clearance in women and the elderly. It is metabolized by CYP450 enzymes 1A2 and 2D6.

Risperidone, Paliperidone, and Iloperidone

Risperidone is one of the most widely used SGA drugs and is available in long-acting injectable (LAI) form. It is considered one of the most effective and the most “first-generation”-like of the SGA drugs, given its potency as a D₂ antagonist, and may have greater risk of EPS compared with other SGA drugs. In addition to dopamine and serotonin antagonism, risperidone is a potent antagonist at α₁ and α_{2A} and α_{2C} receptors, which may account for the potential side effect of hypotension. Risperidone has been associated with

exaggerated systemic hypotension during a spinal anesthetic.¹⁴⁰ Related drugs include **paliperidone** and **iloperidone**. All have elimination half-lives on the order of 20 to 30 hours. Of the SGAs, risperidone and paliperidone are the most commonly associated with prolactin increase and gynecomastia. Iloperidone is less commonly associated with EPS or gynecomastia but may be overall less efficacious.¹³⁰ There is moderate evidence for the prophylactic use of risperidone to prevent delirium after cardiac surgery along with high-quality evidence confirming no increased risk of mortality.¹⁴¹

Aripiprazole, Brexpiprazole, and Cariprazine

Aripiprazole and related drugs **brexpiprazole** and **cariprazine** differ from other SGAs in that they are D₂ receptor partial agonist/antagonists, along with partial agonism or antagonist activity at multiple serotonin receptors including 5-HT_{1A}, 5-HT_{2A-C}, and 5-HT₇. Aripiprazole is one of the most widely used of the SGA drugs, in part given its balance of efficacy and tolerability. It is less likely to cause weight gain or sedation and is frequently used in mood disorders, in line with its FDA-approved indications for all phases of bipolar disorder as an adjunctive intervention in major depressive disorder. Particular side effects, in addition to general risks of the SGA drugs, include akathisia—typically associated with higher starting doses or too-rapid dose escalation—and the potential emergence of compulsive hedonic or risk behaviors, including compulsive gambling, shopping, or sexual behavior. This latter adverse effect may reflect aripiprazole's partial D₃ agonism and is similarly associated with D₃ agonist drugs pramipexole and ropinirole. Aripiprazole is less likely than most other SGA drugs to cause QT prolongation or hyperprolactinemia.¹³⁰ The elimination half-lives of aripiprazole, brexpiprazole, and cariprazine are relatively long, on the order of 3 to 5 days. All three drugs are substrates of CYP450 enzymes 2D6 and 3A4.

Ziprasidone and Lurasidone

Ziprasidone antagonizes D₂ and to a lesser extent D₃ receptors, antagonizes 5-HT_{2A} receptors, and is a partial antagonist at 5-HT_{1A} and 5-HT_{2C}. It is considered a moderately effective medication, prized primarily for its minimal metabolic impact compared to other SGA drugs. It notably is associated with QT prolongation to a greater extent than others, however, and its intestinal absorption depends strongly on food. **Lurasidone** is an antagonist at the dopamine D₂ and D₃ receptors as well as at the 5-HT_{2A}, 5-HT₇, and α_{2C} receptors. It also has partial agonist activity at the 5-HT_{1A} receptor and is minimally active at the 5-HT_{2C} receptor, potentially limiting its effects on appetite and weight. Although valued for its reduced metabolic risk, lurasidone is frequently accompanied by distressing akathisia, particularly when newly initiated or titrated too rapidly to higher dose ranges. Like ziprasidone, absorption is highly influenced by concomitant food intake. Lurasidone is primarily metabolized by CYP3A4, and its half-life is approximately 20 to 40 hours.

Amisulpride

An outlier among the atypical antipsychotics given minimal 5-HT_{2A} antagonism, **amisulpride** is nonetheless a potent D₂ and D₃ antagonist and an antagonist at 5-HT₇ receptors, the latter activity hypothesized to convey antidepressant effects. Although approved in Europe and many other regions outside the United States for treatment of psychotic disorders, in the United States, it has been approved only recently, at a markedly lower dose range and in IV formulation, for treatment of postoperative nausea and vomiting. Although the adverse effect profile of amisulpride at antipsychotic doses is similar to that of other atypical antipsychotic drugs with significant risk particularly of hyperprolactinemia and QTc prolongation,¹⁴² at the low-dose ranges used for postoperative nausea and vomiting, adverse effects are comparable to placebo,¹⁴³ and there are no clinically significant impacts on QTc.¹⁴⁴

Long-Acting Injectable Formulations

A number of drugs used for treatment of psychosis are available in LAI formulations, a dosing strategy aimed to limit nonadherence and symptomatic relapse. These include the dopamine antagonist drugs haloperidol and fluphenazine and the dopamine serotonin antagonist drugs olanzapine, aripiprazole, risperidone, and

paliperidone. Dosing schedules range from every 2 weeks (haloperidol) to every 3 months (paliperidone). Although use of LAI formulations typically follows a period of induction on oral medication, such that unexpected adverse effects should be limited, acute care providers should recognize that full drug washout may take months once injected, and as such, periods of susceptibility to adverse effects and drugs interactions may be similarly prolonged. Injection site irritation and rare complications of administration may also occur: LAI olanzapine is associated with rare occurrences of a postinjection delirium and sedation syndrome felt to represent local tissue injury and inadvertent distribution of olanzapine pamoate into blood, where it is rapidly dissolved into active drug. As with other depot formulations, in the anesthetic setting, it may not be obvious that the patient is being treated with a long-acting formulation. This is particularly problematic with opioid partial agonists but relevant for dopaminergic antagonists as well. The existence of these novel formulations and their potential use when unexpected side effects occur should be on every anesthesiologist's radar.

Dopamine Serotonin Norepinephrine Multimodal Drugs

Quetiapine, like other SGAs, has 5-HT_{2A} antagonism that is more potent than its D₂ receptor antagonism, which may be minimal at lower dose ranges. It notably has an active metabolite—norquetiapine—with potent NET inhibition and thus is considered a dopamine, serotonin, and norepinephrine multimodal drug. The EPS risk is the lowest of any antipsychotic drug with the exception of clozapine, and as such, it is often the antipsychotic of choice in situations when EPS risk is a concern, such as for psychosis associated with Parkinson disease.¹³⁰ It is significantly sedating at low doses—likely due to significant antihistamine activity—and may cause orthostatic hypotension given its α₁ antagonist activity. Antimuscarinic activity is minimal. Quetiapine levels are strongly influenced by CYP450 3A4 inducers (lamotrigine, carbamazepine) or inhibitors (ketoconazole). Elimination half-life is relatively brief, at 7 hours, and as such, an extended-release formulation of quetiapine has been marketed. Extended-release quetiapine has been found to have analgesic efficacy in a double-blind trial of patients with chronic comorbid depression and pain.¹⁴⁵

Drugs With Primarily Glutamatergic Activity

Glutamate Antagonists and Channel Blockers

Valproate, Carbamazepine, and Oxcarbazepine

The anticonvulsants **valproate** and **carbamazepine**, as well as the related drug **oxcarbazepine**, are used commonly in the treatment of bipolar disorder as antimanic and mood stabilizing interventions. The mechanisms of valproate are poorly understood, whereas carbamazepine and oxcarbazepine are thought to bind and inhibit inactive neuronal sodium channels, preventing repetitive action potential firing. As such, they are thought to impact primarily excitatory glutamatergic neurotransmission. Common side effects of valproate include sedation, double vision, tremor, alopecia, gastrointestinal disturbance, and potentially thrombocytopenia. Toxic encephalopathy related to hyperammonemia may also occur at higher doses or in overdose, which may benefit from carnitine supplementation.¹⁴⁶ Valproate is commonly used for migraine prophylaxis, where it has moderate efficacy.¹⁴⁷ Its use is complicated in a large portion of migraine sufferers—young women capable of childbearing—as it has been associated with an increased incidence of birth defects when taken during the first trimester. The pain practitioner should consider this factor when choosing one of the many potential drugs for headache prophylaxis in women with the potential for pregnancy.¹⁴⁸

Adverse effects associated with carbamazepine include hepatitis and hypersensitivity reactions such as Stevens-Johnson syndrome, with individuals carrying HLA-B*1502 felt to be at markedly higher risk. Carbamazepine is also associated with bone marrow suppression, including agranulocytosis and aplastic anemia. Carbamazepine is a CYP450 inducer and may decrease levels of medications, including valproate, warfarin, and oral contraceptives. It also accelerates the elimination of benzodiazepines.¹⁴⁹ Levels of carbamazepine may be increased by concomitant cimetidine, calcium channel blockers, or erythromycin. Oxcarbazepine is thought to be less vulnerable to metabolic interactions than carbamazepine and may have lesser risk of bone marrow suppression or anemia. Oxcarbazepine is commonly associated with decreased blood sodium, and severe hyponatremia may occur in up to 12% of those using the drug. Drug levels, liver

function tests, electrolytes, and complete blood counts should be followed in all patients being treated with these anticonvulsant drugs.

Lamotrigine

Lamotrigine is similarly a channel-blocking anticonvulsant drug that impacts glutamatergic signaling. It has an FDA indication for maintenance treatment in bipolar I disorder. It is generally better tolerated and less often associated with adverse reactions than valproate or carbamazepine; however, use in acute care settings is limited by the risk of Stevens-Johnson syndrome or other hypersensitivity reaction because this risk requires the drug to be initiated via an extended and gradual titration course over weeks. Like other anticonvulsants, lamotrigine should be tapered to discontinuation; however, if stopped for more than 5 days, dose titration should be started from the beginning given Stevens-Johnson syndrome risk. Lamotrigine levels are highly influenced by pharmacokinetic interactions, with levels notably increased by valproate and decreased by concomitant carbamazepine or oral contraceptive medications.

Gabapentin and Pregabalin

Gabapentin and pregabalin are extensively used in pain medicine and increasingly as an opioid adjuvant for postoperative pain. With a molecular structure similar to that of GABA, **gabapentin** and **pregabalin** are anticonvulsant calcium channel subunit blocking drugs that decrease synaptic glutamate release. They are not active at the GABA receptor as previously supposed. Both are FDA approved for treatment of epilepsy and neuropathic pain, and pregabalin is additionally FDA approved for the treatment of generalized anxiety disorder. Gabapentin is perhaps the more commonly used in psychiatry, typically for off-label applications including as a sedative and anxiolytic intervention and for treatment of alcohol use disorder and restless legs. Both drugs are relatively safe across a broad range of dosing, although abrupt discontinuation may lead to withdrawal symptoms, and abuse liability in combination with opioids has been documented. There is some added safety due to gabapentin oral absorption that occurs in the duodenum and is increasingly saturated at approximately 1,200 mg.¹⁵⁰ Principle side effects include sedation/lethargy, and, more rarely, peripheral edema may be observed. In rare cases, gabapentin and pregabalin have been associated with rhabdomyolysis, pancreatitis, thrombocytopenia, and neutropenia. The FDA has recently warned about the potential for respiratory suppression when these drugs are used together with opioids or other CNS depressants. Both gabapentin and pregabalin are renally excreted, and caution should be exercised when prescribed in older adults or others with impaired renal clearance. The elimination half-life of both drugs is brief—around 7 hours.

Glutamate Antagonist Drugs

The anesthetic drug **ketamine**, an NMDA glutamate receptor antagonist, is an important adjuvant in the treatment of perioperative and chronic pain.¹⁵¹ Consensus guidelines were released for chronic pain and acute pain in 2018 by the American Society of Regional Anesthesia and Pain Medicine.^{152,153} It has also been explored with great promise in the treatment of depressive mood disorders. Evidence of its robust and rapid effects can be seen in a meta-analysis of seven double-blind placebo-controlled randomized clinical trials incorporating a total of 147 patients.¹⁵⁴ The FDA has approved a racemic ketamine formulation, intranasal **esketamine**, for refractory depression given evidence provided by a phase III trial of separation from placebo in the primary endpoint.¹⁵⁵ At the same time, there are risks associated with ketamine, including abuse potential and potential suicide risk.¹⁵⁵ With chronic, high-frequency ketamine substance abuse, there have been reports of cognitive impairment and cystitis.^{156,157}

The typical dose of ketamine as an adjuvant analgesic is 0.5 to 1 mg/kg per hour. In contrast, the typical antidepressant dose of ketamine hydrochloride, 0.5 mg/kg delivered IV over 40 minutes, does not produce general anesthetic effects (peak plasma concentrations of 70-200 ng/mL are attained compared with 2,000-3,000 ng/mL when used for general anesthesia).¹⁵⁸ The IV ketamine at antidepressant doses is, however, associated with transient increases in systolic and diastolic blood pressure.¹⁵⁹ Ketamine infusions for treatment of chronic pain and depression should only be performed at sites with expertise in this approach,

with appropriate safeguards in place including plans for monitoring side effects and changes in psychiatric symptoms, and for screening individuals who have current or past substance abuse.¹⁶⁰

Other Glutamate Modulators

A number of other glutamate antagonist drugs have been explored for off-label use in obsessive-compulsive disorder and other conditions thought to be associated with hyperactivity of glutamatergic cortico-striato-thalamo-cortical circuits. In addition to ketamine, these drugs include the NMDA antagonist **memantine**, the sodium channel blocking drugs **topiramate** and **riluzole**, and the glutathione precursor **N-acetylcysteine**.¹⁶¹⁻¹⁶⁴ Memantine is FDA approved for treatment of moderate to severe Alzheimer disease, where it is hypothesized to confer benefit by reducing glutamate-mediated neuronal exitotoxicity. Additional off-label applications have included fibromyalgia, neuropathic, and other types of chronic pain; although high-quality evidence for benefit in these off-label uses is limited, its minimal side effect profile has supported ongoing interest.¹⁶⁵ Topiramate is additionally used off-label for alcohol use disorder and antipsychotic-associated weight gain, and N-acetylcysteine has evidence supporting efficacy in schizophrenia.¹⁶⁶⁻¹⁶⁸ There are minimal risks or drug interactions associated with use of memantine or N-acetylcysteine. Topiramate is a weak carbonic anhydrase inhibitor and as such is associated with nephrolithiasis and may increase risk of hypohidrosis and hyperthermia. Riluzole has been associated with hepatitis, pancreatitis, and rare instance of bone marrow suppression, and in overdose may be associated with methemoglobinemia.

Drugs With Primarily Acetylcholinergic Action

Anticholinergic effects of psychopharmacologic drugs are a common cause of adverse effects and drug-related morbidity, reflecting both peripheral actions (eg, orthostasis, urinary retention) and central actions (eg, cognitive impairment, delirium) that are familiar to the anesthesiologist. A number of procholinergic drugs, however, have utility as psychopharmacologic agents, reflecting the actions of acetylcholine on cortical and subcortical circuits related to cognition, memory, and reward.

Acetylcholinesterase Inhibitors

Donepezil and **rivastigmine** are acetylcholinesterase inhibitors that are approved for treatment of cognitive deficits in mild to moderate Alzheimer dementia. Rivastigmine additionally is FDA approved for use in dementia related to Parkinson disease. Possible adverse effects of the acetylcholinesterase inhibitors include gastrointestinal disturbances (nausea, vomiting, diarrhea), anorexia with weight loss, sweating, muscle cramps, weakness, and nightmares. Given potential for adverse effects, both medications are typically titrated gradually to target dose. A transdermal patch formulation of rivastigmine may allow for decreased frequency of gastrointestinal side effects.¹⁶⁹

Anesthetic Considerations

Importantly, acetylcholinesterase inhibitors may prolong the effects of depolarizing neuromuscular blockade or reverse or decrease the effects of nondepolarizing neuromuscular blockers.^{170,171} This has led to suggestions that these medications be discontinued prior to elective surgeries or that nondepolarizing agents be used in emergency surgeries for patients currently taking acetylcholinesterase inhibitors.¹⁷² This is of questionable relevance if best practices are followed and the nondepolarizing muscle relaxant is titrated to effect with a peripheral nerve stimulator. As with all medications, the benefits of discontinuation need to be balanced against the risks.

The half-life of donepezil is long—at approximately 70 hours—and as such, prolonged washout over 2 weeks may be required prior to elective procedures. Rivastigmine, in contrast, has a short half-life of 3 to 4 hours and can be discontinued the day prior to surgery. The acetylcholinesterase inhibitors have also been associated in case reports with bradycardia and hypotension and may rarely contribute to QTc prolongation and arrhythmia risk.¹⁷³

Acetylcholine Receptor Agonist and Multimodal Drugs

Galantamine, like rivastigmine and donepezil, is a competitive acetylcholinesterase inhibitor; yet, it also acts as an agonist at nicotinic acetylcholine receptors, and as such, it is considered an acetylcholine multimodal drug. It is FDA approved for treatment of cognitive impairment in dementia related to Alzheimer disease, and its benefit is thought to reflect both direct agonist and enzyme inhibitor effects. As with the other acetylcholinesterase inhibitors, gastrointestinal adverse effects are notable upon initiation of the drug, the potential for increased bradycardia and arrhythmia risk should be considered, and it is recommended to be discontinued prior to anesthesia. Due to impacts on neuromuscular blockade, it was even used as a reversal agent in the early 1960s.^{174–176} Like rivastigmine, its half-life is short—at 7 hours—and it can be stopped 1 to 2 days prior to anesthesia.

Varenicline is a partial agonist at multiple nicotinic acetylcholine receptors, with effects most prominently at $\alpha_4\beta_2$ receptors, where it blocks and limits nicotine-driven reward signaling in the mesolimbic dopamine circuits. In this way, it decreases craving for nicotine products and limits nicotine withdrawal symptoms. As such, it is FDA approved for smoking cessation and considered the most effective medication intervention for smoking cessation.¹⁷⁷ The most commonly associated adverse effect is mild nausea. In the initial postmarketing period, concerns were raised about potential neuropsychiatric or cardiovascular risks associated with varenicline, yet a large postmarketing cohort study did not find evidence for increased risk of either neuropsychiatric or cardiac adverse events.¹⁷⁸ There are no reports of varenicline interfering with safe administration of anesthesia, and varenicline has been found beneficial as a component of perioperative smoking cessation interventions.^{179,180}

Drugs With Primarily γ -Aminobutyric Acid (GABA)-ergic Action

Benzodiazepines

Benzodiazepines (see [Chapter 5](#)) are used clinically as short-term anxiolytics, sedatives, anticonvulsants, and muscle relaxants. They appear to produce all these effects by facilitating the actions of GABA, the major inhibitory neurotransmitter in the nervous system. Short-acting benzodiazepines are used for anxiolysis in many if not most general anesthetics. The immediate effectiveness of benzodiazepines, combined with the high frequency of anxiety and insomnia in the adult population, has led to these drugs being widely prescribed. However, reflecting the superiority of SSRIs for first-line pharmacologic treatment of anxiety disorders, and given potential for tolerance, physiologic dependency, and iatrogenic anxiety related to withdrawal, abuse liability, risks related to intoxication (eg, falls and motor vehicle accidents), and risks of overdose and respiratory suppression—particularly when used in conjunction with opioid medications—benzodiazepines are increasingly avoided by psychiatrists, or prescribed only for time-limited periods of intermittent use.

When benzodiazepines are used, low doses (eg, **clonazepam** 0.5 mg, 1-3 times daily) are typically selected to minimize sedation. A total daily dose of greater than 3 mg **lorazepam** or its equivalent is almost never needed and may signal further evaluation due to the potential for substance abuse. A history of alcohol abuse or substance abuse is a relative contraindication to use of benzodiazepines for treatment of anxiety. Problems with benzodiazepine rebound and withdrawal symptoms can be minimized if low-potency, long-acting drugs are used. Elderly patients manifest greater sedation and greater impairment of psychomotor performance than younger persons receiving the same dose, and benzodiazepine use is thus relatively contraindicated in the elderly.

Other GABA_A Receptor Modulators

The “z-drugs” **zolpidem**, **zopiclone**, **eszopiclone**, and **zaleplon**, like the benzodiazepines, are positive allosteric modulators of the GABA_A receptor and are licensed for short-term use as sleep-promoting drugs. The drugs differ primarily by their typically short half-lives. These drugs may have less potential for tolerance and dependency than the benzodiazepines; however, abrupt discontinuation after prolonged and high-dose use has been associated with benzodiazepine-like withdrawal phenomena. Use of this medication class has been associated with abnormal sleep behaviors. Inhibitors of CYP450 enzymes 3A4 and 1A2 may

increase levels of zolpidem, the most commonly used of this class, and women are known to metabolize zolpidem more slowly than men, for which reason lower starting doses are recommended for women.

Lithium

Lithium salts have been studied in the treatment of mood disorders since the 1890s.¹⁸¹ In addition to the antimanic and relapse-preventative effects of lithium in bipolar disorder, lithium is an evidence-based adjunctive treatment in treatment-resistant major depressive disorder and is one of only a few drugs shown to decrease risk of suicide.¹⁸² Lithium's narrow therapeutic index, significant potential for toxicity, and potential for drug interactions are discussed in detail in the following text.

Mechanisms of Action

Lithium has many neurobiologic effects, but the basis for lithium's efficacy in bipolar disorder has long been unclear.¹⁸³ Contemporary models invoke lithium's influence on multiple neurochemical pathways, including increases in serotonin production and presynaptic release and decreases in glutamatergic neurotransmission. Lithium modulates a number of intracellular signaling cascades, causing reduction in amplitude of Gi and Gs signaling cascades, decreases in inositol signaling, and modulating other enzymes requiring magnesium as a cofactor, including GSK3 β and β -arrestin. These in turn may modulate pathways leading to neurotrophic effects or to influence on chronobiologic systems.¹⁸⁴

Dosage and Monitoring

Safe and effective use of lithium can be achieved only by monitoring plasma concentrations. Oral doses of lithium chloride typically range from 600 to 1,800 mg daily in divided doses; yet, dosing is always based on target serum level. For maintenance treatment of bipolar disorder, consensus guidelines suggest a plasma level of 0.6 to 0.8 mEq/L, although lower levels may be used in unipolar depression.¹⁸⁵ For treatment of acute mania, levels between 1.0 and 1.2 mEq/L may be targeted. Because the elimination half-time is about 24 hours, plasma concentrations should be measured no sooner than 5 days after a change in dosage, unless toxicity is suspected. In elderly patients and in patients with renal disease, the elimination half-time for lithium is prolonged; the time to equilibration can be delayed to 7 days or longer. If toxicity is suspected, lithium should be withheld and the plasma concentration determined immediately, taking into account the time that has elapsed since the last dose.

Adverse Effects

Lithium-treated patients may experience a number of potential side effects, all considered dose dependent. Mild side effects include fine motor tremor, typically resolving with dose reduction, but tremor present at lower doses when lithium is combined with bupropion or other SRIs or norepinephrine reuptake inhibitors. If necessary, β -adrenergic antagonists may mitigate tremor. Clinically important dermatologic toxicities of lithium include cystic acne and exacerbations of psoriasis. Lithium also may cause gastric irritation, typically managed by nighttime-only dosing or use of an extended-release formulation.

Renal Effects

The most common serious side effects of lithium occur at the kidneys. Acutely, within weeks of initiating lithium treatment, approximately 50% of patients will demonstrate polyuria to some degree. Approximately 20% of these may develop nephrogenic diabetes insipidus, with possible effects including hypovolemia, hypernatremia, hyperchloremic metabolic acidosis, and distal renal tubular acidosis.¹⁸⁶ These changes are thought to be due to intracellular signaling changes resulting in downregulation of aquaporin-2 in the collecting duct. With chronic exposure to high lithium doses over years or decades, chronic kidney disease may develop characterized by nephrogenic diabetes insipidus, proteinuria, and histologic changes consistent with tubulointerstitial nephritis. The potassium-sparing diuretic amiloride is effective in decreasing urine volume without affecting the plasma concentrations of either lithium or potassium, although it is unclear whether this diuretic may prevent chronic kidney disease.¹⁸⁷ It is recommended that renal function be evaluated by measuring blood urea nitrogen or plasma creatinine every 6 months.

Cardiac Effects

Cardiac effects of lithium treatment may include changes on the ECG characterized by T-wave flattening or inversion, yet there seem to be no related clinical effects. The ECG changes are reversible within 2 weeks when lithium is discontinued. Clinically significant lithium-induced cardiac conduction disturbances are rare, although sinoatrial node dysfunction and sinoatrial node block have been described. Patients with preexisting sinoatrial node dysfunction (sick sinus syndrome) should probably be treated with lithium only if they have an artificial cardiac pacemaker in place.

Endocrine Effects

Hypothyroidism develops in about 5% of patients treated with lithium and is more common in women than men. For this reason, it is recommended that thyroid-stimulating hormone levels be measured every 6 months, along with lithium level, electrolytes, and blood urea nitrogen/creatinine. If necessary, levothyroxine therapy may be initiated without discontinuing lithium. Provided no autoimmune or other cause of hypothyroidism is present, thyroid status may be expected to normalize if and when lithium is discontinued.

Drug Interactions

Lithium may interact pharmacodynamically or pharmacokinetically with many classes of medication ([Table 43.7](#)). Rarely, lithium may cause or potentiate extrapyramidal effects of dopamine antagonist medications, and, in case literature, lithium has been associated with neuroleptic malignant syndrome. Similarly, given potential to increase serotonergic neurotransmission, lithium may cause serotonin syndrome when added to SSRIs or MAOIs; however, its use together with SSRIs or MAOIs is not generally contraindicated.

TABLE 43.7

Drug interactions with lithium

Drug	Interaction
Thiazide diuretics	Increased plasma lithium concentration as a result of decreased renal clearance
Furosemide	Usually no change in the plasma lithium concentration
Nonsteroidal antiinflammatory drugs	Increased plasma lithium concentration as a result of decreased renal clearance (exceptions are aspirin and sulindac)
Aminophylline	Decreased plasma lithium concentration as result of increased renal clearance
Angiotensin-converting enzyme inhibitors	May increase plasma lithium concentration
Dopamine antagonist drugs	Lithium may exacerbate EPS or increase the risk of the neuroleptic malignant syndrome.
Anticonvulsant drugs (carbamazepine)	Concurrent use with lithium may result in additive neurotoxicity
β-Adrenergic antagonists	Decrease lithium-induced tremor
Neuromuscular blocking drugs	Lithium may prolong the duration of action.

Adapted from Price LH, Heninger GR. Lithium in the treatment of mood disorders. *N Engl J Med.* 1994;331(9):591-598.

Diuretic drugs may significantly influence lithium levels. Lithium is distributed throughout the total body water and is excreted almost entirely by the kidneys. Lithium, like sodium, is filtered by the glomerulus and reabsorbed by the proximal, but not distal, renal tubules. Thus, its renal excretion is not enhanced by thiazide diuretics, which act selectively on the distal renal tubules. In fact, because proximal reabsorption of lithium and sodium is competitive, depletion of sodium as produced by dehydration, decreased sodium intake, and thiazide and loop diuretics may increase reabsorption of lithium by proximal renal tubules, resulting in as much as a 50% increase in the plasma concentration of lithium. Potassium-sparing diuretics (triamterene, spironolactone) do not facilitate reabsorption of lithium and, in fact, may increase excretion.

Nonsteroidal antiinflammatory drugs, by altering renal blood flow, may produce marked increases in the plasma concentration of lithium and should be used with care.

Anesthetic Considerations

The association of sedation with lithium therapy suggests that anesthetic requirements for injected and inhaled drugs could be decreased. High plasma concentrations of lithium may delay recovery from the CNS depressant effects of barbiturates.¹⁸⁸ Responses to depolarizing and nondepolarizing neuromuscular blocking drugs may be prolonged in the presence of lithium.¹⁸⁹

Toxicity

Lithium toxicity may present acutely, as a consequence of overdose, or may be chronic. Diuretic therapy, nonsteroidal antiinflammatory drugs, sodium restriction, and sodium wasting may increase reabsorption of lithium and thus increase plasma lithium concentrations.

Many symptoms and signs of toxicity are closely correlated with the plasma lithium concentration (**Table 43.8**).¹⁸³ Mild lithium toxicity is reflected by sedation, nausea, skeletal muscle weakness, and changes on the ECG characterized by widening of the QRS complex. Atrioventricular heart block, hypotension, cardiac dysrhythmias, and seizures may occur when plasma concentrations of lithium are greater than 2 mEq/L. Significant lithium toxicity is a medical emergency that may require aggressive treatment, including hemodialysis. Monitoring for rebound in lithium levels after hemodialysis is essential, as absorption may continue from gastrointestinal contents and lithium may equilibrate slowly between intra- and extracellular stores.¹⁹⁰ If renal function is adequate, excretion of lithium ions can be modestly accelerated by osmotic diuresis and IV administration of sodium bicarbonate.

TABLE 43.8

Signs and symptoms of lithium toxicity

		Toxic effects	Plasma lithium concentration (mEq/L)	Signs and symptoms
Mild	1.0–1.5			Lethargy Irritability Skeletal muscle weakness Tremor Slurred speech Nausea
Moderate	1.6–2.5			Confusion Drowsiness Restlessness Unsteady gait Coarse tremor Dysarthria Skeletal muscle fasciculations Vomiting
Severe	>2.5			Impaired consciousness (coma) Delirium Ataxia Extrapyramidal symptoms Seizures Impaired renal function

Cannabinoids

Cannabis is an alkaloid mixture of more than 400 compounds derived from the cannabis sativa plant. Cannabis has been used for thousands of years and is presently the most commonly used illicit drug in the world. The most abundant cannabinoids are δ -9-tetrahydrocannabinol (D9THC), cannabidiol, and cannabinol.¹⁹¹ The D9THC is the main psychotropically active cannabinoid. Two principal endogenous cannabis receptors (CB_1 and CB_2) have been identified. The CB_1 receptors are present in the CNS (especially spinal cord), and CB_2 receptors are located peripherally and linked with cells in the immune system. Both receptors are members of the G protein family and like opioid receptors exert their actions by modulating second messenger activity (adenylate cyclase activity) and calcium ion function. Endogenous cannabinoid agonists (anandamide, 2-arachidonoylglycerol) have been identified and produce effects similar to D9THC.

Pharmacokinetics

Cannabinoids undergo substantial hepatic first-pass metabolism following oral administration such that only 10% to 20% of the ingested dose reaches the systemic circulation. This metabolism produces large amounts of active metabolite, 11-hydroxy- δ -9-tetrahydrocannabinol, which is as active as the parent compound (D9THC) and has a prolonged half-time. The peak clinical effect after oral administration occurs after 1 to 2 hours and duration of action is 4 to 6 hours. In contrast, inhalation administration results in onset of action within seconds.

Toxicity

Euphoria and feelings of relaxation occur at plasma cannabinoid concentrations of about 3 ng/mL, and this can be produced by 2 to 3 mg of D9THC. Acute intoxication may cause perceptual alterations, distortion of time, intensification of normal sensory experiences, decreased reaction times, poor motor skills, increased appetite, impairment of skilled activities, tachycardia, and hypotension. The greatest concern is the creation of long-term toxicity, development of physical dependence associated with withdrawal symptom during a period of abstinence after frequent use.¹⁹² Cannabis is often mixed with tobacco to make it burn more efficiently. Materials that are present in cannabis smoke are carcinogenic. Chronic inhalation of cannabis smoke is associated with an increased incidence of chronic obstructive lung disease and carcinoma of the lung and larynx. Persistent use of cannabis may be associated with decreased reproductive potential and reduced production of testosterone.

Clinical Uses

The D9THC is increasingly used for the long-term treatment of nausea, vomiting, cachexia, and management of chronic pain including migraine.¹⁹³ The role of the endogenous cannabinoid system is not fully understood, but evidence suggests it is involved with analgesia, cognition, appetite, vomiting, bronchodilation, inflammation, and immune control.¹⁹¹ Drugs that target the endocannabinoid system have been studied for use in addiction treatment, with a recent study reporting cannabidiol can reduce cue-induced craving and anxiety in drug-abstinent individuals with heroin use disorder.^{194,195} Cannabinoids are highly lipid soluble, and the presence of CB_1 receptors in the spinal cord suggests potential analgesic efficacy if placed in the epidural or intrathecal space. Although use of cannabis for analgesia introduces the potential for psychic and physical dependence, there is considerably less risk of life-threatening side effects compared to those associated with opioids. Pure D9THC may be effective in the treatment of chemotherapy-induced nausea and vomiting and is a recognized appetite stimulant in patients with terminal disease. Relief of skeletal muscle spasms in patients with multiple sclerosis has been described. The use of D9THC may be associated with an increased risk of myocardial infarction and thromboangiitis obliterans, perhaps reflecting D9THC-induced platelet activation.¹⁹³

The CB_1 receptors are principally expressed on neurons, and their activation has been associated with antinociception. The CB_2 receptors are principally expressed on glia and immune cells, and their activation is associated with antiinflammatory activity and reduction in chronic and neuropathic pain. Subtype-specific agonists are under investigation for pain therapy in order to overcome the problem of a narrow therapeutic window seen with non-subtype-selective cannabinoid drugs between pain relief and psychogenic effects.¹⁹⁶

¹⁹⁸ There have been many studies of the use of cannabinoids in chronic noncancer pain that have been of moderate quality and largely inconclusive when considered together. A recent meta-analysis concluded that the number needed to treat is likely high and the number needed to harm is low. Now that recreational use of cannabis is legal in multiple states, it is not uncommon for patients to be affected by cannabis in the perioperative period. A recent retrospective propensity-matched study of patients having major orthopedic surgery found that those on preoperative cannabinoids had higher pain scores at rest and with movement in the early postoperative period. There was also more sleep interruption in patients who were taking cannabinoids preoperatively.¹⁹⁹ As with any retrospective study, causality cannot be inferred. The cannabinoids may have been used to treat preoperative pain.

Conclusion

In conclusion, this thorough review of drugs used for psychopharmacologic therapy needs to be viewed in the context of the statistics mentioned in the second paragraph of this chapter. Nearly 13% of Americans older than age 12 used antidepressant medications in the past month.³ Twenty-four million prescriptions were issued in the United States in 2017 for the six most commonly prescribed antipsychotic drugs.⁴ A large portion of patients that we care for each day—whether you practice ambulatory, cardiac, or regional anesthesia, in the ICU or the pain clinic—will be taking drugs that affect their psychopharmacology. It behooves us to maintain an up-to-date understanding of the pharmacology, physiology, and potential drug interactions and bring this to bear in our practice.

PART IX Special Populations

Physiology of the Newborn*

Updated by: Becky J. Wong • Lisa Wise-Faberowski

In the absence of inborn metabolic dysfunction or birth trauma, the neonate is able to meet his or her physiologic needs when not under stress. However, neonatal physiology is characterized by decreased functional reserve. Increased physiologic demands may place a significant burden on organ systems that have not yet developed normal adult functional reserve.

Neonatal Physiology

Neonatal oxygen consumption is approximately 6 mL/kg per minute compared to 3 mL/kg per minute in the adult. The high metabolic rate of the neonate is the crucial determinant of cardiopulmonary function. Even under normal physiologic circumstances, the immature cardiac and respiratory systems operate near the edge of their functional reserve to support this metabolic demand. Immaturity of multiple neonatal organ systems creates important developmental differences in drug handling and response when compared to the older child and adults.¹

Neonatal Cardiovascular Physiology

The newborn infant is in a state of transition from the fetal, intrauterine to the newborn, extrauterine circulatory pattern. As described in [Chapter 45](#), the fetal circulation is characterized by high pulmonary vascular resistance, low systemic vascular resistance (including the placenta), and right-to-left cardiac shunting via the foramen ovale and ductus arteriosus. Expansion of the lungs at birth increases PO₂ and causes a rapid decline in pulmonary vascular resistance and an increase in pulmonary blood flow. The decrease in pulmonary vascular resistance at birth is mediated by the endogenous production of nitric oxide. Increasing blood return to the heart via the pulmonary veins raises the pressure of the left atrium above that of the right, causing a functional closure of the foramen ovale. The functional closure of the ductus arteriosus is, in part, mediated by an increase in arterial oxygen partial pressure and is normally complete within the first 10 to 15 hours of life in the term neonate. However, anatomic closure of the foramen ovale usually occurs between 3 months and 1 year of age. The foramen remains anatomically patent in 10% to 30% of people throughout life.² These individuals are described as having a “probe patent” foramen ovale, meaning that a probe or other surgical instrument can be passed through the foramen ovale. In most of these individuals, the foramen is functionally closed by the lack of any significant pressure gradient between the left and right atria; however, in conditions where the pulmonary vascular resistance rises, significant right-to-left shunting can occur. Individuals with a probe patent foramen ovale are also at risk for systemic air embolism and resultant stroke when air emboli pass from the pulmonary to the systemic circulation. Because the foramen ovale and ductus arteriosus are only functionally closed in the neonatal period, the neonatal circulation is able to readily revert to the fetal pattern, particularly in response to physiologic stresses occasionally encountered in the perinatal period. The neonatal pulmonary circulation is very reactive. Hypoxemia, hypercarbia, or acidosis cause both pulmonary vasoconstriction and dilation of the ductus arteriosus. Increases in pulmonary vascular resistance result in right-to-left shunting across the foramen ovale and ductus arteriosus. Right-to-left shunting, by causing arterial hypoxemia, causes a further increase in pulmonary vascular resistance, thus creating a vicious cycle. This “cycle” of persistent pulmonary hypertension may be seen in premature neonates and those with diaphragmatic hernia, meconium aspiration, infection, congenital heart disease, and polycythemia.

The neonatal myocardium contains immature contractile elements and is less compliant than the adult myocardium. The Frank-Starling relationship is functional only within a very narrow range of left ventricular

end diastolic pressure ([Figure 44.1](#)).³ Thus, there is a limited increase in cardiac output to be gained from aggressive volume loading in the normovolemic newborn. However, if preload is reduced by hypovolemia or dehydration, normalization of volume status will generally restore cardiac output. However, because stroke volume cannot be significantly augmented by volume loading, and because contractile reserve is limited, neonatal cardiac output is exquisitely dependent on heart rate.

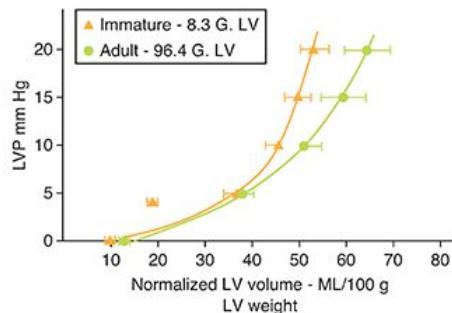

FIGURE 44.1 Pressure-volume curve for neonatal and adult heart. Pressure-volume curves for adult and neonatal canine heart. The immature heart is less compliant than the adult heart. As a result, the pressure-volume curves diverge above a left ventricular pressure (LVP) of about 5 mm Hg.

Although adrenergic receptors are thought to be mature at birth, sympathetic innervation is incomplete. After birth, neurotransmitter concentrations increase progressively, reflecting the maturation of sympathetic innervation. When compared to the adult, neonatal myocardium is more sensitive to norepinephrine.⁴ This phenomenon is a reflection of the relatively denervated status of neonatal myocardium. Dopamine is an indirectly acting inotrope that depends, in part, upon endogenous norepinephrine release for its action. Neonatal myocardium, being deficient in sympathetic innervation, is therefore less responsive to dopamine.

To meet the elevated metabolic demand, neonatal cardiac output, relative to body weight, is twice that of the adult. This is achieved with a relatively rapid heart rate (140 beats per minute) because as described earlier, stroke volume cannot be significantly increased. The neonatal circulation is characterized by centralization (increased peripheral vascular resistance and distribution of cardiac output primarily to vital organs), a situation comparable to an adult in compensated shock. Because neonatal baroreflex activity is impaired, the response to hemorrhage produces little increase in heart rate or change in total peripheral resistance. Thus, even a modest (10%) reduction in blood volume will cause a 15% to 30% decrease in mean blood pressure in the newborn infant. The structural and functional immaturity of the neonatal cardiovascular system severely limits the reserve that is available in the face of common perinatal and perioperative events such as hypovolemia, anesthetic-induced depression of contractility, relative bradycardia and positive pressure ventilation-induced decreases in venous return. The marginal cardiovascular reserve of the neonate and leftward shift of the fetal hemoglobin dissociation curve, decreased oxygen unloading to the tissues, are the rationale underlying the recommendation that the hematocrit be maintained at 30% or higher to prevent tissue ischemia in the newborn.

Respiratory Physiology of the Newborn

The respiratory system of a term neonate at birth is immature and postnatal development continues through early childhood. Although the conducting airways are fully developed by 16 weeks of gestation, the number of alveoli is reduced at birth. A premature infant born at 24 to 28 weeks of gestation is just beginning to develop alveoli from the distal saccules of the lung.⁵ Complete alveolar maturation does not occur until 8 to 10 years of age. At birth, the infant possesses approximately one-tenth of the adult population of alveoli. Thus, the ratio of alveolar surface area to body surface area is one-third that of the adult. To satisfy increased oxygen demand, neonatal alveolar minute ventilation is twice that of the adult. Increasing respiratory rate rather than tidal volume is the most efficient means to increase alveolar ventilation in the newborn. The diaphragm is less efficient in neonates, as it is flatter/less dome-shaped with fewer high-oxidative, less fatigued muscle fibers than in the adult. Ventilation-perfusion imbalance occurs as a result of distal airway

closure, as the closing volume can exceed functional residual capacity (FRC) in neonates. Overall, FRC is lower in the neonate due to the high elastic recoil of the chest wall during normal tidal breathing. This phenomenon is responsible for an increase in the alveolar-arterial oxygen tension gradient compared to adults.

Adequate gas exchange depends on adequate alveolar recruitment and thus surfactant function. Production of surfactant begins by 23 to 24 weeks of gestation and reaches maturity at approximately 35 weeks of gestation. Surfactant-deficient preterm infants have decreased lung compliance and are at risk for the development of respiratory distress syndrome.⁵ Administration of corticosteroids to mothers in preterm labor may accelerate lung maturation in the fetus. Furthermore, the instillation of intratracheal exogenous surfactant in preterm babies has considerably improved the prognosis for premature infants. Infants born to mothers with intrauterine infection have a paradoxical increase in pulmonary maturation. The enhancement in lung maturation can be mimicked with lipopolysaccharide, suggesting that the effect is due to local inflammatory mediators rather than a downstream effect of corticosteroids.⁶ In humans, the effect of inflammation on lung maturation is not enhanced by corticosteroid administration.⁷

The neonatal chest wall is more compliant and has less outward but more inward recoil than that of the adult. Thus, the neonatal lung has a greater tendency to collapse and the infant is obliged to use active mechanisms to maintain normal lung volumes (**Table 44.1**). First, by breathing at a relatively rapid rate, the duration of expiration is limited. In this way, inspiration is initiated before the lung has completed recoiling to its end-expiratory volume. Second, the neonate uses intercostal muscle activity during expiration to stabilize the chest wall, thus retarding the decline in lung volume during expiration. Last, the neonate exhales through a partially closed glottis, also retarding expiratory flow and maintaining end-expiratory lung volume. The awake neonate has an FRC that is similar, when normalized to body weight, to that of an adult. However, because neonatal alveolar ventilation is twice that of an adult, the ratio of alveolar ventilation to FRC in the neonate is twice that of the adult. The high ratio of minute ventilation to FRC causes a much more rapid wash out or wash in of oxygen and anesthetic drugs in response to changes in inspired concentrations.

TABLE 44.1

Active mechanisms used by neonates to maintain lung volume^a

- Rapid respiratory rate—early termination of expiration
- Intercostal muscle activity in expiration—stabilizes compliant chest wall
- Expiration against partially closed glottis—retards expiratory flow

^aSignificantly attenuated by general anesthesia.

The active mechanisms used by the newborn to protect lung volume are exquisitely sensitive to the effects of general anesthesia. Therefore, the neonatal FRC may decrease significantly during anesthesia, particularly during periodic breathing and apnea. The combination of increased oxygen consumption and a reduced ratio of alveolar ventilation to FRC in the newborn explains why apnea and hypoventilation are associated with marked and rapid arterial oxygen desaturation.

Although the peripheral chemoreceptors are active from 28 weeks of gestation, their function is immature until several days after birth. Therefore, the neonate and preterm infant exhibit an altered response to hypoxia and hypercarbia. When challenged with hypoxic inspired gas mixtures, both the term and preterm infant have an initial 1- or 2-minute period of hyperventilation followed by sustained hypoventilation. As postnatal age increases, the hyperventilatory response becomes sustained. However, this protective response develops more slowly in the preterm infant and the ventilatory response to hypercarbia is impaired. The impaired neonatal ventilatory responses to hypoxia and hypercarbia are contributing factors to the development of life-threatening apnea and hypoventilation in the postoperative period.⁸ Nasal continuous positive airway pressure and high-flow nasal cannula are two methods for ventilatory support after extubation in the neonatal period. However, in very premature neonates, less than or equal to 1,250 g, the increased fraction of inspired oxygen with high-flow nasal cannula may promote respiratory pauses post extubation.⁹ Although airway resistance is relatively low in infants, in absolute terms, the airways are very narrow.

Relatively minor quantities of secretions or trivial inflammatory disease can produce serious respiratory embarrassment in small infants.

Neonatal Thermoregulation

The neonate tends to become hypothermic during general anesthesia much more rapidly than the adult. Accelerated heat loss in the neonate is related to its relatively large surface area compared to body mass, thinner layer of insulating subcutaneous fat, and a limited capability for thermogenesis. The neonate primarily relies on nonshivering or chemical thermogenesis in brown adipose tissue for heat production. Thermogenesis in brown fat is mediated by the sympathetic nervous system and is stimulated by norepinephrine, resulting in triglyceride hydrolysis. The thermoregulatory range is the ambient temperature range within which an unclothed subject can maintain normal body temperature. The lower limit of the thermoregulatory range (ambient temperature at which core temperature can be maintained) is 1.25°C for an adult but is as high as 23°C and 28°C for the full-term infant and premature infant, respectively.

Therefore, the thermoregulatory range of the neonate is much narrower than that of the adult. During anesthesia and surgery, heat loss in the pediatric patient is further enhanced by decrease in the thermoregulatory threshold due to anesthesia, low ambient temperatures of the operating suite (20°C-22°C), preparation of skin with cold solutions, infusion of cold solutions, anesthesia-induced vasodilatation, and use of dry anesthetic gases in high-flow, nonrebreathing systems. Intraoperative hypothermia will markedly delay emergence. Furthermore, with the return of the thermostatic reflexes, oxygen consumption increases by three- to fourfold as the metabolic rate is increased in an attempt to generate heat. This additional demand on an immature cardiorespiratory system that is already compromised due to the residual effects of anesthesia and surgery may precipitate cardiorespiratory failure.

The loss of heat during anesthesia and surgery can be prevented by a number of simple measures, such as raising operating room temperature to 28°C to 30°C, radiant heat lamps, wrapping the head and extremities with insulating material, using nonvolatile warmed solutions for skin preparation, and administration of warmed intravenous fluids and blood products. Inhaled gases should be heated and humidified. Forced air warming devices are also effective in maintaining perioperative normothermia in neonates.

Neonatal Fluid, Electrolyte, and Renal Physiology

The neonate is characterized by an increased total body water (70% vs 55% in adults), increased extracellular fluid volume, increased water turnover rate, and reduced glomerular filtration rate. The neonatal renal tubules have a decreased ability to absorb sodium, bicarbonate, glucose, amino acids, and phosphates. Neonates are obligate sodium wasters and require sodium supplementation. All of these factors contribute to the potential for overhydration, dehydration, metabolic acidosis, and hyponatremia, necessitating meticulous attention to intraoperative fluid therapy. Compared to adult levels, the glomerular filtration rate in term neonates is only 35% and increases to 90% by the end of infancy.¹⁰ Although third-space translocation of fluids is relatively similar in neonates and adults, neonatal insensible losses vary greatly. Fever, radiant warmers, phototherapy, increased ambient temperature, and decreased humidity all increase insensible loss.

Neonatal Neurophysiology

Electroencephalogram rhythms that are mediated by subcortical integration of cortical and subcortical processes are present from 20 weeks' gestation.¹¹ Somatosensory evoked potentials can be recorded from the fetal cerebral cortex at 29 weeks' gestation.¹² As such, the functional circuitry required for sensation of pain is likely to be present between 20 and 30 weeks' gestation. The neonatal brain is comparatively large at birth compared to the adult. Myelination is incomplete at birth and is typically accomplished before the third year of age.

Although myelination is incomplete, and nerve conduction velocity may be diminished, the shorter conduction distances found in the neonate facilitate rapid transmission of nociceptive impulses to the brain.¹³ As in adults, most nociceptive impulses are transmitted by unmyelinated C fibers and by poorly myelinated A δ fibers. Painful stimuli produce withdrawal, autonomic stimulation, and neuroendocrine stress responses. The concept of plasticity of the nervous system has important implications for the management of pain in

newborns. The failure to provide analgesia for neonates leads to changes in nociceptive pathways in the dorsal horn of the spinal cord and in the brain. As a result, future painful insults result in exaggerated pain perception. Indeed, in human newborns, the failure to provide adequate anesthesia or analgesia for circumcision is associated with long-term changes, including an increased response to immunization later in childhood.¹⁴

The adequate treatment of pain in the neonatal period is challenging because of the fear of respiratory depression associated with opioid administration. Fortunately, several nonpharmacologic behavioral interventions have analgesic effects in infants.¹⁵ Analgesia may be induced by the administration of sucrose and by suckling. These effects are mediated via descending endogenous opioid and nonopioid mechanisms originating in the brainstem and may be partially reversed by the administration of naloxone.¹⁶

The germinal matrix has a rich blood supply, thin vessel walls, and scant vascular supporting tissue, causing the vessels of this region to be susceptible to rupture. With increasing gestational age, the germinal matrix involutes and is absent in the full-term infant. Intraventricular hemorrhage in the premature infant and in the fetus originates predominantly in the germinal matrix and occasionally in the choroid plexus. Periventricular-intraventricular hemorrhage occurs in 40% to 50% of premature infants and is a major cause of neonatal morbidity and mortality. The factors in the pathogenesis of intraventricular hemorrhage include abrupt changes in cerebral hemodynamics, changes in intracranial pressure, disturbances in osmotic equilibrium, and coagulopathy.

Preterm infants are also at risk for retinopathy of prematurity in which abnormal growth of retinal vessels can lead to scarring and blindness. Although gestational age is the primary etiologic factor in the development of retinopathy of prematurity, hyperoxia, hypocarbia, vitamin E deficiency, and acidemia have also been implicated as contributing factors.

Neonatal Hepatic Physiology

Liver functions can be classified into three main categories: metabolism, detoxification, and bile synthesis. Neonates have decreased glycogen stores and are prone to hypoglycemia after relatively brief periods of starvation. The preterm infant is at even greater risk for hypoglycemia. Glucose is therefore an essential element of the intraoperative fluid plan. The term neonate requires 3 to 5 mg/kg per minute and preterm neonates 5 to 6 mg/kg per minute of glucose to maintain serum glucose between 35 and 125 mg/dL.

Bilirubin is a by-product of hemoglobin catabolism in the neonate. Hepatic enzyme uridine diphosphate glucuronyl transferase catalyzes the conjugation of bilirubin with glucuronide. Levels of hepatic uridine diphosphate glucuronyl transferase reaches adult levels during the first few weeks of life.¹⁷ Hyperbilirubinemia and physiologic jaundice is common in the 2-week-old neonate and is multifactorial: increased bilirubin production, deficient conjugation, increased reabsorption of unconjugated bilirubin via the enterohepatic circulation, and insufficient oral intake.¹⁸ The hyperbilirubinemia is exaggerated in the preterm neonate compared to the term neonate.

Pharmacology and drug metabolism in neonates are not extensively studied as drug companies often classify neonates as an at-risk population and exclude them from their studies. Therefore, many drugs are considered off-label use in neonates. In light of this, the clinician should be cognizant of the neonate's renal and liver maturation, along with the metabolism of certain drugs, which may not reach normal adult levels until around 6 months of age.¹⁹

Maternal and Fetal Physiology and Pharmacology

Amy W. Willett • Pamela Flood

Introduction

As many as 1 out of every 50 pregnant women will undergo some type of surgery during their pregnancy. This rate is likely to increase with increasing indications and improved outcomes from fetal interventions. There are currently no data-driven recommendations best practices for anesthesia for nonobstetric surgery during pregnancy given the barriers to conducting large-scale randomized clinical trials. Thus, it is critical for the anesthesiologist to be an expert on maternal physiology and pharmacology to optimize intraoperative maternal-fetal well-being in multiple clinical scenarios.

Pregnancy causes significant physiologic changes that provide for the metabolic demands of the growing fetus. The pharmacokinetics and pharmacodynamics of many drugs are altered during pregnancy. When possible, surgery is performed during the second trimester of pregnancy to avoid affecting major organogenesis during the first trimester and to reduce the risk of preterm delivery that is increased in the third trimester. The immediate effects of anesthesia are normally well tolerated by the fetus. The fetus does not depend on alveolar ventilation for oxygenation or carbon dioxide removal and has the maternal organs to help manage drug metabolism and excretion. However, the fetal cardiac output is sensitive to depression by anesthetic drugs. Drugs used in anesthesia cross the placenta to a variable extent (**Table 45.1A–G**).^{1–82}

TABLE 45.1A

Antihypertensive drugs^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Atenolol	No change in dose required	0.94	1.6-6.8	D	Increased oral absorption compensates for increased renal clearance Unchanged $t_{1/2}$ 100% renally cleared
Clonidine	Increased dose/shorter dosing interval may be needed	1.0	1.5	C	Renal clearance increased 2 times $t_{1/2}$ significantly decreased
Diltiazem	Unknown	Unknown	1	C	Unknown
Furosemide	No change in dose required	~1	Excreted in breast milk	C	Clearance unchanged in third trimester
Hydralazine	Unknown	0.72	Small amount of active compound in breast milk	C	Unknown
Labetalol	Increased dose or more frequent dosing	0.4-0.8	0.8-2.6	C	Oral labetalol, clearance increased with advancing pregnancy (1.4 times at 12 weeks, 1.6 times at term) Due to increased activity of hepatic blood flow and induction of UGT1A1
Methyldopa	Unknown	1.2	0.19-0.34	B	Unknown
Metoprolol	Increased dose or more frequent dosing	1	3	C	Oral clearance 4 times greater in third trimester Peak serum concentrations 12%-55% Mechanism increased hepatic blood flow and CYP2D6 induction More effective at lower plasma concentrations in pregnancy
Nifedipine	Increased dose/shorter dosing interval	Unknown	<0.05	C	Oral clearance 4 times higher $t_{1/2}$ decreased by 50% Mechanism increased hepatic blood flow and CYP3A4 induction
Sotalol	Unknown	1.1	>1	B	Unknown

Abbreviations: FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; PK/PD, pharmacokinetic/pharmacodynamics.

TABLE 45.1B

Anticoagulants and antiplatelet drugs^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Acetylsalicylic acid	Unknown, possibly increased dose requirement based on PK	1 for salicylic acid, lower for acetylsalicylic acid due to placental esterases	Peak levels 9-12 hours after dose	N	Slower uptake, lower peak plasma concentration after single dose
Argatroban	Unknown	Unknown, low molecular weight, moderate protein binding Likely crosses placenta	Unknown, low molecular weight, moderate protein binding Likely crosses into breast milk	B	Unknown
Clopidogrel	Unknown	Unknown likely crosses placenta, low molecular weight	Unknown likely crosses into breast milk, low molecular weight	B	Unknown
Dabigatran	Unknown	0.33	Unknown	C	Unknown
Enoxaparin	Must titrate to Xa levels given wide swings in pharmacokinetics through pregnancy; once-daily dosing is likely insufficient given higher clearance.	Does not readily cross placenta due to large molecular weight	Very little excreted into breast milk due to high molecular weight; milk/plasma ratio of <0.025-0.224; also not absorbed orally	B	Increased clearance; larger volume of distribution with major increase in last 2 months of pregnancy Progressive reduction in anti-Xa activity during pregnancy
Fondaparinux	Unknown	0.1 large molecular weight	Unknown	B	Potentially unchanged, case report data
Heparin	Higher doses and/or more frequent intervals aPTT is not valid in pregnancy, measure Xa levels	Does not cross placenta due to large molecular weight	Not excreted into breast milk due to high molecular weight	C	Peak plasma concentration 50% that of nonpregnant controls Reduced efficacy in pregnancy ACCP recommends 10,000 U every 12 hours or monitoring anti-Xa levels
Rivaroxaban	Unknown	Unknown	Manufacturer reports rivaroxaban is excreted in breast milk.	C	Unknown
Warfarin	Highly variable	0.15—not metabolized readily by fetal liver leading to higher INR in fetus	Not excreted into breast milk	X (D if mechanical heart valve)	PK unknown; postpartum patients require more drug than nonpregnant women to achieve therapeutic anticoagulation.

Abbreviations: ACCP, American College of Chest Physicians; aPTT, activated partial thromboplastin time; FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; INR, international normalized ratio; PK/PD, pharmacokinetic/pharmacodynamics.

TABLE 45.1C

Opioids^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Alfentanil	No major dosing changes anticipated	0.3	Excreted into breast milk at low concentrations	C	No change in volume of distribution or clearance
Buprenorphine	Dose increase in third trimester; decreased risk of neonatal withdrawal compared with methadone (adjusted odds ratio; 2.55)	Minimal data; estimated F/M ratio was 6.3 in 1 patient	More data needed; known to cross into breast milk; values not reported; poor oral bioavailability makes absorption during breast-feeding low.	C	Increased metabolism to inactive metabolites via induction of CYP3A4
Codeine	Should not be used because of variable metabolism and excretion into breast milk	See morphine.	See morphine.	C	Prodrug metabolized by CYP2D6 that is induced in pregnancy and has extensive genetic variability
Fentanyl	Unknown	0.5-0.9	1.4-3; low oral bioavailability in neonate	C	Peak maternal concentration 0.5 ng/mL with epidural dosing
Hydrocodone	Unknown; more research needed	Unknown	Fully breastfed neonates received 1.6%-3.7% (range, 0.2%-9%) of the maternal weight-adjusted hydrocodone dose.	C	Increased activity of hepatic CYP2D6 enzyme increases conversion to the more potent opiate, hydromorphone; can result in higher and more rapid peak effect
Hydromorphone	Unknown	Unknown	2.6. Estimated infant dose was 0.67% of the mother's weight-adjusted dose	C	Metabolized by CYP2D6
Meperidine	No change, caution with repeat dosing in breastfeeding	35-106	0.8-1.6. Long $t_{1/2}$ of meperidine and normeperidine in infants—no >1 dose is recommended in breastfeeding women	C	Increased metabolism (inactivation) is expected via induction of CYP3A4 in pregnancy; likely counterbalanced by decreased clearance; no change in $t_{1/2}$
Methadone	Higher dose and shorter dosing interval required. Mean increased dose of 24 mg in methadone maintenance by third trimester, and many authors recommend splitting total daily dose into twice a day. Dose returns to normal by 6 weeks postpartum.	0.2. Withdrawal symptoms occur in 60%-90% of the infants exposed in utero to methadone.	Average = 0.8, wide range of 0.05-1.2. Concentration in breast milk can help with symptoms neonatal abstinence syndrome.	C	Increased clearance; largely due to induction of CYP3A4 and CYP2B6; placental aromatase CYP19 also metabolizes methadone; reduced elimination half-life of 8-20 hours compared with the 24-hour half-life in a nonpregnant patient
Morphine	May require increased dose and/or increased dosing interval	0.61-1; undetectable in most infants 1-2 hour after a single IV maternal dose	<1; low oral bioavailability (26%) in infant; receives 8%-12% maternal dose	C	Volume of distribution unchanged, clearance >70%, decreased half-life, glucuronide conjugation by UGT
Oxycodone	May require a shorter dosing interval due to faster elimination half time	Maternal plasma/umbilical plasma ration of 1	3.2	B	Increased clearance via increased GFR as well as induction of CYP3A4 and CYP2D6 induction; shorter elimination half time in laboring

					women (decreased from 3.8 to 2.6 hours)
Remifentanil	May require higher dose to achieve the same plasma concentration due to increased clearance	0.29-0.88; extensive fetal and placental metabolism occurs, as evidenced by a large decrease from the UV; MA ratio of 0.88	Unknown; low molecular weight and high lipid solubility suggest that it will be excreted into breast milk	C	Clearance more than doubles, likely due to larger blood plasma volume, increased cardiac output, and increased renal blood flow

Abbreviations: FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; GFR, glomerular filtration rate; IV, intravenous; MA, maternal artery; PK/PD, pharmacokinetic/pharmacodynamics; UGT, glucuronosyltransferase; UV, umbilical vein.

TABLE 45.1D

Sedative hypnotic drugs^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Diazepam	Not recommended	1	0.2-2	D	No change in clearance
Etomidate	Unknown	0.5-0.86	1.2; undetectable in 4 hours	C	Unknown
Ketamine	Unknown	1.26	Unknown	NA	No human data; unchanged in pregnant ewe
Midazolam	Not recommended during first trimester; may require dose increase for intended effect at term	0.15-0.66	0.15; cleared in 4 hours	D	Peak plasma concentration is reduced; half-life unchanged CYP3A-induced hepatic metabolism increased
Propofol	2 mg/kg resulted in less neonatal depression	0.7-1.3	Negligible	B	C ₅₀ for loss of consciousness unchanged first trimester
Thiopental	No dose change	0.4-1.1	<1	NA	Volume of distribution and clearance increased resulting in lower plasma concentrations but more efficacious in pregnancy

Abbreviations: FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; NA, not applicable; PK/PD, pharmacokinetic/pharmacodynamic.

TABLE 45.1E

Muscle relaxants^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Atracurium	Unchanged	0.12	Unknown; not orally absorbed by infant	C	VD, V _{ss} , and V _c unchanged; clinical duration unchanged
Pancuronium	Unchanged	0.2-0.5	Unknown; not orally absorbed by infant	C	Faster clearance no change in VD
Rocuronium	No change in initial dose; some studies suggest prolonged duration and therefore decreased redosing	0.1-0.6	Unknown; not orally absorbed by infant	C	PK unknown; onset unchanged; possible increased clinical duration of action
Succinylcholine	No change except avoid in women with atypical cholinesterase	Not detectable	Unknown; not orally absorbed by infant	C	Slightly prolonged recovery time postpartum Reduced cholinesterase not significant with 1 mg/kg dose, prolonged

					blockade may occur with larger doses
Vecuronium	May require more frequent monitoring	0.1-0.5	Unknown; not orally absorbed by infant	C	VD, Vss, and Vc unchanged; terminal half-life reduced but clinical duration is prolonged

Abbreviations: FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; PK/PD, pharmacokinetic/pharmacodynamics; Vc, central volume; VD, volume of distribution; Vss, steady state volume.

doi:10.1213/ANE.0000000000001143. Review, with permission.

TABLE 45.1F

Local anesthetic drugs^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
2-Chlorprocaine	N/A; titrated to effect	Rapidly hydrolyzed by esterases, and only traces of this compound reach the fetus, even after overdose, suggesting safety for the fetus	Unknown	C	Unknown
Bupivacaine	N/A; titrated to effect	0.3-0.7; 90% binding to maternal α_1 -acid glycoprotein that exceeds fetal protein binding (50%); fetal acidosis will cause increased fetal accumulation and possible toxicity.	0.3	C	No change in absorption or peak concentration; some changes in metabolism—less 4'-hydroxylation, enhanced N-dealkylation
Lidocaine	N/A; titrated to effect	0.5-0.9; acidosis increases transfer to fetus	1	B	Unknown
Mepivacaine	N/A; titrated to effect	0.5-0.7	Unknown	C	Unknown
Prilocaine	N/A; titrated to effect	1	Unknown	B	Unknown
Ropivacaine	N/A; titrated to effect	0.3-0.7	0.25	B	Unknown

Abbreviations: FDA, U.S. Food and Drug Administration; F/M, fetal/maternal ratio; N/A, not applicable; PK/PD, pharmacokinetic/pharmacodynamics.

^aFrom Ansari J, Carvalho B, Shafer SL, Flood P. Pharmacokinetics and pharmacodynamics of drugs commonly used in pregnancy and parturition. *Anesth Analg*. 2016;122(3):786-804.

TABLE 45.1G

Antibiotic drug^a

Drug	Dose adjustment	F/M ratio	Breast milk/maternal plasma ratio	Former FDA category	PK/PD alteration
Amoxicillin	Higher more frequent dosing	0.18 after 3 minutes	0.014, 0.013, and 0.043 at 1, 2, and 3 hours	B	Increased clearance
Ampicillin	Higher more frequent dosing	0.3-0.7 at 1 hour after dose; 1.1-10 2-6 hours after dosing	0.2	B	Increased clearance in pregnancy
Azithromycin	500 mg before cesarean delivery leads to sustained concentrations greater than MIC for <i>Ureaplasma</i>	0.2-0.4	Accumulates reaches steady state in 3 days	B	Clearance by hepatobiliary excretion may be reduced in pregnancy.

Cefazolin	Higher dose to reliably keep plasma concentration above MIC	0.35-0.69	0.02	B	Clearance and volume of distribution are increased.
Cefepime	Higher dose or increased frequency may be required	0.23	Low concentration	B	Clearance and volume of distribution are increased.
Cefoxitin	Higher dose or increased frequency may be required; more studies needed	0.1-0.9	Minimal secretion	B	Clearance and volume of distribution are increased
Ceftriaxone	More studies needed	Unknown	0.03-0.06	B	? longer half-life in pregnancy
Ciprofloxacin	Unknown	Unmeasured but crosses placenta and concentrates in amniotic fluid	4.71	C	Unknown
Clindamycin	Increased dosing may be required depending on degree of protein binding; more research needed	0.5	0.08-3.1	B	Decreased AUC/MIC ratio
Ertapenem	Unknown	Low molecular weight; may pass	0.13-0.38	B	Unknown
Gentamicin	Increased frequency of dosing; may require measurement of plasma levels	0.34-0.44 were at 1-2 hours	0.1 at 1 hour and 0.4 at 7 hours	D	Increased volume of distribution and increased clearance result in low-peak concentrations.
Meropenem	Unknown	Unknown	0.18	B	Unknown
Metronidazole	No dose adjustment required	1	1	B	Unchanged
Moxifloxacin	Requires increased dosing	0.78	Unknown	C	Peak serum concentrations decreased; clearance increased; AUC 0.2 times nonpregnant values
Piperacillin and tazobactam	Increased frequency of dosing	0.17-0.27	Unknown	B	Increased clearance and volume of distribution; concentration less than MIC at 4 hours
Sulfonamides	Likely reduced concentration due to dilution but not described	0.5 sulfasalazine; 0.06 sulfisoxazole	Competes with bilirubin for albumin binding at birth	Sulfasalazine-B Sulfamethoxazole/trimethoprim-D Sulfamethoxazole-C	Unknown
Tetracyclines	Not tested; teratogenicity	Crosses and leads to dental discoloration	Crosses and leads to dental discoloration	D	Unknown
Vancomycin	20 mg/kg every 8 hours measurement of maternal plasma levels for sustained treatment	1 with steady state reached at 1-2 hours	1	C	Increased volume of distribution, and clearance, unknown changes in half-life

Abbreviations: AUC, area under the curve; FDA, U.S. Food and Drug Administration; F/M, fetal/maternal; MIC, minimum inhibitory concentration; PK/PD, pharmacokinetic/pharmacodynamics.

^aFrom Ansari J, Carvalho B, Shafer SL, Flood P. Pharmacokinetics and pharmacodynamics of drugs commonly used in pregnancy and parturition. *Anesth Analg*. 2016;122(3):786-804.
doi:10.1213/ANE.0000000000001143. Review, with permission.

As a general rule, molecular characteristics that favor the passage of drugs across the blood-brain barrier also allow for passage across the placenta. Knowledge of principles of placental transfer is important and can be utilized to achieve certain anesthetic goals. For example, during fetal surgery, drugs that cross the placenta

are used when possible to provide fetal anesthesia and analgesia. Drugs that do not cross the placenta such as muscle relaxants have to be directly administered to the fetus through the umbilical vein.

During cesarean section, limiting cardiac and respiratory depressant drugs that cross the placenta minimizes the risk of neonatal depression at birth. For example, whereas most benzodiazepines have a fetal to maternal (F/M) ratio of 1, midazolam is the exception with an F/M ratio that has been measured at 0.15 to 0.66, making it the preferred benzodiazepine when needed peripartum.⁸³ The ratio of breast milk to maternal plasma concentration is low at 1.2 and cleared by 4 hours. It is important to note that older recommendations restricting breastfeeding based on peripartum treatment with opioids, benzodiazepines and anesthetics have been revised in view of the importance of early initiation of breastfeeding success and overall health benefits from breastfeeding.⁸⁴ Many, but not all, drugs commonly used in pregnancy have available information on F/M ratio (see [Table 45.1A–G](#)) and breast milk to maternal plasma ratio.

Maternal Physiology

Physiologic Changes During Pregnancy and Delivery

During pregnancy and the peripartum period, substantial changes in maternal anatomy and physiology occur secondary to changes in hormone activity, increased maternal metabolic demands, biochemical alterations from the fetus, and the mechanical effects of an enlarging uterus ([Table 45.2](#)).

TABLE 45.2

Change in physiologic values in pregnancy

Factors	% Change from nonpregnant state
Central nervous system	
Minimal alveolar concentration for volatile anesthetics	-40
Cardiovascular system	
SVR	-15
HR	+15
SV	+30
BP	+35
CO	+40
PV	+45
Respiratory system	
FRC	-20
HCO ₃	-15
Paco ₂	-15
Pao ₂	+10
RR	+15
Oxygen consumption	+20
Tidal volume	+40
Minute ventilation	+50
Hematologic system	
Hemoglobin	-20
Clotting factors	+50-200
Renal system	
GFR	+50

Abbreviations: BP, blood plasma; CO, cardiac output; FRC, functional residual capacity; GFR, glomerular filtration rate; HCO₃, bicarbonate; HR, heart rate; PV, peripheral vasodilation; RR, respiratory rate; SV, stroke

volume; SVR, systemic vascular resistance.

Cardiovascular Changes

Pregnancy-induced changes in the maternal cardiovascular system include increased blood volume and cardiac output, decreased vascular resistance, and supine hypotension.

Intravascular Volumes and Hematology

Maternal intravascular fluid volume begins to increase in the first trimester of pregnancy as the result of increased production of renin, angiotensin, and aldosterone, which together promote sodium absorption and water retention. These changes are likely induced by progesterone.⁸⁵ With increases in plasma volume, there is an associated reduction in maternal plasma protein concentration. By term gestation, the plasma volume increases approximately 50%, and the red cell volume increases about 25%. The greater increase in plasma volume is the cause of the “physiologic anemia of pregnancy” (Figure 45.1).⁸⁶ Because the increase in red cell mass lags behind the increase in plasma volume, hematocrit typically reaches a nadir in the second trimester and increases by term. Maternal hemoglobin normally remains at 11 g/dL or greater even at term, and lower values at any time during pregnancy represent anemia. The physiologic anemia of pregnancy does not cause a reduction in oxygen delivery because of a coincident increase in cardiac output. The additional intravascular fluid volume (1,000–1,500 mL at term) compensates for an average 300 to 500 mL blood loss with vaginal delivery and 800 to 1,000 mL estimated blood loss with cesarean section. Following delivery, uterine contraction creates an autotransfusion of blood often in excess of 500 mL that also compensates for the acute blood loss from delivery. Mild thrombocytopenia is a normal finding.⁸⁷ However, 8% of otherwise healthy women have thrombocytopenia with a platelet count less than 150,000/ μ L. In the absence of other hematologic abnormalities, the cause for gestational thrombocytopenia is a diagnosis of exclusion. Platelet count does not usually drop below 70,000/ μ L and is not associated with abnormal bleeding. Gestational thrombocytopenia is thought to result from a combination of hemodilution and accelerated platelet turnover.

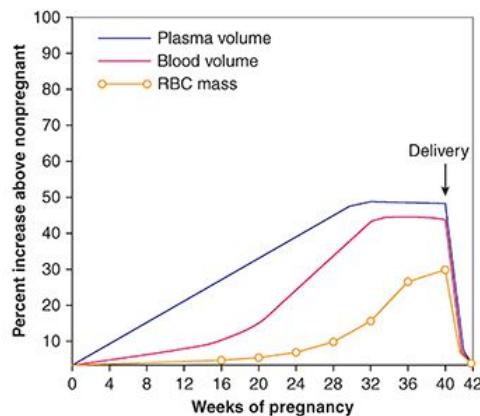

FIGURE 45.1 Blood volume changes during pregnancy. Plasma volume increases during pregnancy more rapidly than red cell mass leading to a physiologic anemia of pregnancy. Abbreviation: RBC, red blood cell.

Mild leukocytosis unrelated to infection is common during pregnancy.⁸⁸ In particular, the neutrophil count increases at term and is further increased during labor. These changes revert to normal during the week after delivery. In spite of mild thrombocytopenia, pregnancy is a hypercoagulable state with increased clotting and decrease in fibrinolytic capacity. Thrombogenic factors such as VII, VIII, and X, von Willebrand factor, and fibrinogen are increased,⁸⁷ whereas protein S and antithrombin III are decreased. These result in important changes to standard laboratory analyses depending on trimester (Table 45.3). Because pregnancy is associated with a near fivefold increased risk of venous thromboembolism, it is important to consider strategies that balance the maternal risk of thrombosis with hemorrhage while considering the potential fetal

risk from exposure to the anticoagulant agent. For example, warfarin is considered to provide the best protection against thromboembolic events; however, it crosses the placenta and therefore carries a dose-dependent risk of adverse fetal outcomes. Heparin preparations, on the other hand, do not cross the placenta and therefore do not exert direct effects on the fetus. When low molecular weight heparin is used, peak anti-Xa levels should be assessed and maintained between 1.0 and 1.2 U/mL. However, low-risk pregnant women who are on low molecular weight heparin for prevention likely do not need special monitoring. For patients on therapeutic anticoagulation, switching to intravenous unfractionated heparin is indicated in anticipation of planned delivery as its rapid onset and clearance minimizes potential complications from bleeding. Fondaparinux use is safe during pregnancy and recommended in the setting of heparin allergy or heparin-induced thrombocytopenia. Use of oral direct thrombin and factor Xa inhibitors during the pregnancy is limited as these agents cross the placenta.⁸⁹

TABLE 45.3

Standard hematology laboratory values during pregnancy^a

	First trimester	Second trimester	Third trimester
aPTT (seconds)	26.4-41.9	24.4-35.8	25.6-34.9
PT (seconds)	9.7-12.5	8.5-13.2	8.6-12.4
Fibrinogen (g/L)	2.38-4.44	2.40-5.97	2.79-5.91

Obstetric hemorrhage has unique features in that there is a disproportional coagulopathy observed relative to total blood loss when compared with surgical or traumatic hemorrhage.⁹⁰ The rapid development of coagulopathy in obstetric hemorrhage is likely multifactorial and not completely understood, but the active consumption of procoagulant factors is thought to occur as the placenta separates from the uterus. Increased fibrinolysis and platelet activation are observed, as well as release of tissue factor into the blood stream, further activating consumption of procoagulant factors. Viscoelastic assays measure the hemostatic properties of whole blood by providing a real-time examination of the initiation, propagation, strength, and dissolution of clot. Thromboelastograph (TEG) and rotational thromboelastometry (ROTEM) are more representative of in vivo coagulation than standard laboratory tests and are increasingly being used in the management of obstetric hemorrhage and hemostatic disorders. Interestingly, a strong correlation has been identified between ROTEM variables and standard coagulation parameters in healthy women soon after delivery.⁹¹ Meanwhile, use of TEG has demonstrated increased coagulability in preeclamptic patients that was not revealed in standard laboratory tests.⁹² The correlation between TEG and standard laboratory values has been inconsistently described in the literature. Issues such as fibrinogen overestimation⁹³ have also been reported with the use of TEG. The FIBTEM component of the ROTEM assay evaluates fibrinogen and appears to correlate well with standard laboratory fibrinogen levels. Thus, ROTEM analyses may be better suited for perioperative guidance in fibrinogen administration. Until there is a direct comparison between TEG and ROTEM in the obstetric population, it remains unclear which is superior for the diagnosis and goal-directed management of coagulopathy during obstetric hemorrhage.

Cardiac Output

By the end of the first trimester, maternal cardiac output increases, on average, by 35% above prepregnancy values and continues to increase to 50% above nonpregnant values by the end of the second trimester, remaining at similar, elevated levels throughout the third trimester. This increased cardiac output is the result of both increases in stroke volume and heart rate (Figure 45.2).⁹⁴ Labor is associated with further increases in cardiac output, which increases with each uterine contraction. Increases above prelabor values of 10% to 25% are noted during the first stage of labor and a 40% increase occurs during the second stage. The largest increase in cardiac output occurs immediately after delivery, when cardiac output can be increased by 80% to

100% above prelabor values. This large increase is secondary to the autotransfusion from the final uterine contraction, reduced vascular capacitance from loss of the placenta, and decreased lower extremity venous pressure from release of the aortocaval compression. This massive increase in cardiac output represents a moment of unique risk for patients with cardiopulmonary disease, particularly those with valvular stenosis and pulmonary hypertension. Cardiac output returns toward prelabor values by about 24 hours postpartum and returns to nonpregnant levels within 12 weeks after delivery. It is critical to monitor patients with cardiac disease closely in the postpartum period.

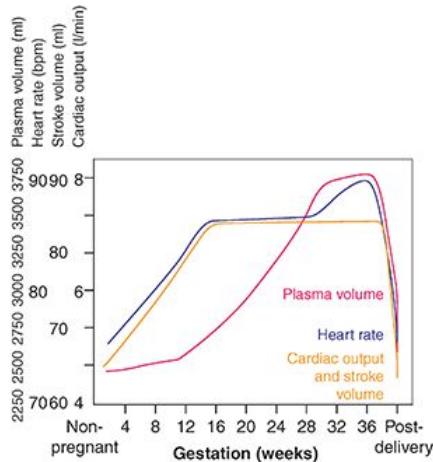

FIGURE 45.2 Maternal hemodynamic changes of pregnancy. Maternal heart rate and cardiac output increase early in the first trimester and plateau in the second trimester. There is an additional increase in heart rate during the third trimester. Plasma volume increases throughout the first and second trimester and reaches a plateau during the third trimester. All values drop rapidly in the days after delivery. *Reproduced from Thorne SA. Pregnancy in heart disease. Heart. 2004;90(4):450-456 with permission from BMJ Publishing Group Ltd.*

Systemic Vascular Resistance

In spite of increases in cardiac output and plasma volume, systemic blood pressure normally decreases secondary to a 20% reduction in systemic vascular resistance by term. Blood pressure decreases approximately 20% by 20 weeks' gestational age and then increases toward nonpregnant values as the pregnancy reaches term. Central venous pressure and pulmonary capillary wedge pressure are unchanged during normal pregnancy despite the increase in plasma volume because of the concurrent increase in venous capacitance.

Aortocaval Compression

In the supine position, blood pressure commonly decreases as the result of aortocaval compression by the gravid uterus. At term, there is often nearly complete occlusion of the inferior vena cava in the supine position, with return of blood from the lower extremities through the epidural, azygos, and vertebral veins. Despite the increase in collateral venous return to the heart, magnetic resonance imaging in healthy late term pregnancy shows a 16% reduction in cardiac output associated with the supine position.⁹⁵ Aortocaval compression can manifest in symptoms of diaphoresis, nausea, vomiting, and dizziness and may exacerbate lower extremity venous stasis, thereby resulting in ankle edema, varices, and increased risk of venous thromboembolism.

Compensatory mechanisms to mitigate supine hypotension from aortocaval compression include an increase in sympathetic nervous system activity to increase systemic vascular resistance and maintain systemic blood pressure despite a reduced cardiac output. Because neuraxial or general anesthesia may impair this compensatory sympathetic response, traditional clinical practice during surgical delivery has been to

place the patient in 15 degree left lateral tilt to displace the gravid uterus away from the inferior vena cava. For the healthy parturient, debate exists regarding the practicality and the continued need in contemporary clinical practice, when maternal blood pressure is maintained by expanding intravascular volume afterload is assured with prophylactic phenylephrine infusion during cesarean delivery.⁹⁶ These considerations do not apply to emergency situations with unstable mothers or fetuses. As of its latest update, the American Heart Association continues to recommend placing the unstable pregnant patient in full left lateral decubitus position while investigating and treating precipitating factors (class I; level of evidence C). However, in the event of maternal cardiac arrest, chest compressions should be delivered with the patient in the supine position with a firm backboard while a separate provider performs continuous manual left uterine displacement.⁹⁷

It is important for the anesthesiologist to recognize changes to the normal cardiac exam as a result of aforementioned cardiovascular changes of pregnancy. Auscultation may reveal an accentuated first heart sound (S_1) with an increased splitting of the first heart sound caused by dissociated closure of the tricuspid and mitral valves. A third heart sound (S_3) is often heard in the final trimester and a fourth heart sound (S_4) can also be heard in a minority of pregnant patients as a result of increased volume and turbulent flow. A mild systolic ejection (grade 2/6) murmur is commonly noted over the left sternal border and is secondary to mild regurgitation at the tricuspid valve from increased cardiac volume.

Pulmonary Changes

Pregnancy results in significant alterations in the upper airway, lung volumes, minute ventilation, oxygen consumption, and metabolic rate.

Airway

The occurrence of difficult and failed tracheal intubation are both more common in the pregnant patient (**Table 45.4**). During pregnancy, there is vascular engorgement of the mucosal lining of the oro- and nasopharynx, which can result in bleeding with instrumentation of the airway. Therefore, attempts at laryngoscopy should be minimized and a smaller size cuffed endotracheal tube (6.0- to 6.5-mm internal diameter) should be considered. Labor considerations can worsen the maternal airway—bearing down and Valsalva maneuver can increase hydrostatic venous pressure; oxytocin administration, which contains antidiuretic properties, can increase hydrostatic venous pressure thereby further worsening airway tissue edema. It is important to note that both normotensive and preeclamptic patients are susceptible to increases in soft tissue thickness at the level of the hyoid bone as well as the progression to a higher Mallampati grading score following labor and delivery.⁹⁸ In addition, pregnancy-associated weight gain, particularly in women of short stature or with preexisting obesity, can exacerbate difficult laryngoscopy because of a shorter neck and heavy breast tissue.

TABLE 45.4

Effect of pregnancy on intubation^a

	Nonpregnant population	Pregnant population
Incidence of difficult intubation	1:50	1:21
Incidence of failed intubation	1:2,230	1:280

Video laryngoscopy has become routine use to prevent or rescue a difficult intubation. Changes in the pregnant woman's airway can make laryngeal mask airway (LMA) insertion and front-of-neck airway access (FONA) particularly challenging. Guidelines have incorporated the immediate use of a second-generation supraglottic airway after failed intubation as an alternative to facemask ventilation in the pregnant patient. A critical concern in the parturient is the risk of regurgitation and aspiration due to increased intragastric pressure and decreased lower esophageal sphincter tone. However, the use of an LMA as a rescue airway in the carefully selected low-risk obstetric patient has several advantages—large-scale studies have demonstrated high rates of successful first insertion attempts as well as rapid time to establish ventilation without clinical evidence of gastric regurgitation or aspiration.^{99–101} If an LMA is to be used, it is recommended that it contain a double lumen with separate respiratory and gastrointestinal tract to allow suctioning of gastric contents.

The severely obese parturient poses an increased risk of failed intubation during general anesthesia for cesarean section that may deteriorate to a “cannot intubate, cannot oxygenate” scenario. Because FONA would be the definitive life-saving management in this situation, there has increased attention on the utility of certain ultrasound-based measurements to expedite the location of the cricothyroid membrane. A brief preprocedural ultrasound of the anterior infraglottis to identify a bright hyperechoic line indicating the cricothyroid membrane air-tissue border may aid in the airway management of severely obese parturients. Should the scenario of failed intubation arise and FONA is required, preobtained knowledge of the cricothyroid membrane depth would help the clinician more accurately access the airway lumen, lessen the risk of airway trauma, and minimize the risk of hypoxic injuries ([Figure 45.3](#)).¹⁰² While preprocedural ultrasound examination of the infraglottic airway may not always be feasible, all necessary equipment for difficult airway management should be immediately available and the patient's position fully optimized before proceeding with intubation.

Minute Ventilation and Oxygenation

In order to accommodate the increased oxygen demand and carbon dioxide production of the growing placenta and fetus, minute ventilation is increased 45% to 50% above nonpregnant values during the first trimester and remains at this increased level for the remainder of the pregnancy. This greater minute ventilation is attained primarily as a result of a greater tidal volume with a small increase in the respiratory rate ([Figure 45.4](#)).¹⁰³ Maternal PaCO_2 is commonly reduced from 40 mm Hg to approximately 30 mm Hg during the first trimester. Arterial pH, however, is only slightly increased (pH 7.42–7.44) because of metabolic compensation from increased renal excretion of bicarbonate (HCO_3^- is typically 20 or 21 mEq/L at term).

During the first trimester, maternal PaO_2 may be above 100 mm Hg due to hyperventilation and decreased alveolar CO_2 . Later, PaO_2 becomes normal or even slightly decreased, most likely reflecting small airway closure with normal tidal volume ventilation and intrapulmonary shunt. Arterial oxygenation can be significantly improved by changing position from supine to lateral. Maternal hemoglobin is right shifted with the P_{50} increasing from 27 to approximately 30 mm Hg.¹⁰⁴ The higher P_{50} in the mother and lower P_{50} in the fetus favors off-loading of oxygen across the placenta. At term, oxygen consumption is increased by 20%. During the first stage of labor, oxygen consumption increases above prelabor values by 40% and during the second stage, it is increased by 75%. In the absence of analgesia, the pain of labor can result in severe hyperventilation causing PaCO_2 to decrease below 20 mm Hg.

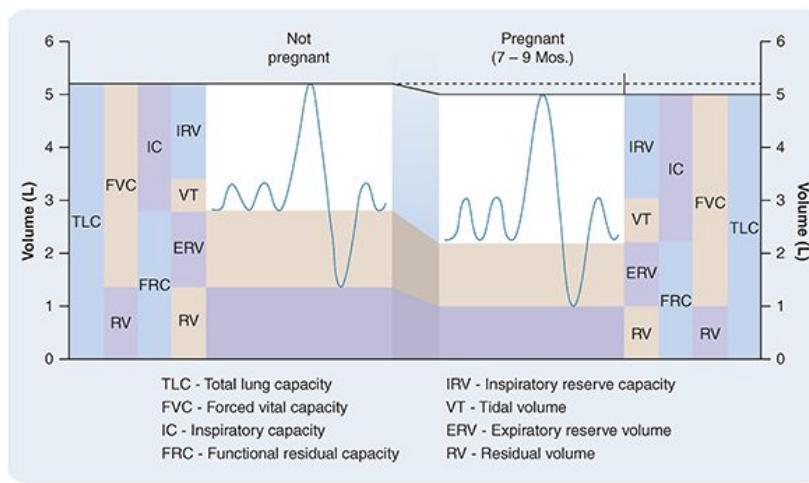

FIGURE 45.4 Changes in maternal pulmonary function. Functional residual capacity is reduced by virtue of reductions in expiratory reserve volume and residual volume during pregnancy. Inspiratory capacity is increased resulting from an increase in tidal volume. *Reprinted from Hegewald MJ, Crapo RO. Respiratory physiology in pregnancy. Clin Chest Med. 2011;32(1):1-13. Copyright © 2011 Elsevier. With permission.*

Lung Volumes

During pregnancy, the growing uterus elevates the diaphragm and causes a reduction in functional residual capacity by 20% at term. This reduction in functional residual capacity is a result of equal reduction in both the expiratory reserve volume and residual volume (see [Figure 45.4](#)). The closing capacity remains unchanged. The reduced ratio of functional residual capacity to closing capacity favors small airway closure with reduced lung volumes and in the supine position causing atelectasis. Vital capacity is not significantly changed with pregnancy. The combination of increased minute ventilation and decreased functional residual capacity results in a greater rate at which changes in the alveolar concentration of inhaled anesthetics can be achieved with spontaneous ventilation in the case of mask induction.

During induction of general anesthesia in a pregnant patient, desaturation occurs more rapidly than in a nonpregnant patient because of decreased functional residual capacity and increased metabolic rate. Administration of 100% oxygen prior to the induction of general anesthesia is critical to allow as much time as possible for safe airway management. Inhalation of 100% oxygen for 3 minutes or, in an emergency, 4 maximal breaths over the 30 seconds will significantly prolong the period between apnea and arterial oxygen desaturation.

A novel technique for oxygenating the pregnant patient during induction of general anesthesia is with transnasal humidified rapid-insufflation ventilatory exchange—an open-airway technique that refers to the use of warmed and humidified high-flow nasal oxygen (70-90 L per minute) in an apneic patient. There are several advantages to this strategy—the high flow generates turbulence, thereby facilitating gas exchange and generating continuous positive pressure to reduce the likelihood of atelectasis and collapse of soft airway

tissue. Because transnasal humidified rapid-insufflation ventilatory exchange can be continued during efforts to secure an airway, it should be considered for any patient identified as a potential difficult airway. However, judicious use in certain pregnant patients is warranted as there are risks of an unprotected airway as well as maternal accumulation of carbon dioxide, albeit at a slower rate than with classic apneic oxygenation. While the use of high-flow nasal oxygen to optimize preoxygenation of the pregnant patient prior to induction of general anesthesia is currently supported by guidelines,¹⁰⁵ further investigation is needed to determine the precise rate of maternal carbon dioxide level accumulation and quantification of fetal acidosis risk.

Gastrointestinal Changes

After midgestation, pregnant women are thought to be at increased risk of aspiration pneumonia with administration of general anesthesia. This increased risk is caused by several factors. There is upward movement of the esophageal sphincter by the gravid uterus. Increased progesterone and estrogen concentrations during pregnancy also contribute to reduced esophageal sphincter tone. Gastrin is secreted by the placenta, which increases gastric acid secretion. Together, these changes result in an increased incidence of gastroesophageal reflux during pregnancy. Gastric emptying is not changed during pregnancy before the onset of labor in women who are of normal weight or obese.^{106,107} However, during labor, pain, anxiety, and the administration of opioids (including those administered neuraxially) decrease gastric emptying. An increase in the residual volume of gastric content can further increase the risk of aspiration, which is already elevated during pregnancy.¹⁰⁸ As a result, all women in labor are considered to have “full stomachs” and to be at increased risk for pulmonary aspiration with induction of anesthesia. In studies comparing a nonparticulate antacid in addition to an H₂ antagonist, the H₂ antagonist is superior to achieve an intragastric pH of greater than 2.5 at intubation compared to placebo or antacid alone.¹⁰⁹

It was traditionally recommended that women past midgestation receive general anesthesia with rapid sequence induction, cricoid pressure, and placement of a cuffed endotracheal tube rather than monitored anesthesia care or an LMA for aforementioned reasons. However, the incidence of pulmonary aspiration during deep sedation for second-trimester dilation and evacuation in an outpatient pregnant population between 14 and 24 weeks’ gestation was found to be 0.04% to 0.08%.^{110,111} Thus, although there remains a theoretical risk of aspiration, the true incidence appears small. As always, the risks and benefits of tracheal intubation must be weighed in this midgestation population.

Although blood flow to the liver does not change beyond that related to the increased cardiac output during pregnancy, markers of liver function including aspartate aminotransferase, alanine aminotransferase, and bilirubin all increase to the upper limits of normal. Alkaline phosphatase levels more than double as a result of the placental production of this enzyme. Hemodilution during pregnancy is responsible for lower plasma protein concentrations. Lower serum albumin concentrations can result in elevated free blood levels of highly protein-bound drugs. Plasma cholinesterase (pseudocholinesterase) activity is decreased about 30% from the 10th week of gestation up to 6 weeks postpartum, but this decreased cholinesterase activity is not associated with clinically relevant prolongation of neuromuscular blockade from succinylcholine or mivacurium in patients with normal baseline levels of the enzyme. Gallbladder disease is common during pregnancy due to incomplete gallbladder emptying and changes in bile composition.

The use of bedside ultrasonography of the gastric antrum in nonpregnant adults has been well described and may serve as a vital tool in the preoperative assessment of the pregnant patient. Pregnancy presents unique challenges to this exam given the cephalad displacement of the stomach by the gravid uterus as well as difficulty in probe placement between the xiphoid process and abdomen. Mathematical models using magnetic resonance imaging measurements of the gastric antrum in pregnancy are currently being developed to allow for correlation of antrum area to content volume. This is currently an active area of research with many variables at play given that gastric emptying is delayed during labor, institutions vary based on fasting policy, and different intravenous and regional opioids may be utilized. The gastric ultrasound examination may one day prove useful in identifying the “full stomach” patient, thereby allowing the anesthesiologist to identify those at greatest risk for pulmonary aspiration should general anesthesia be required.

Renal Changes

Renal blood flow and glomerular filtration rate are increased 50% by the second trimester and remain elevated until 3 months postpartum ([Figure 45.5](#)). As a result, clearance of creatinine, urea, and uric acid are increased during pregnancy. Increased urine protein and glucose concentrations result from decreased renal tubular resorption capacity. The upper limit of the normal 24-hour urine elimination during pregnancy is 300 mg of protein and 10 g glucose. Medications that are renally excreted may require preemptive dose escalation throughout pregnancy.

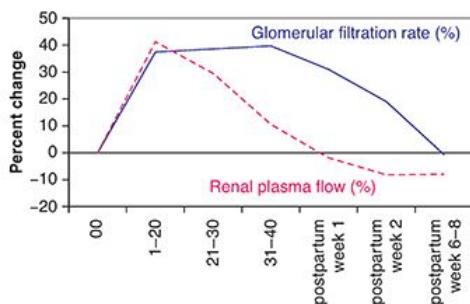

FIGURE 45.5 Percentage change from baseline glomerular filtration rate and renal plasma flow throughout each trimester of pregnancy and initial postpartum period. *Reprinted from Cheung KL, Lafayette RA. Renal physiology of pregnancy. Adv Chronic Kidney Dis. 2013;20(3):209-214. Copyright © 2013 National Kidney Foundation, Inc. With permission.*

Neurologic Changes

Pregnant patients are more sensitive to both inhaled and local anesthetic agents. The minimum alveolar concentration (MAC) is reduced by 30% by the first trimester of pregnancy. The MAC or immobility in response to volatile anesthetics occurs at the level of the spinal cord. A study using electroencephalography suggested that anesthetic effects of sevoflurane on the brain are similar in the pregnant and nonpregnant state.¹¹² Fortunately, anesthetic concentrations required for hypnosis and amnesia are approximately half of MAC or the concentration required to prevent activation of spinal reflexes. Unanticipated awareness is more common during cesarean section. The reasons are likely multifactorial. There is often a desire to prevent anesthetic exposure to an already depressed fetus and the requirement for rapid surgery to allow for neonatal resuscitation may not allow the anesthetic to come to steady state before surgery begins. Even if not used subsequently, the muscle relaxant used to facilitate intubation will likely be in effect during delivery when the anesthetic concentration is increasing.

Pregnant women are more sensitive to the local anesthetics. A lower dose can provide the same level of either spinal or epidural neuraxial blockade compared to nonpregnant women. At term, distention of epidural veins decreases the size of the epidural space, and volume of cerebrospinal fluid in the subarachnoid space. Cerebrospinal fluid pressure is not increased during pregnancy until labor, when it is increased both during uterine contractions and expulsion of the fetus. Although the decreased volume of these spaces may facilitate spread of local anesthetics, the decreased local anesthetic required during pregnancy occurs as early as the first trimester, before mechanical or pressure related changes occur. As such, pharmacodynamic changes are likely more important in causing increased nerve sensitivity to local anesthetics (see “[Postoperative Pain Management](#)” section).

Uteroplacental Physiology

The placenta is composed of both maternal and fetal tissues and is the interface of maternal and fetal circulation systems. It provides a substrate for physiologic exchange between mother and fetus without immunologic rejection. Maternal blood is delivered to the placenta by the uterine arteries and enters the intervillous space via the spiral arteries. The deoxygenated fetal blood arrives at the placenta via two umbilical arteries that form umbilical capillaries that cross the chorionic villi. Following placental exchange,

oxygenated, nutrient-rich, and waste-free blood is returned from the placenta to the fetus through a single umbilical vein ([Figure 45.6](#)).

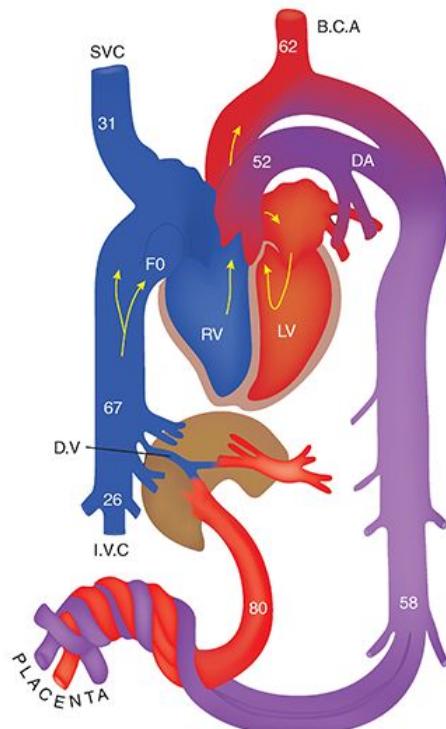

FIGURE 45.6 Diagram of the fetal circulation. Oxygenated blood flows in through the umbilical vein. It passes through the ductus venosus (DV) where it is diluted by deoxygenated blood returning from the inferior vena cava (IVC). Oxygenated blood passes to the right atrium, where little passes through the fetal lungs because of high pulmonary vascular resistance. Part of the circulation passes through the foramen ovale (FO) directly to the left atrium to enter the fetal systemic circulation. Another portion bypasses the lungs by passing from the pulmonary artery through the ductus arteriosus (DA) where it proceeds directly to the aorta. The numbers represent oxygen saturation at various points in the fetal circulation. Abbreviations: BCA, brachial cephalic artery; LV, left ventricle; RV, right ventricle; SVC, superior vena cava. *Reprinted with permission from Born GV, Dawes GS, Mott JC, et al. Changes in the heart and lungs at birth. Cold Spring Harb Symp Quant Biol. 1954;19:102-108. Copyright © 1954 by Cold Spring Harbor Laboratory Press.*

Uterine Blood Flow

An understanding of uteroplacental blood flow is important for the anesthesiologist caring for a pregnant patient. Uterine blood flow increases progressively during pregnancy from about 100 mL per minute in the nonpregnant state to 700 mL per minute (about 10% of cardiac output) at term gestation. Uterine blood flow has minimal autoregulation and the vasculature remains essentially fully dilated during normal pregnancy. Uterine and placental blood flows are dependent on maternal cardiac output and are directly related to uterine perfusion pressure. Decreased perfusion pressure can result from maternal hypotension secondary to hypovolemia, aortocaval compression, or decreased systemic resistance from either general or neuraxial anesthesia. Increased uterine venous pressure can also decrease uterine perfusion. This can occur from supine positioning with vena caval compression as discussed previously, frequent or prolonged uterine contractions, or significant prolonged abdominal musculature contraction (Valsalva) during pushing. Additionally, extreme hypocapnia ($\text{Paco}_2 < 20 \text{ mm Hg}$) associated with hyperventilation secondary to labor pain can reduce uterine blood flow with resultant fetal hypoxemia and acidosis. Neuraxial blockade does not alter uterine blood flow in the absence of maternal hypotension.

Endogenous maternal catecholamines and exogenous vasopressors may cause an increase in uterine arterial resistance and a decrease in uterine blood flow, depending on the type and dose given. In early studies in pregnant ewes, ephedrine was found to have no effect on uterine blood flow despite drug-induced increases in maternal arterial blood pressure, whereas other vasopressors including phenylephrine resulted in vasoconstriction and fetal acidosis.^{113,114} From this animal data, ephedrine was long considered the vasopressor of choice for the treatment of hypotension caused by the administration of neuraxial anesthesia to pregnant women. In complete contrast, however, clinical trials demonstrate the use of phenylephrine is not only effective in preventing hypotension but also is associated with less fetal acidosis and base deficit than the use of ephedrine.^{115,116} Thus, many clinicians have now switched from ephedrine to phenylephrine as the vasopressor of first choice for treating hypotension during labor and delivery. More recently, trials have investigated the utility of norepinephrine infusion to prevent maternal hypotension. A recent systemic review and meta-analysis reported on three randomized controlled trials that compared norepinephrine and phenylephrine between 2015 and 2018.¹¹⁷ The authors found that the two vasopressors were equally effective in treating maternal hypotension and both were considered safe with regard to neonatal outcomes based on umbilical vein blood gases and Apgar scores. Norepinephrine use was associated with less bradycardia and improved nausea and vomiting rates. Although it may serve as a promising alternative to phenylephrine, more studies are needed before changes to routine clinical practice can be recommended. Until then, the prudent use of norepinephrine should include consideration of tissue necrosis risk due to extravasation and avoidance in patients with known or suspected coronary artery disease.

Oxygen Transfer

The delivery of oxygen from the mother to the fetus is dependent on a variety of factors including placental blood flow, the oxygen partial pressure gradient between the two circulations, the diffusion capacity of the placenta, the respective maternal and fetal hemoglobin concentrations and oxygen affinities, and the acid-base status of the fetal and maternal blood (Bohr effect). The fetal oxyhemoglobin dissociation curve is left-shifted ($P_{50} = 19$ mm Hg, greater oxygen affinity), whereas the maternal oxyhemoglobin dissociation curve is right-shifted ($P_{50} = 27$ mm Hg, less oxygen affinity). This occurs because fetal hemoglobin does not interact with 2,3-disphosphoglycerate, facilitating oxygen transfer to the fetus (Figure 45.7). Fetal PaO_2 is normally 40 mm Hg and does not exceed 60 mm Hg even if the mother is breathing 100% oxygen. This is because significant oxygen has been extracted by the mother's tissues prior to arrival at the fetoplacental unit. Carbon dioxide easily crosses the placenta and is limited by blood flow and not diffusion.

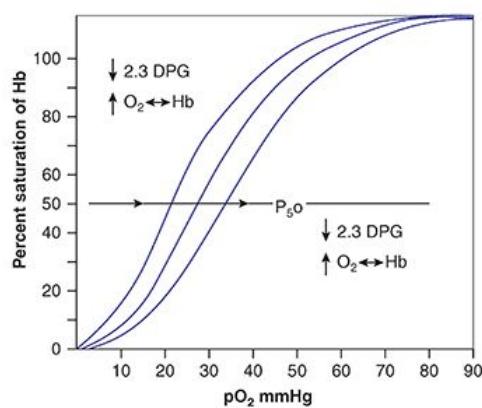

FIGURE 45.7 Right shift of maternal hemoglobin oxygen dissociation curve. Increased interaction with 2,3-disphosphoglycerate (2,3-DPG) results in hemoglobin with lower oxygen affinity and a right shift in the hemoglobin oxygen saturation curve. As a result, oxygen is more easily off-loaded to fetal hemoglobin, which has a left shifted hemoglobin oxygen dissociation curve. Reprinted with permission from Jepson JH. Factors influencing oxygenation in mother and fetus. *Obstet Gynecol*. 1974;44(6):906-914. Copyright © 1974 The American College of Obstetricians and Gynecologists.

Principles of Nonobstetric Surgery During Pregnancy

Fetal Heart Rate Monitoring

The most frequently used fetal electronic monitoring is based on Doppler ultrasound technology, relying on fetal cardiac activity itself or arterial flow through a major fetal vessel. After 18 weeks, fetal heart rate monitoring is practical, and after 25 weeks, variability in fetal heart rate is a reliable sign of well-being. The American College of Obstetrics and Gynecology states, “Although there are no data to support specific recommendations regarding non-obstetric surgery and anesthesia in pregnancy, it is important for non-obstetric physicians to obtain obstetric consultation before performing non-obstetric surgery. The decision to use fetal monitoring should be individualized and each case warrants a team approach for optimal safety of the woman and her baby.”¹¹⁸ Anesthetic agents reduce both baseline fetal heart rate and heart rate variability, so readings must be interpreted in context; general anesthesia, opioid use, and lower maternal body temperature may alter autonomic tone leading to an absence of fetal heart variability that is not necessarily indicative of fetal acidemia. Fetal bradycardia, of more concern, can also be affected by factors such as hypothermia, maternal acidosis, or the maternal administration of drugs that cross the placenta. Thus, knowledge of placental transfer of drugs that may affect fetal heart rate (such as β-blockers or acetylcholinesterase inhibitors) is paramount.

The theoretical benefit of intraoperative fetal heart rate monitoring is to detect early compromise, thereby allowing prompt optimization of maternal hemodynamics and oxygenation. Should fetal decelerations be observed, the surgeon should be notified and the obstetric team consulted. Monitoring of uterine activity is also important as variable decelerations caused by contractions or increased uterine irritability can alert whether surgical intraabdominal manipulation should be ceased or if tocolytic therapy is needed. Maternal hemodynamics should be addressed while in consultation with the obstetrician on the appropriateness of suppression therapy such as a magnesium infusion or bolus doses of IV nitroglycerin (100 µg) or terbutaline (0.25 mg).

Intraoperative Considerations for Nonobstetric Surgery

No single anesthetic approach has demonstrated a clear detriment to the fetus. Regardless of whether general, neuraxial, or regional anesthesia is administered, the principles of anesthetic management should be the following: Maintain the pregnant state, preserve maternal physiology with minimal perturbation, and ensure maternal oxygenation and uteroplacental perfusion by avoiding hypovolemia, hyperventilation, severe anemia, hypoxia, hypothermia, and uterine hypertonus. The choice of anesthesia should be guided by maternal indications as well as the site and nature of surgery.

If possible, a regional anesthesia may help allay concerns about teratogenicity in the first trimester. A reliable peripheral or neuraxial nerve block would limit unnecessary drug exposure to the fetus (assuming heavy sedation is avoided) and has the advantage of not interfering with fetal heart rate variability as much as general anesthesia. Furthermore, airway control is maintained and avoids the potential risk of prolonged or failed intubation, hypoxia, or aspiration, particularly in full stomach patients. However, pregnancy does lower the threshold for local anesthetic toxicity, so a dose reduction should be considered (about 30%).

Management of neuraxial anesthesia for nonobstetric surgery in the pregnant patient would be the same for cesarean delivery where the major concern is maternal hypotension and aggressive prevention and treatment of hypotension is critical. Volatile agents cause uterine relaxation, which may help prevent preterm contractions but induces undesirable hypotension in escalating doses. Because autoregulation is absent for the uteroplacental circulation, any reduction in maternal cardiac output or blood pressure may compromise placental perfusion and lead to fetal ischemia. Regardless of technique, focus should be on optimization of hemodynamics by maintaining uterine displacement (if the patient is beyond 20-24 weeks' gestational age), vasopressor therapy (selection of ephedrine or phenylephrine to be determined by maternal heart rate), and judicious resuscitation with either crystalloid or colloid.

Hemostatic resuscitation is vital to the stabilization of the pregnant trauma patient or during an obstetric hemorrhage. In the event of ongoing bleeding and resuscitation, the development of a dilutional coagulopathy is likely. Treatment with fibrinogen concentrate is most effective in patients with severe hypofibrinogenemia (see [Table 45.3](#)) and can help reduce the risk of overtransfusion and development of pulmonary edema.¹¹⁹ Although pregnant patients are at an elevated baseline risk for thromboembolism, this should not deter the clinician from considering antifibrinolytic therapy in the setting of hemorrhage. The landmark WOMAN (World Maternal Antifibrinolytic Trial) trial showed a survival benefit in postpartum hemorrhage when tranexamic acid was administered within 1 to 3 hours after delivery without increasing the rate of thromboembolic complication.¹²⁰ Hemorrhage from threatened abortions during the second or third trimester may benefit from tranexamic acid by arresting bleeding and prolonging pregnancy.¹²¹ Current clinical trials are underway to determine whether the use of tranexamic acid therapy is superior to expectant management for bleeding of unknown etiology during the second trimester.¹²²

Safety concerns exist surrounding blood product administration during pregnancy and the postpartum period given exposure of the mother to risks of alloimmunization and hemolytic disease of the fetus. Transfusion is rarely required in hemodynamically stable pregnant patient with hemoglobin >7.0 g/dL and should be reserved only in the event of active bleeding, major hemorrhage, or immediate need to correct cardiac decompensation. All products should be leukocyte depleted, and red blood cells should be tested for cytomegalovirus to reduce the risk of serious infection to the fetus.

Postoperative Pain Management

Maternal pain control after nonobstetric surgery is of paramount importance to maternal and fetal well-being as pain has been shown to increase the risk of premature labor. Although all opioids may be used in pregnancy, they do readily cross the placenta and may reduce fetal heart rate variability (although there is no evidence, this is detrimental to the fetus, and neonatal outcomes are usually reassuring). Repeated opioid exposure during third trimester should alert the neonatologist to monitor for neonatal abstinence syndrome. If the fetus is born shortly after exposure to maternal systemic opioids, reversal with naloxone and/or respiratory support may be necessary.

Regional nerve or plexus blockade can provide excellent postoperative analgesia and reduce the need for systemic opioids. Single-injection blocks have been performed in pregnant patients without significant complication to either mother or fetus.¹²³ In current practice, the long-acting local anesthetics ropivacaine and bupivacaine are most frequently used. The half-life of bupivacaine in the nonpregnant adult is 3.5 hours but can exceed 9 hours in the parturient.¹²⁴ α_1 Acid glycoprotein, a plasma protein that is significantly reduced in pregnancy, has a high binding affinity for local anesthetics and serves as a primary buffer to prevent local anesthetic toxicity. Because there is a decreased safety margin of local anesthetic infusions during pregnancy and an increase in susceptibility to local anesthetic systemic toxicity exists, the practice of catheter-based chronic local anesthetic infusion following peripheral nerve block during pregnancy is not supported.

Effective postoperative analgesia can also be provided by administering a long-acting narcotic neuraxially, such as preservative-free morphine, or by continuation of a combined opioid and local anesthetic epidural infusion. The addition of opioid permits reduction in the dose of local anesthetic needed. Thus, the low volume of local anesthetic and low dose of opioid drug associated with effective neuraxial dosing rarely poses a problem. Nonsteroidal anti-inflammatory drugs, although useful adjuvant analgesics outside of pregnancy, should be used with caution in pregnancy. They are associated with an increased risk of miscarriage and fetal malformation when used in early pregnancy and premature closure of the ductus arteriosus, reduced fetal renal reduction, and oligohydramnios when used after 32 weeks' gestation. Acetaminophen is an excellent opioid adjuvant and is the analgesic of choice for treatment of mild to moderate pain during any state of pregnancy.

Postoperative pain medications may make it difficult for the patient to note early contractions and patient perception should not be considered a substitute for standard monitoring. Thus, following surgery, both the fetal heart rate and uterine activity should be evaluated. In addition, venous thrombosis prophylaxis should be

instituted unless surgically contraindicated or until the patient can mobilize. Continued observation is important because the risk for adverse delivery outcome is elevated in women who have had nonobstetric surgery (after adjusting for age and other comorbidities).¹²⁵

Fetal Physiology

Characteristics of the Fetal Circulation

Approximately two-third of the fetal-placental blood volume is contained within the placenta. The fetal blood volume increases throughout gestation. During the second and third trimester, the fetal blood volume has been estimated to be approximately 120 to 160 mL/kg of fetal body weight.

The fetal blood passes from the placenta through the umbilical vein (see [Figure 45.6](#)).¹²⁶ Approximately one-third of the blood volume passes through the ductus venosus to the inferior vena cava. The rest of the blood volume passes to the fetal liver, joins the portal vein, and passes to the right atrium. As a result, drugs and toxic substances are detoxified by the fetal liver prior to exposure to the fetal brain and heart. The fetal circulation is characterized by high pulmonary vascular resistance, low systemic vascular resistance (including the placenta), and right-to-left cardiac shunting via the foramen ovale and ductus arteriosus. As such, the majority of the blood bypasses the fetal lungs. The blood is pumped from the fetal left ventricle through the body to the internal iliac arteries where it passes through the umbilical arteries back to the placenta to be detoxified and reoxygenated.

Drug Transfer

Maternal-fetal exchange of most drugs and other substances with molecular weights of less than 1,000 Da occurs primarily by diffusion. The rate of diffusion and peak levels in the fetus depend on maternal-to-fetal concentration gradients, maternal protein binding, molecular weight of the substance, lipid solubility, and the degree of ionization of that substance. The maternal blood concentration of a drug is normally the primary determinant of how much drug will ultimately reach the fetus. The high molecular weight and poor lipid solubility of nondepolarizing neuromuscular blocking drugs result in minimal transfer of these drugs across the placenta.^{16–23} Succinylcholine has a low molecular weight but is highly ionized and therefore does not readily cross the placenta unless given in very large doses.^{13–15} Thus, during administration of a general anesthetic for cesarean delivery, the fetus/neonate is not paralyzed. If paralysis is desired, for example, during fetal surgery, muscle relaxants must be injected directly into the umbilical vein. Both heparin and glycopyrrolate have minimal placental transfer because they are highly charged.⁵² Placental transfer of volatile agents,^{24–30} benzodiazapines,^{257–60} local anesthetics,^{42–51} and opioids^{31–41} is facilitated by the relatively low molecular weights, neutral charge, and relative lipophilicity of these drugs.

Fetal blood is more acidic than maternal, and the lower pH creates an environment where weakly basic drugs such as local anesthetics can cross the placenta as a nonionized molecule and become ionized in the fetal circulation. Because the newly ionized molecule has more resistance to diffusion back across the placenta, the drug can accumulate in the fetal circulation and reach levels higher than the maternal blood. This process is called “ion trapping.” During fetal distress (lower pH in the fetal circulation), higher concentrations of weakly basic drugs, such as local anesthetics, can be trapped. High concentrations of local anesthetics in the fetal circulation decrease neonatal neuromuscular tone. Extremely high levels such as those associated with unintended maternal intravascular local anesthetic injection result in a variety of fetal effects that include bradycardia, ventricular arrhythmias, acidosis, and severe cardiac depression.

Fetal Liver Function and Drug Metabolism

The anatomy of the fetal circulation helps to decrease fetal exposure to potentially high concentrations of drugs in umbilical venous blood. Approximately 75% of umbilical venous blood initially passes through the fetal liver, which may result in significant drug metabolism by the fetal liver before the drug reaches the fetal heart and brain (first-pass metabolism). Fetal/neonatal enzyme activities are less developed than those of adults, but most drugs that cross the placenta can be metabolized. In addition, drugs entering the fetal inferior vena cava via the ductus venosus are initially diluted by drug-free blood returning from the fetal lower

extremities and pelvic viscera of the fetus. These anatomic characteristics of the fetal circulation markedly decrease fetal plasma drug concentrations compared to maternal concentrations. Although fetal liver function is not yet mature, coagulation factors are synthesized independent of the maternal circulation. These factors do not cross the placenta and their serum concentrations increase with gestational age. However, fetal clot formation in response to tissue injury is less robust in comparison to adults.

Anesthetic Toxicity in the Fetus

All general anesthetic drugs cross the placenta. Although there is no clear evidence for toxicity of specific anesthetic drugs in humans, there is concerning animal data in rodents and primates suggesting that prolonged exposure to general anesthetic drugs including inhaled anesthetics,¹²⁷ propofol,¹²⁸ and ketamine¹²⁹ induce inappropriate neuronal apoptosis that is associated with long-lasting behavioral abnormalities in animals including primates. Although these preclinical results are concerning, it is not clear whether or when these drugs might cause toxicity in humans as the critical period of rapid synaptic development extends from the prenatal period through 2 years of postnatal life.

Efforts to elucidate the neurotoxicity of anesthetic agents on the human developing brain has been far more complicated. There exist methodologic limitations in the face of ethical challenges to designing a randomized controlled trial that could address this central question. Although retrospective human studies have suggested a dose-dependent association between multiple exposures in early childhood and subsequent learning disability,¹³⁰ the effects of anesthetic drug exposure often cannot be distinguished from the underlying disease process or indication for surgery. Furthermore, observational studies do not account for the timing or duration of anesthesia or surgery type, preventing any conclusions on causality from being drawn.

There are no data specifically assessing any association of anesthetic exposure in utero in human fetuses with postnatal neurodevelopmental outcomes. Numerous studies have assessed whether pregnant women undergoing nonobstetric surgery are at an enhanced risk for adverse obstetrical outcomes. Taken together, the most reliable findings suggest a higher rate of spontaneous abortion, preterm delivery, and cesarean section.¹²⁵

Certain lower abdominal or lower extremity procedures can be performed under spinal anesthesia in young infants. The General Anesthesia Compared to Spinal Anesthesia trial¹³¹ is a large multinational trial of children less than 60 months postmenstrual age who were randomly assigned to have awake regional or general anesthesia for hernia surgery. There was no difference in neurodevelopmental outcome between groups at 2- or 5-year follow-up providing some reassurance that a short exposure to general anesthesia does not cause neurodevelopmental damage.¹³²

The U.S. Food and Drug Administration released a safety communication update on April 27, 2017, that touched on potential fetal effects of general anesthesia exposure. The statement verified that pregnant women only have surgery and anesthesia when medically necessary and that exposures are usually less than 3 hours. The advisory stated that pregnant women should not delay or avoid necessary surgeries or procedures during pregnancy as doing so can negatively affect themselves and their infants. The U.S. Food and Drug Administration MedWatch program is available to follow reports of adverse effects.¹³³

As current efforts are attempting to increase the reproducibility and clinical relevance of animal studies and to identify neuroprotective strategies for the immature human brain, it is important to remember that no clear evidence for toxicity of a specific anesthetic drug has been demonstrated so far. Therefore, should the need for general anesthesia arise during pregnancy, the most reasonable anesthetic regimen is one that uses the lowest effective concentration for the shortest amount of time possible. Dexmedetomidine and opioids are the only drugs in clinical use for sedation and anesthesia that have not shown to cause neurodegeneration in animal models.¹³⁴ Although not sufficient for general anesthesia alone, they may become increasingly utilized as adjuvants to offset the required dose of anesthesia in pediatric or nonobstetric surgery.

Fetal Neurophysiology

Fetal Pain

The gestational age at which the fetus can feel pain is highly controversial. The experience of pain requires two conditions: (1) nociception and (2) perception with emotional response. Afferent sensory fibers required for nociception are in place and a functional spinal reflex is present by 20 weeks' gestation ([Figure 45.8](#)).¹³⁵ The second requirement for the experience of pain, perception with emotional response, is much more difficult to establish. In the verbal patient, pain is established by self-report. In the nonverbal, it is measured with observation of complex behaviors thought to be representative of emotional response such as grimace. Neither measurement is practical or necessarily representative in the fetus because of coincident development of motor and intermediary circuitry.

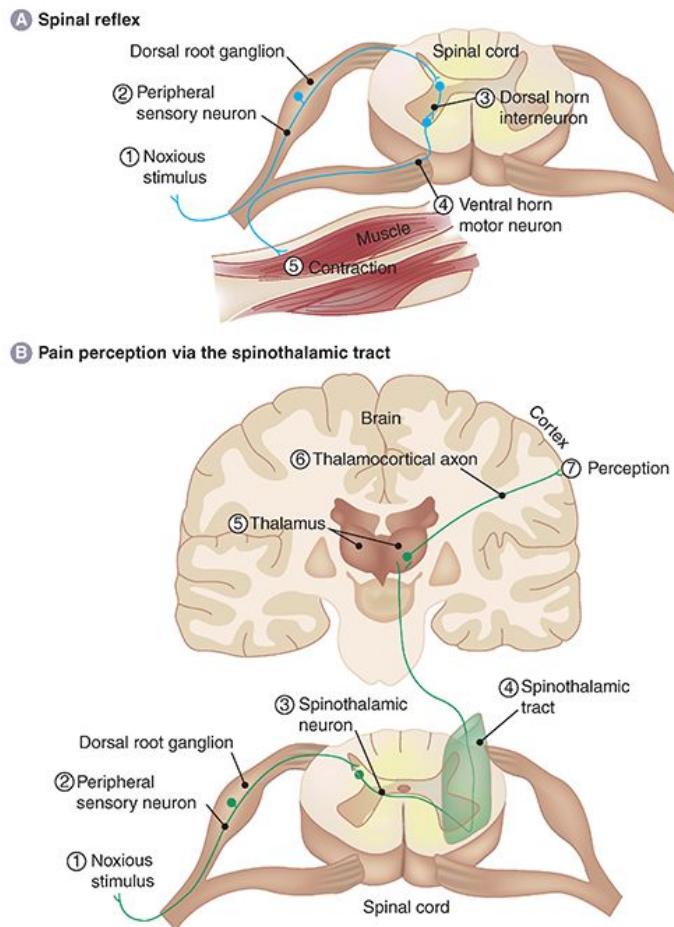

FIGURE 45.8 Spinal reflex and pain perception pathways. **A**, Spinal reflex responses to noxious stimuli occur early in fetal development before cortical connections are functional. **B**, Later in fetal development, a noxious stimulus will activate a peripheral sensory neuron that projects to neurons that form the spinothalamic tract. These neurons in turn project to neurons in the thalamus. Thalamic neurons project to neurons in the subplate zone and the somatosensory cortex. This sequence is the anatomic basis for nociception, the sequence of neuronal events that lead to the conscious perception of pain. The functional circuitry required for apprehension of pain is likely to be present between 20 and 30 weeks' gestation. *Modified from Lowery CL, Hardman MP, Manning N, et al. Neurodevelopmental changes of fetal pain. Semin Perinatol. 2007;31(5):275-282. Copyright © 2007 Elsevier. With permission.*

In humans, after about 2 to 3 months of age, pain can be both apprehended and comprehended. Comprehension requires a relationship with the object. The fetus can likely not comprehend, but only apprehend. Consciousness requires certain anatomic structures to be in place and functional. The neural circuitry that is required for apprehension includes thalamocortical pathways (see [Figure 45.8](#)). The subplate

zone contains the earliest cortical cells and is partially a transient compartment that is required for normal cortical maturation. There is thalamic fiber penetration of an outer layer of brain cells, which stimulate development of the subplate zone by 11 weeks' gestation. Most nociceptive pathways connect from the thalamus to the subplate zone by gestational week 17.¹³⁶ Maturation of the primary somatosensory cortex continues into neonatal life. Evidence for the functionality required for consciousness, thought to be represented by certain electroencephalogram rhythms that are mediated by subcortical integration of cortical and subcortical processes are present from 20 weeks' gestation.¹³⁷ Somatosensory evoked potentials can be recorded from the fetal cerebral cortex at 29 weeks' gestation.¹³⁸ As such, the functional circuitry required for apprehension of pain is likely to be present between 20 and 30 weeks' gestation (**Table 45.5**). These details are of concern to the anesthesiologist to inform decisions about anesthesia for fetal surgery and whether and at what point a live fetus requires anesthesia and analgesia prior to abortion.

TABLE 45.5

Anatomic and functional development of nociception and pain perception^a

Anatomic/functional characteristic	Description	Gestational age (weeks)
Peripheral cutaneous sensory receptors	Perioral cutaneous sensory receptors	7.5
	Palmar cutaneous sensory receptors	10-10.5
	Abdominal cutaneous sensory receptors	15
Spinal cord	Spinal reflex arc in response to nonnoxious stimuli	8
	Neurons for nociception in dorsal root ganglion	19
Thalamic afferents	Thalamic afferents reach subplate zone	20-22
	Thalamic afferents reach cortical plate	23-24
Cortical function ^b	Somatosensory evoked potentials with distinct, constant components	29
	First electrocardiographic pattern denoting wakefulness and active sleep	30

Physiology and Pharmacology of the Elderly

Andrea Girnius • Pamela Flood

The US population is aging, and the percentage of patients older than 65 years is increasing rapidly. The 2010 US census found that patients older than the age of 65 years comprised 13% of the U.S.

population, or 40,300,000 people.¹ The United States Census Bureau estimates that by 2060, the number of patients older than age 65 years will double from their 2018 levels, and their proportion of the population will rise from 16% in 2018 to 23% in 2060. As elderly people are more likely to require invasive procedures, the number presenting for surgery can only be expected to increase. It is important that anesthesiologists understand the differences in pharmacology and physiology in elderly patients in order to be able to properly use anesthetic and analgesic drugs and compensate for aging-related functional decline in major organ systems. Some fortunate individuals remain physically vigorous until very late in life, whereas others deteriorate physically at a younger age. The cumulative effects of smoking, alcohol, and environmental toxins can accelerate the deterioration of aging in exposed individuals. Thus, it is not surprising that variability in physiology increases throughout life.² Increased physiologic variability results in potentially decreased physiologic reserve and increased pharmacokinetic and pharmacodynamic variability in elderly subjects.³ The clinical result of this increased variability is an increased incidence of adverse drug reactions in elderly patients.⁴ Thus, elderly patients require more careful attention to drug titration and overall physiologic parameters.

Aging and the Cardiovascular System

Increasing age is associated with increasing cardiac morbidity. Aging is associated with an increasing prevalence of cardiovascular disease and decreasing cardiovascular functional reserve.⁵ Heart failure is the most frequent cause of hospitalization in patients older than 65 years of age. However, it is important to separate the cardiovascular effects of aging from those of common diseases with increased prevalence in the elderly, such as atherosclerosis, hypertension, and diabetes mellitus. The decline in cardiac function that occurs with aging in the healthy individual appears to be related, in part, to decreasing functional demand. Indeed, when exercise and low-calorie diet are maintained into the later decades, the decline in cardiovascular function is markedly attenuated.⁶ Aging is associated with the development of heart failure, particularly in women in whom its prevalence increases greater than twofold from age 65 to 69 (6.6%) to age 85 years (14%).⁷ Almost half the people presenting with heart failure appear to have normal left ventricular systolic function, a phenomenon that is more common in women.⁸ It has been suggested that cardiovascular function is directly related to skeletal muscle mass. Aging also has discrete effects on the heart, large vessels, endothelial function, cardiac conduction system, and the cardiovascular autonomic response (**Figure 46.1**).⁶

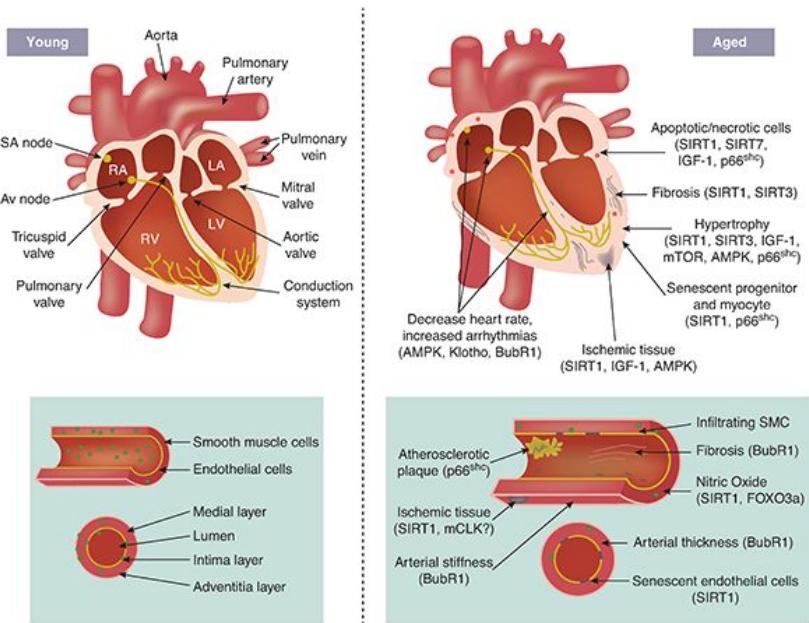

FIGURE 46.1 Age-dependent changes to cardiovascular tissues. Both the heart and vasculature undergo numerous alterations during aging as a result of deregulation of molecular longevity pathways, leading to compromised function. Important functional changes include arterial hypertrophy resulting in increased afterload, ventricular hypertrophy resulting in elevated systolic blood pressure, loss of cells in the electrical conduction system predisposing to arrhythmia, and loss of sensitivity to catecholamines resulting in reduced maximal heart rate and heart rate variability. Abbreviations: AMPK, 5' adenosine monophosphate-activated protein kinase; Av, atrioventricular; BubR1, budding uninhibited by benzimidazole-related 1; FOXO3a, forkhead box O3a; IGF-1, insulin like growth factor 1; LA, left artery; LV, left ventricle; mLCK, myosin light chain kinase; mTOR, mammalian target of rapamycin; p66shc, p66 SHC-transforming protein 1; RA, right artery; RV, right ventricle; SIRT1, NAD-dependent deacetylase sirtuin 1; SIRT3, NAD-dependent deacetylase sirtuin 3; SIRT7, NAD-dependent deacetylase sirtuin 7; SMC, smooth muscle cell. Heart

The heart increases in size during aging as a result of concentric ventricular hypertrophy. This occurs in response to the increase in left ventricular afterload. This increase in afterload occurs as the result of fibrosis and endothelial damage, which increases arterial stiffness and reduces the capacity for nitric oxide-induced vasodilation. Hypertrophy of cardiac myocytes accounts for a 30% increase in left ventricular wall thickness. Meanwhile, the number of cardiac myocytes is decreased due to necrosis and apoptosis. These changes result in an increased incidence of hypertension that can be followed by reduced cardiac function. Initially, sympathetic hyperactivity compensates and systolic function is preserved. However, with chronic stimulation, β -adrenergic receptors become less responsive and contractility is reduced.⁹ Despite these changes, resting systolic function tends to be well preserved in healthy individuals. However, the heart rate response to strenuous exercise is diminished.

Diastolic dysfunction and heart failure with preserved ejection fraction are now recognized as a major contributor to cardiovascular disease in the elderly population. The prevalence of heart failure with preserved ejection fraction is increasing as the population ages and currently accounts for 50% of patients with clinical heart failure. It is exacerbated by several coexisting diseases, such as systemic hypertension, coronary artery disease, cardiomyopathy, aortic stenosis, atrial fibrillation, diabetes, and chronic renal disease ([Table](#)

46.1).^{7,10} The impairment in diastolic function is likely due to an age-related increase in cardiac connective tissue that, when combined with ventricular hypertrophy, increases wall stiffness and reduces diastolic compliance.¹¹ Ventricular filling in the elderly is especially dependent on active diastolic relaxation. In this process, calcium is removed from troponin C binding sites, triggering the dissociation of actin and myosin, thus facilitating isometric relaxation. Active diastolic relaxation uses approximately 15% of the energy consumed during the cardiac cycle. This process is significantly impaired in the elderly and exacerbates the adverse effects of ventricular hypertrophy on diastolic filling. Therefore, the elderly heart is markedly dependent on the atrial “kick” for adequate ventricular preload. It is estimated that atrial contraction contributes approximately 30% of ventricular filling in the elderly versus 10% in younger individuals. Because passive ventricular filling is impaired by reduced ventricular compliance and because of the importance of atrial contraction, ventricular filling is typically not complete until very late in diastole. Tachycardia and the resulting shortened diastolic intervals will markedly decrease ventricular preload in the elderly. Atrial fibrillation is a common rhythm in the elderly in which the benefit of atrial contraction is lost. As previously noted, loss of coordinated atrial contraction is particularly important in elderly patients. Perioperative events that reduce venous return, such as hypovolemia, positive pressure ventilation, and increased venous capacitance, may be accompanied by significant decreases in cardiac output. Conversely, excessive perioperative increases in blood volume or decreases in contractility can precipitate congestive cardiac failure.

TABLE 46.1

Diseases commonly encountered in the elderly that are associated with diastolic dysfunction

Systemic hypertension

Coronary artery disease

Cardiomyopathy

Aortic stenosis

Atrial fibrillation

Diabetes

Chronic renal disease

It is difficult to identify diastolic dysfunction during routine clinical evaluation. Dyspnea in the elderly is nonspecific and may indicate congestive heart failure, pulmonary disease, or both. Furthermore, routine preoperative echocardiographic indices of cardiac function such as left ventricular ejection fraction will fail to identify diastolic dysfunction. However, diastolic filling can be evaluated by comparing Doppler echocardiographic measurements of mitral valve inflow velocities during the early and late (atrial contraction) phases of diastole, Doppler measurements of pulmonary vein inflow during systole and diastole, and tissue Doppler measurements of the mitral valve annulus.

Large Vessels

Structural changes in the large vessels are an important element of the aging process and contribute significantly to the age-related changes in the heart.⁵ The large vessels become elongated, tortuous, and dilated in the elderly. Their intima and media thicken, causing them to be less distensible. The normal cushioning function of the large vessels is impaired; causing accelerated and enhanced pulse wave propagation. In the elderly, the pulse wave from systolic contraction is reflected back relatively quickly from the peripheral circulation and increases systolic pressure. In young adults, the reflected pulse wave generally has lower amplitude and its return from the peripheral circulation is delayed such that diastolic rather than systolic pressure is augmented. Thus, in the elderly, both systolic pressure and pulse pressure are increased and left ventricular afterload is elevated. In contrast, diastolic pressure tends to be lower in the elderly than in younger individuals. Isolated systolic hypertension accounts for a large percentage of clinical hypertension in the elderly. All of the aforementioned age-related vascular structural changes are accelerated in the presence of hypertension or atherosclerosis.

Endothelial Function

The vascular endothelium is an important regulator of vasomotor response, coagulation, fibrinolysis, immunomodulation, and vascular growth and proliferation. Endothelial dysfunction is an important element in the early pathogenesis of atherosclerosis, diabetes mellitus, and systemic hypertension.¹² Aging is associated with altered endothelial structure and function, even in the absence of disease. Endothelial dysfunction is accelerated by smoking, diabetes, hypertension, and hyperlipidemia. Endothelial nitric oxide is a key mediator of vascular relaxation. In the elderly, the bioavailability of endothelial nitric oxide is decreased due to both decreased production and increased degradation. This is due in part to alterations of level and activity of key enzymes and substrates as well as increased levels of reactive oxygen species mediated by chronic inflammation.⁵ Furthermore, the vasodilator response to nitric oxide of the adjacent vascular smooth muscle is reduced. Vasodilator responses to β_2 agonists and vasoconstrictor responses to α -adrenergic stimulation are similarly attenuated in the elderly. Thus, age-related endothelial dysfunction can be characterized as a decrease in the ability of the endothelium to dilate or contract blood vessels in response to physiologic and pharmacologic stimuli.

Conduction System

There are several important age-related structural and functional changes in the cardiac conduction system.¹³ The sinoatrial node undergoes progressive fibrosis over time so that the proportion of pacemaker cells decreases from 50% in late childhood to less than 10% at 75 years. The atrioventricular node, and conduction bundles similarly become infiltrated with fibrous and fatty tissue. These changes are responsible for the increased incidence of first- and second-degree heart block, sick sinus syndrome, and atrial fibrillation in the elderly. The development of atrial fibrillation is also facilitated by left atrial enlargement, which typically accompanies aging in otherwise healthy individuals. The prevalence of atrial fibrillation doubles with each decade. Eighty-four percent of patients with atrial fibrillation are older than 65 years. Elderly patients also experience an age-related increase in the prevalence, frequency, and complexity of ventricular ectopy and ventricular arrhythmias, even in the absence of structural heart disease.¹³

Autonomic and Integrated Cardiovascular Responses

Aging is associated with increased norepinephrine release into the circulation and deficient catecholamine reuptake at nerve endings. The resulting elevated circulating concentration of norepinephrine generates chronically increased adrenergic receptor occupancy. However, the cardiovascular response to increased adrenergic stimulation is attenuated by the decreased number of the β -adrenergic receptors in the elderly myocardium, the downregulation of postreceptor signaling pathways, and the reduced contractile response of the myocardium.¹¹ Alterations in the mechanism by which the receptor binding is coupled to cyclic adenosine monophosphate also contribute to the decreased chronotropic and inotropic response of elderly patients to β -adrenergic drugs. The response to exogenously administered β agonists, such as isoproterenol, is similarly attenuated. Receptor downregulation is responsible for the age-related decline in maximum heart rate during exercise. Indeed, receptor downregulation in the elderly makes their baseline cardiovascular function similar to that of a younger individual who has received β -adrenergic antagonists.

Orthostatic hypotension is common in the elderly. The prevalence is reported as 15% in patients aged 65 to 69 years but increases to 26% in patients older than age 85 years.¹⁴ It is associated with syncope, falls, cognitive decline, and increased mortality. Orthostatic hypotension is more common in patients who are hypertensive at baseline. Several age-related changes contribute to the increase in orthostatic hypotension, including impaired baroreceptor reflexes, attenuated peripheral vasoconstriction, hypovolemia, and salt depletion. These factors can be the result of iatrogenic antihypertensive and diuretic administration or increased atrial natriuretic peptide release. It is difficult to separate the effects of aging per se from those of age-related chronic increases in systolic pressure and iatrogenic treatment of elevated systolic pressure. Straining against a closed glottis (Valsalva maneuver) typically produces a decrease in venous return and cardiac output. The normal baroreceptor response to this maneuver includes an increase in heart rate and peripheral vascular tone and restoration of blood pressure. However, this response is markedly attenuated in

the elderly.¹⁴ Similarly, age-related impairment of baroreceptor responses makes hypotension more likely after the initiation of positive pressure ventilation, particularly in the presence of hypovolemia. Neuraxial local anesthetic-induced sympathetic blockade is also more likely to be accompanied by hypotension in the presence of an impaired baroreceptor response. The relationship between medications and orthostatic hypotension is important to consider, as many elderly patients are on multiple antihypertensive agents. The Irish Longitudinal Ageing Study found that antidepressants and β blockers were associated with orthostatic hypotension, and hypnotics and sedatives worsened preexisting orthostatic intolerance.¹⁵ Antihypertensive drugs that did not act through β -adrenergic blockade were not associated with orthostatic hypotension with the possible exception of diuretics. Multiple studies have demonstrated that patients on multiple antihypertensives experience more orthostatic hypotension, but other studies have not found this association. The Systolic Blood Pressure Intervention Trial found that the intensive treatment group had significantly better cardiovascular outcomes but experienced less orthostatic hypotension.^{14,16} These findings should be considered in the mobilization of elderly patients who may have received these drugs in the perioperative period.

Anesthetic and Ischemic Preconditioning in the Aging Heart

It is now recognized that, under certain circumstances, exposure to volatile anesthetics (anesthetic preconditioning) or several brief periods of ischemia (ischemic preconditioning) may enhance tolerance to subsequent ischemia, enhance cardiac function, and reduce infarction size.¹⁷ Because the incidence of atherosclerosis and coronary artery disease is age related, the elderly would seem to be most likely to benefit from a preconditioning strategy. However, both anesthetic and ischemic preconditioning may be markedly attenuated in the elderly, potentially explaining the difficulty of translating promising preclinical results to treatment.^{18,19} Furthermore, potent volatile drugs may induce significant cardiovascular depression in this age group. Therefore, the clinical utility of preconditioning strategies in this age group is uncertain.

Aging and the Respiratory System

The respiratory system undergoes a multifactorial decline in functional reserve with aging (**Tables 46.2** and **46.3**).²⁰ Under normal circumstances, this decrease in respiratory function is not associated with significant limitation of daily activity. However, decreased respiratory reserve may be unmasked by illness, surgery, anesthesia, and other perioperative events. Common respiratory diseases and the effects of smoking and environmental pollution frequently exacerbate the decline in respiratory function with aging. The anticipation and amelioration of their effects is critically important to anesthetic management in the elderly, as age greater than 65 years has been shown to be an independent risk factor for postoperative respiratory complications, contributing significantly to perioperative mortality in this population.²¹

TABLE 46.2

Intrinsic and extrinsic events that influence the respiratory system during aging

Intrinsic to the aging process	Environmental, behavioral, and disease related
Decreased bronchiolar caliber	Industrial and environmental pollution
Decreased alveolar surface area	Smoking
Increased lung collagen content	General deconditioning
Decreased lung elastin content	Coexisting disease
Kyphoscoliosis	
Increased thoracic cage rigidity	
Decreased diaphragmatic strength	

TABLE 46.3

Functional consequences of the intrinsic and extrinsic events that influence the respiratory system during aging

Decrease in lung elastic recoil
Increase in lung compliance
Decrease in oxygen diffusing capacity
Premature airway closure causing V/Q mismatch and increased alveolar-to-arterial oxygen gradient
Small airway closure and gas trapping
Decreased expiratory flow rates

Abbreviation: V/Q, ventilation-perfusion.

Respiratory System Mechanics and Architecture

The chest wall becomes less compliant with aging, presumably related to changes in the thoracic skeleton and a decline in costovertebral joint mobility. These changes in and of themselves produce a restrictive functional impairment. The noncompliant thoracic cage makes intercostal muscle activity less efficient. Therefore, the diaphragm and abdominal muscles assume a greater role in tidal breathing. However, diaphragmatic function also declines with age, predisposing the elderly to respiratory fatigue when required to significantly increase minute ventilation. Diaphragmatic strength is decreased likely due to atrophy and relative loss of large myelinated muscle fibers. It also occupies a flatter position and therefore has a less favorable mechanical advantage.²² These changes increase the risk of respiratory insufficiency in the setting of high regional anesthesia.

The lungs become more distensible with age due to a loss of lung elasticity, which leads to decreased lung recoil. Changes in surfactant function contribute to age-related changes in lung compliance. The net result of these changes in the elastic properties of the lung and chest wall is an increase in intrapleural pressure that significantly impacts respiratory function. Intrapleural pressure is a critical determinant of small airway caliber. Increased intrapleural pressures increase the tendency for small airway collapse to occur, causing air trapping and/or expiratory airflow limitation.²²

Lung Volumes and Capacities

Vital Capacity

Vital capacity (VC) is the volume generated when a maximal inspiration is followed by a maximal expiration. There is a progressive loss of VC with aging that results from increased chest wall stiffness, decreased lung elastic recoil, and decreased respiratory muscle strength.

Residual Volume

The residual volume (RV) is the volume remaining in the lungs after a maximal expiration. In young individuals, the RV is determined primarily by ability of the expiratory muscles to overcome the elastic recoil properties of the lung and chest wall. However, in the elderly, dynamic small airway closure also limits expiration and increases the RV. Therefore, aging is associated with a progressive increase in RV of up to 10% per decade ([Figure 46.2](#)).²³

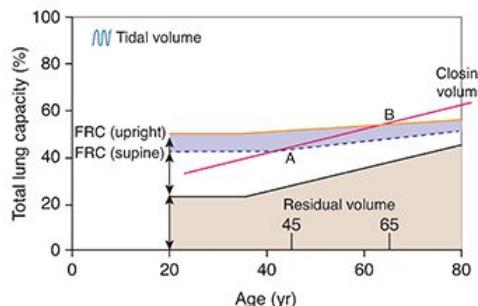

FIGURE 46.2 Effect of aging on lung volumes. Functional residual capacity (FRC) increases with age as a result of increasing residual volume. Closing volume also increases with age and exceeds FRC in the upright

position around age 65 years and in the supine position at age 45 years. These changes lead to ventilation perfusion mismatch and shunt, resulting in reduced resting Po_2 with age. *Reprinted by permission from Springer: Sprung J, Gajic O, Warner DO. Review article: Age related alterations in respiratory function—anesthetic considerations. Can J Anaesth. 2006;53(12):1244-1257. Copyright © 2006 Springer Nature. Modified with permission from Zaugg M, Lucchinetti E. Respiratory function in the elderly. Anesthesiol Clin North Am. 2000; 18(1):47-58. Copyright © 2000 Elsevier.*

Total Lung Capacity

Total lung capacity is the sum of the RV and the VC. The combined effect of the decline in VC and increase in RV is that the total lung capacity remains relatively constant with aging.

Functional Residual Capacity

The functional residual capacity (FRC) is the volume remaining in the lungs at the end of a normal expiration. The FRC is the volume at which the elastic recoil forces of the lung and chest wall are at equilibrium. The opposing recoil forces of the lung and chest wall generate the subatmospheric intrapleural pressure. Aging is associated with a decreased elastic recoil force of the lungs, which leads to a progressive increase in FRC. However, the increase in FRC is less than would be predicted from the change in lung elastic recoil alone. This is because the increased stiffness of the chest wall counteracts the increase in lung volume.

Closing Capacity

Spontaneous airway closure may occur in small airways (<1 mm) whose caliber is determined by their transmural pressure. Airway closure typically occurs in dependent areas of the lung where the surrounding intrapleural pressure is likely to be greater. In young adults, airway closure occurs only at low lung volumes (approximately 10% of VC). Thus, airway closure is unlikely during normal tidal breathing. However, as intrapleural pressure increases with age, airway closure occurs at progressively greater lung volumes. Indeed, in the elderly, airway closure occurs at approximately 40% of the VC, reflecting lung volumes that exceed FRC. Although the FRC increases by up to 3% per decade, closing capacity increases at a greater rate. Thus, gas exchange impairment due to shunting in regions of airway closure is typical in the elderly during normal tidal breathing. The supine position is associated with a decrease in FRC when compared to the standing position. Therefore, the supine position makes airway closure during normal tidal breathing more likely. Indeed, airway closure may occur during tidal breathing as early as the mid-40s in the supine position.²⁴

Expiratory Flow

There is a progressive decline in forced exhaled volume in 1 second and forced VC with age that is independent of smoking or environmental exposure. Age-related loss of lung elastic recoil predisposes to dynamic airway collapse during forced expiratory maneuvers. Expiratory muscle strength also declines with age.

Diffusing Capacity and Alveolar-to-Arterial Oxygen Gradient

Gas exchange efficiency declines with aging as a result of increasing intrapulmonary shunting and decreasing lung diffusing capacity. The result is a linear decline in resting supine Pao_2 between early adulthood and 65 years of age (Figure 46.3).²⁵ The cause of this decline is multifactorial. Small airway closure causes ventilation-perfusion mismatch and shunting. Cardiac output is often decreased in the elderly to the extent that mixed venous oxygen tension is decreased. Thus, even modest amounts of shunting may produce a significant decrease in Pao_2 because of the contribution of desaturated venous blood. The diameter of the alveolar ducts is increased and their respective alveoli are wider and shallower. These architectural changes significantly reduce alveolar surface area. As a result, diffusing capacity for carbon monoxide may decline by up to 50% between early adulthood and 80 years of age.

Upper Airway Protective Reflexes

Cough effectiveness is reduced in the elderly because of diminished reflex sensitivity and impaired muscle function. The mechanisms of cough reflex impairment include desensitization of airway epithelial irritant receptors and impaired swallowing.²⁰ Cough reflex attenuation is associated with an increased incidence of aspiration pneumonia. Smoking further exacerbates the situation by causing airway sensory nerve neuropeptide depletion and inhibition of C fiber transmission by nicotine in the lower respiratory tract.²⁶ Coexisting medical conditions that are associated with cough reflex suppression include stroke, laryngectomy, and Parkinson disease. General anesthetics inhibit the cough reflex through inhibition of central respiratory neurons.²⁷ Caution is needed during intubation and extubation of the elderly, especially those patients with additional risk factors for impaired airway protection.

Control of Breathing, Chemoreceptors, and Integrated Responses

The reflex cardiorespiratory responses to hypoxia and hypercarbia are mediated via central and peripheral chemoreceptors. The increases in heart rate and minute ventilation in response to elevations in PaCO₂ or decreases in PaO₂ are markedly attenuated in the elderly. The attenuated ventilatory response is multifactorial and reflects decreased peripheral chemoreceptor sensitivity, reduced respiratory muscle activity, decreased respiratory mechanical efficiency, and general respiratory deconditioning. These important protective reflexes are further attenuated by the administration of opioids and sedative/hypnotic drugs. Thus, the elderly are at particular risk from life-threatening respiratory depression in the perioperative period. Multiple reports have shown that the risk of opioid-induced ventilatory depression is increased in patients aged older than 65 years.^{28,29} Although the risk of respiratory depression from opioids is greater in the elderly, the same is not true for all opioid side effects.

Opioids are a major cause of postoperative nausea and vomiting in young and middle-aged patients, with a nearly fourfold increased risk over older patients in one study.³⁰ The relationship between age and the incidence of nausea and vomiting is actually inverse unlike most adverse physiologic effects and side effects.^{29,31,32}

Sleep-Disordered Breathing

The incidence of sleep-disordered breathing increases with age, especially in men. It is estimated that approximately 20% of elderly people have clinically significant obstructive sleep apnea.³³ The prevalence of snoring is highest in the seventh decade and is associated with an increased risk of stroke and heart disease. Morbidity associated with sleep apnea includes systemic and pulmonary hypertension, dysrhythmias,

myocardial infarction, stroke, sudden death, and automobile accidents. In addition, obstructive sleep apnea doubles the risk for postoperative delirium (POD) in the elderly.^{34,35}

The Coagulation System in the Elderly

The coagulation system undergoes changes with age. The plasma concentration of many coagulation factors, including factors V, VII, VIII, and IX, as well as von Willebrand factor is increased. Data are less conclusive regarding anticoagulant proteins such as protein C, protein S, and antithrombin. The overall balance of these changes is a relatively procoagulant state. In addition, multiple comorbidities that accumulate with age, including diabetes and cancer, confer a prothrombotic state. The effects of these comorbidities are difficult to distinguish from the normal aging process.³⁶

The incidence of venous thromboembolism (VTE) and pulmonary embolism increases with age. Patients younger than 65 years experienced 231 events per 100,000 people, whereas those 65 years and older experienced 1,382 VTE events per 100,000 people.³⁷ Pulmonary embolism accounts for an increasing percentage of VTE events as age increases.³⁸ The incidence of VTE overall is increasing and is expected to more than double by 2050. The elderly population will likely be disproportionately affected by this trend.³⁷ Even in patients on vitamin K antagonists, there is a higher risk of thrombosis as age increases.³⁹

As the coagulation system is altered with age, perioperative hemostasis may be expected to be altered as well. A study on coagulation parameters in elderly (>80 years) and younger patients (<60 years) undergoing cardiac surgery revealed that, based on thromboelastogram data, the elderly patients were relatively hypocoagulable before their surgery and had greater blood loss and transfusion requirements than the younger patients.⁴⁰ This contradicts the data showing an increase in most clotting factors and VTE incidence with age. In addition, elderly patients are more likely to be on anticoagulants at baseline (eg, for atrial fibrillation or history of VTE). The effect of aging on hemostasis and coagulation is not necessarily straightforward, and elderly patients may be predisposed to both increased thrombosis and increased bleeding perioperatively.

Thermoregulation in the Elderly

There is ample evidence that hyperthermia and hypothermia in the elderly are poorly tolerated and that extreme cold and heat stress are associated with increased mortality compared to younger individuals.⁴¹ Several physiologic alterations contribute to this, including decreased sweating and alterations in skin blood flow in response to thermal challenge and may be due to reduced physiologic reserve.⁴² Although there are clear physiologic alterations in temperature regulation in the elderly, the observed greater susceptibility to thermal stress in the population may also be related to underlying socioeconomic conditions, general fitness, activity levels, and the effects of coexisting disease in the elderly.

Resting Core Temperature

Aging is associated with a greater variability in core temperature. It is estimated that up to 10% of people older than 65 years of age have early morning core temperatures of less than 35.5°C (**Table 46.4**).⁴¹ The regulation of body temperature is complex and involves many systems including the cardiovascular and respiratory systems. As discussed earlier, these systems have reduced function with advancing age, resulting in a negative impact on the control of body temperature. Some changes such as those that occur in the musculoskeletal system can be slowed or even prevented by exercise partially preventing decrements in thermoregulatory functions. Some deficits such as skin changes and metabolic slowing are unavoidable.⁴²

TABLE 46.4

Factors associated with reduced resting core temperatures in the elderly

Neurologic disease
Diabetes
Low body weight
Lack of self-sufficiency
Consumption of less than two meals per day

Smoking

Alcohol consumption

In old age, circadian rhythms break down and organisms lose their ability to adapt to the periodic environment. Sleep disorders are frequently observed in older people and are believed to be caused, at least partly, by changes in the circadian system.^{43,44}

Response to Cold Stress

The elderly do not tolerate cold stress as well as younger people. The usual physiologic response to cold stress is to decrease heat loss by peripheral vasoconstriction and to increase heat production via shivering and nonshivering thermogenesis. Aging is associated with attenuated vasoconstrictor responses to cold.⁴¹ The inability to efficiently conserve heat in the elderly is exacerbated by the age-related decrease in skeletal muscle mass. Loss of skeletal muscle mass is responsible for the age-related decline in basal heat production. It is estimated that resting heat production declines by 20% between the ages of 30 and 70 years. There is a significant gender-related difference in cold stress response in the elderly. Mortality during cold weather is higher in men compared to age-matched women.⁴⁵ It is likely that the higher percentage of body fat and lower surface area-to-mass ratio in females is responsible for their better outcome. The attenuated cold stress responses of the elderly are further diminished by general and regional anesthesia. Perioperative hypothermia is very likely to occur in the elderly patient unless active measures are taken to maintain normothermia.

Gastrointestinal Function in the Elderly

Liver

Although aging is associated with a 25% to 35% decrease in liver mass and a 40% reduction in hepatic blood flow, hepatocellular metabolic function appears to be relatively well preserved throughout life. Protein synthetic function may be diminished in some elderly individuals, particularly those with poor nutritional intake. The resulting reduced serum albumin concentrations affect the bioavailability of highly protein-bound drugs.⁴⁶ On the other hand, the concentration of another important drug-binding protein, α_1 acid glycoprotein, is typically increased in the elderly. Hepatic synthesis of plasma cholinesterase may be diminished, particularly in men, but this is not likely to be clinically important in the absence of concurrent genetic mutation.⁴⁷

Although in vitro data indicates that the function of hepatic enzymes involved in phase I and II metabolism (including the cytochrome P450 enzymes) is maintained,⁴⁶ the reduction in hepatic mass and blood flow is responsible for an in vivo decrease in first-pass metabolism of several drugs that are important in the aging population.⁴⁷ Nondepolarizing neuromuscular-blocking agents such as vecuronium and rocuronium have prolonged effects in the elderly for this reason. Conversely, prodrugs, such as the angiotensin-converting enzyme inhibitor enalapril, codeine, and tramadol, require activation by the liver before they exert their pharmacologic effect. Therefore, the bioavailability of these drugs may be decreased in the elderly.

Gastroesophageal Physiology

With age, both skeletal and smooth muscle in the esophagus hypertrophies, impairing the coordination of peristalsis. Transit of food in the esophagus is not impaired, but transit of liquids is delayed.⁴⁸ Gastric emptying of solid material appears to be relatively normal in the healthy elderly population. However, gastric emptying of liquids may be delayed compared to younger individuals.⁴⁹ Gastroesophageal reflux disease (GERD) is common in the elderly. Recent studies show that most patients with GERD are older than 70 years old. However, this demographic trend may be shifting as more young people are diagnosed with GERD. Therefore, the overall ratio of older-to-younger patients with GERD is decreasing (**Table 46.5**).⁵⁰ The typical symptoms of GERD seen in the younger population (heartburn and regurgitation) are less frequent in the elderly, making diagnosis more difficult.⁵¹ Dysphagia, vomiting, respiratory symptoms, weight loss, and

anemia are more common presenting symptoms in the elderly. Several medications that are commonly prescribed in the elderly population predispose them to GERD by decreasing lower esophageal sphincter tone ([Table 46.6](#)).

TABLE 46.5

Factors that predispose to the increased incidence of gastroesophageal reflux disease in the elderly
Increased prevalence of sliding hiatal hernia
Shortened intra-abdominal segment of the lower esophageal sphincter
Impaired clearance of refluxed acid
Use of medications that reduce lower esophageal sphincter pressure
Decreased esophageal peristalsis pressure

TABLE 46.6

Medications that are commonly administered in the elderly that reduce lower esophageal sphincter tone and predispose to gastroesophageal reflux
Anticholinergics
Antidepressants
Nitrates
Calcium channel blockers
Theophylline

Renal Function in the Elderly

Aging is accompanied by a reduction in renal mass and a decrease in the cortical nephron population. The medullary nephron population is relatively preserved, and age-related vascular changes in the medulla are minimal. Renal blood flow and glomerular filtration rate (GFR) both decline with age.⁵² The average male GFR is 125 mL per minute. This value decreases by approximately 1 mL/min per minute per year after the age of 40 years as a result of the decline in nephron population and hyalinization of cortical afferent arterioles. Despite the significant decline in GFR with aging, the serum creatinine concentration increases minimally because there is also an age-related decrease in skeletal muscle mass. This diminished renal function is sufficient to maintain homeostasis under normal physiologic conditions. However, common perioperative stresses such as hypotension and hypovolemia may unmask the diminished renal reserve, and acute renal dysfunction may manifest.⁵³ Although the elderly individual is able to maintain acid-base balance under everyday physiologic conditions, the response to increased acid loads such as during ischemia and sepsis is attenuated due to impaired renal tubular ammonium secretion.

The elderly are at risk for both free water deficit and free water overload because of impaired renal response. Urine concentrating ability prevents free water loss and is critically dependent on the presence of a hypertonic renal medulla. However, medullary perfusion is relatively increased in the elderly, resulting in a washout of solute and a reduction in osmolality in that region. Thus, the collecting tubules are not exposed to the usual concentration gradient necessary to produce concentrated urine.⁵⁴ Reduced numbers of cortical nephrons also contribute to impaired salt conservation. This suboptimal renal response to dehydration is compounded by age-related deficiencies in thirst mechanisms. Water deprivation is associated with a reduced thirst response in elderly subjects despite significant increases in plasma osmolality.⁵⁵ As a result of these factors, the elderly are at enhanced risk for dehydration and hypernatremia.

The response to free water excess is similarly attenuated in the elderly. This is particularly relevant because the perioperative neuroendocrine stress response is associated with arginine vasopressin (antidiuretic hormone) release and water retention. When combined with iatrogenic hypotonic fluid administration, these factors make the elderly patient particularly susceptible to perioperative free water overload and hyponatremia.

Skeletal Muscle Mass and Aging

Aging is associated with a significant decline in neuromuscular performance. Neuromuscular decline results predominantly from loss of skeletal muscle mass (sarcopenia), which declines by approximately 40% between the ages of 20 and 60 years. By the seventh and eighth decades, maximal voluntary contractile strength is reduced by 20% to 40%. This leads to functional disability, loss of independence, and increased mortality.^{56,57} The decline in muscle function is multifactorial (**Table 46.7**). However, strength losses with aging may be attenuated by continued physical activity, particularly resistance training. Diminished skeletal muscle mass has significant implications for the elderly patient in the perioperative period (**Table 46.8**).

TABLE 46.7

Factors that are thought to be responsible for the significant decrease in lean muscle mass that occurs with aging

Decreased motor neuron innervation
Decreased physical activity
Endocrine shift toward catabolism (reduced insulin-like growth factor 1 secretion)
Decreased androgen (testosterone and estrogen) secretion
Decreased total caloric intake
Decreased protein consumption and protein synthesis
Inflammatory mediators and cytokines (interleukins 1 and 6, tumor necrosis factor)

TABLE 46.8

Perioperative functional consequences of the loss of skeletal muscle mass that typically accompanies aging

Impaired postoperative mobilization and ambulation
Reduced cough effectiveness
Reduced shivering thermogenesis
Altered drug disposition
Reduced neuromuscular functional reserve
Prolonged recovery and hospitalization

Neurophysiology of Aging

The elderly have increased sensitivity to benzodiazepines, opioids, and volatile anesthetic agents. The minimum alveolar concentration of potent volatile anesthetic agents decreases about 6% with each decade. This is likely due to altered ion channel activity and increased receptor sensitivity.⁵⁸ The addition of nitrous oxide is more effective in reducing the requirements for potent inhaled anesthetic drugs in the elderly.

Undergoing surgery at an advanced age puts patients at increased risk for POD and postoperative cognitive dysfunction (POCD). Each of these entities is a strong risk factor for mortality.⁵⁹ The POD is a syndrome of fluctuating consciousness, inattention, memory impairment, and perceptual abnormalities that typically occurs after a lucid interval of 1 to 3 days after emergence from general anesthesia. The POCD is more loosely defined as a new, temporary decline in cognitive function (memory and executive function) manifesting 1 to 12 months after surgery and potentially lasting 2 to 3 years. A landmark study, the International Study of Postoperative Cognitive Dysfunction 1 described POCD in 26% of elderly patients 1 week after anesthesia and in 10% after 3 months using a variety of well-recognized neurocognitive assessments.⁶⁰ Subsequent studies have demonstrated incidence of POCD as 47% at 1 month, 23% at 2 months, and 15% at 6 months after surgery and anesthesia.⁶¹

The relationship between POD and POCD is unclear. There are a large number of shared risk factors, including advanced age, extent of surgery and duration of anesthesia, infection, and preexisting dementia or

cognitive decline.⁶² This suggests a shared pathogenesis. However, recent data from the Successful Aging after Elective Surgery trial did not show a correlation between POD and POCD beyond 1 month after surgery, suggesting that they may be distinct entities.⁶¹

A POD is equally common after both regional and general anesthesia, whereas POCD may be more common after general anesthesia.⁶³ A recent Cochrane review compared intravenous versus inhalational maintenance anesthetic for elderly patients undergoing noncardiac surgery. They could not make a conclusion about rates of POD between the two methods but found low-certainty evidence that POCD may be reduced with a propofol-based intravenous anesthetic.⁶⁴ Whereas some studies suggest a lighter depth of anesthesia is associated with decreased POD, other studies have not found this association.^{62,65,66} Despite this lack of consensus, the American Geriatric Society Expert Panel on Postoperative Delirium in Older Adults recommends the use of processed electroencephalography to maintain a lighter plane of anesthesia in an attempt decrease the incidence of POD.⁶²

The pathophysiology of acute POD in the elderly is undetermined. However, a neuroinflammatory response exacerbated by a faulty blood–brain barrier is thought to be mechanistically important. Surgical trauma induces a systemic inflammatory response, which leads to an inflammatory cascade mediated by neutrophils and macrophages in the central nervous system, which release cytokines, leukotrienes, free oxygen radicals, and proteolytic enzymes, damaging surrounding tissues and resulting in POCD. Other factors such as hypercapnia, hypotension, and cerebral microemboli have been areas of active investigation.⁶⁷

Although POCD is a risk factor for early mortality, in an 11-year follow-up of the International Study of Postoperative Cognitive Dysfunction cohort, it was not found to be a risk factor for dementia.⁶⁸ As the population ages and requires more surgical intervention, the pathogenesis of this syndrome and its best management are important areas for investigation.

Pain and Aging

Pain is a part of daily life for many elderly patients. In a large population-based study, 53% of older adults report “bothersome pain” in the last month. The prevalence of pain is increased in women, obese patients, and patients with multiple comorbid conditions.⁶⁹ Biologic, psychological, and social changes occur in the elderly that impact on the pain experience. The complexities of the pain response in the elderly are beyond the scope of this chapter, but clearly, aging is associated with changes in all three mentioned earlier.

In the simplest setting, experimental studies in healthy volunteers show that older adults are more sensitive than young adults to mechanically evoked pain but not heat-evoked pain.^{70,71} Descending inhibitory pathways, which function as an endogenous analgesic response to pain, are reduced in elderly patients. The number, density, and proportion of undamaged myelinated and unmyelinated nociceptive fibers decrease with age. Older individuals are more responsive to placebo interventions, which can be beneficial when used with appropriate informed consent.⁷²

As a general rule, elderly patients are more sensitive to opioids. Electroencephalographic, pharmacokinetic, and pharmacodynamic studies of subjects treated with fentanyl, alfentanil, sufentanil, and remifentanil support a 50% dose reduction for elderly patients.^{73–77} Aging results in less important pharmacokinetic effects of these drugs with variable reports of small reductions in clearance. Alterations in pharmacodynamics are more likely to be responsible for the observed dose reduction. It is important to remember that these drugs do not have active metabolites.

In contrast, morphine and meperidine do have active metabolites, which accumulate in the elderly. Morphine is altered by glucuronidation into two metabolites, morphine-3-glucuronide, which is mostly inactive, and morphine-6-glucuronide, which is itself a potent analgesic. Although the potency of intrathecal morphine-6-glucuronide is 650-fold higher than that of morphine, morphine-6-glucuronide crosses the blood–brain barrier so slowly that it is unlikely that it contributes to the acute analgesia provided by morphine. However, with chronic administration, the levels of morphine-6-glucuronide will rise to pharmacologically active concentrations.⁷⁸ Morphine-6-glucuronide is eliminated by the kidneys. Creatinine clearance is reduced with advancing age. Thus, morphine-6-glucuronide will accumulate more in elderly patients,

necessitating a reduction in dose of chronically administered morphine. Of course, in a patient with renal insufficiency, an opioid without a renally excreted active metabolite is a more appropriate choice.

Elderly patients have reduced meperidine clearance, resulting in a prolonged half-life. Meperidine will also accumulate in elderly subjects with repeated administration.⁷⁹ A toxic metabolite, normeperidine, is highly epileptogenic. Renal excretion of normeperidine is particularly reduced in elderly patients. The result is that normeperidine can accumulate with repeated doses in elderly patients.⁸⁰ This has resulted in several major healthcare policy organizations to state that meperidine is inappropriate for use in the elderly.⁸¹

Conclusion

The alterations in physiology and pharmacology discussed in this chapter encompass every organ system and result in overall decreased physiologic reserve, increased interindividual variability, and significant alterations in drug metabolism. This makes the anesthetic management of elderly patients more challenging. The continued aging of the population means that more and more elderly patients will require surgery, making anticipation and management of these factors critical. With careful drug titration and pre- and postoperative management, even the extremely old can safely undergo surgery in order to improve the quality of their lives.

Physiology and Pharmacology of Resuscitation

Michael J. Murray • Sean M. Dennig

The term *resuscitation* for many people means resuscitation from cardiac arrest, so much so that the term *cardiopulmonary resuscitation (CPR)* is widely used not only by healthcare professionals but by lay people as well. This is justifiably so because cardiovascular disease is the number 1 cause of death in the United States, and in 2017, it is estimated that 647,457 Americans died of cardiovascular disease.^{1,2} Unfortunately, the first manifestation of cardiovascular disease is often sudden death due to ventricular tachycardia, ventricular fibrillation, or asystole. To improve outcome from cardiac arrest, the American College of Cardiology, American Heart Association, and many other organizations have joined together to educate healthcare professionals and lay people on how to resuscitate patients who have had a cardiac arrest by promoting the American Heart Association's Basic Life Support (BLS) and Advanced Cardiovascular Life Support (ACLS) programs. To incorporate the latest information on CPR, the programs are continuously updated.³

Resuscitation could equally apply to resuscitation from traumatic injury. Death from traumatic injury is the third leading cause of death overall in the United States and the primary cause of death in individuals younger the age of 45 years.⁴ These individuals most often die because of hemorrhage, and similar to what the American Heart Association has done, the American College of Surgeons through its Committee on Trauma has developed the Advanced Trauma Life Support course for healthcare professionals⁵ and the "Stop the Bleed"⁶ programs for the lay public to improve the outcome of patients who have sustained traumatic injury.

For a pediatrician, the mention of resuscitation might bring to mind the resuscitation of neonates with apnea.⁷ However, apnea or respiratory arrest is equally important in the resuscitation of adults from respiratory arrest, as it is distinct from cardiac arrest. If either is not recognized in a timely manner and treated effectively, then one will quickly precipitate the other.

Common to all these scenarios and the actual mechanism by which patients die is inadequate oxygen delivery to tissues. Oxygen delivery is defined as follows:

$$\dot{D}O_2 = CO \times CaO_2$$

where $\dot{D}O_2$ is equal to oxygen delivery, CO represents cardiac output, and CaO_2 is the oxygen content of arterial blood. In a 70-kg person, oxygen delivery is assumed to be 1000 mL per minute derived by multiplying cardiac output (50 dL per minute) times arterial oxygen content (20 mL of oxygen/dL), which in turn is calculated by multiplying 15 g hemoglobin/dL times 1.39 (the amount of oxygen each gram of hemoglobin can hold when fully saturated) times the arterial oxygen saturation (for this calculation, we are assuming a hemoglobin oxygen saturation of 100%). From this equation, one can gain insight into the three mechanisms from which death might occur if the patient is not resuscitated in a timely and effective fashion. During ventricular tachycardia, ventricular fibrillation, or asystole, cardiac output decreases to zero, as will oxygen delivery. During hemorrhagic shock, as hemoglobin levels decrease, the arterial oxygen content decreases at the same time that cardiac output falls because of decreased intravascular volume, resulting in decreased left ventricular end diastolic volume. During apnea from whatever cause, as whatever oxygen is contained in the functional residual capacity (FRC) of the lung decreases, the amount of oxygen available to bind with hemoglobin decreases, which also results in a steadily decreasing oxygen delivery and eventually cell death.

For the purposes of this chapter, the focus is on resuscitation from cardiac events, traumatic injury, and decreased fractional inspired concentration of oxygen (FIO_2).

Pathophysiology

The basic physiology of death from hypoxia due to decreased oxygen delivery is relatively straightforward but, at the same time, quite complex. As oxygenated hemoglobin is delivered to peripheral tissues, oxygen dissociates from hemoglobin because of the concentration gradient between the oxygenated hemoglobin in red blood cells and the decreased PaO_2 in capillary blood perfusing tissue. The dissociation of oxygen from hemoglobin is facilitated by the Bohr effect. Carbon dioxide that is produced by cellular respiration is released into capillary blood, combining with water to produce carbonic acid, which quickly dissociates into bicarbonate and hydrogen ion. The increased concentration of hydrogen ions results in a relative acidosis, which promotes the dissociation of oxygen from hemoglobin (shift of the oxygen-hemoglobin dissociation curve to the right). As oxygen dissociates from hemoglobin, it diffuses out of red blood cells and down a concentration gradient through the plasma, across cell membranes and into the cytoplasm where it is taken up by mitochondria, which in turn use the oxygen to catabolize pyruvate, derived from glucose, amino acids and fatty acids, in the Krebs cycle. Water and carbon dioxide are the byproducts, and the energy produced is used by the coenzymes nicotinamide adenine dinucleotide and flavin adenine dinucleotide to add a phosphate molecule to adenosine diphosphate to create adenosine triphosphate (ATP). The energy stored in the third phosphate bond of ATP can be used by cells for protein synthesis, for endocytosis and exocytosis, to provide energy for other transporter processes, for maintenance of the electrical potential across the membrane, and indeed to maintain the integrity of the cell membrane itself.

Oxygen is the molecule that serves as the electron acceptor by which nicotinamide adenine dinucleotide and flavin adenine dinucleotide produce more ATP than can be created by anaerobic metabolism. The chemical reactions involved in the anaerobic metabolism of pyruvate lead to the production of 4 molecules of ATP, whereas the metabolism of pyruvate in the presence of oxygen can lead to potentially 38 molecules of ATP. Anaerobic metabolism is insufficient in the long term to produce sufficient ATP to maintain cell integrity. In the absence of oxygen, cells die at a variable rate depending on their metabolic rate ([Figure 47.1](#)). Typically, neurons are the most sensitive to lack of oxygen and will develop irreversible damage within 3 to 5 minutes; myocytes and hepatocytes on the other hand can survive 1 to 2 hours in the absence of oxygen, whereas muscle cells may survive for several hours. By decreasing metabolic rate, hypothermia can prolong the “safe” ischemic time. Neurons, for example, decrease their metabolic rate by approximately 7% for every 1°C decrease in temperature.⁸ There is a limit, however, to how much hypothermia can delay a cell’s demise. For example, during circulatory arrest while a patient is on cardiopulmonary bypass, at 15°C to 20°C neurons do not display irreversible cell damage for as long as 30 to 40 minutes, but at 40 minutes, the risk for stroke and cognitive dysfunction increases significantly.⁹ Hypothermia has the same effect on other cells such as myocytes and hepatocytes as well as cells in other organs, which allow transplant surgeons to prolong the amount of time between when an organ is procured and when it is transplanted.

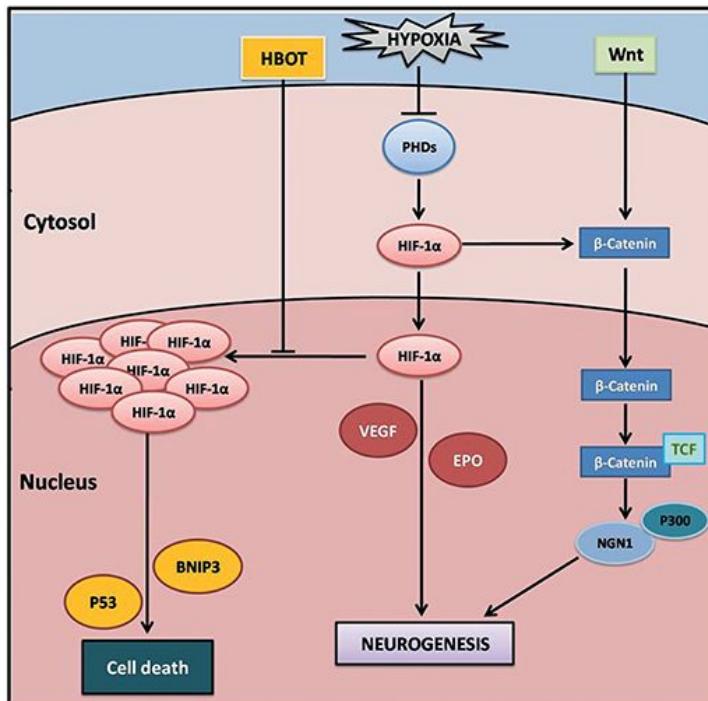

FIGURE 47.1 Physiologic pathways underlining hypoxic cellular responses in the brain. Abbreviations: BNIP3, BCL2/adenovirus E1B 19 kDa protein-interacting protein 3; EPO, erythropoietin; HBOT, hyperbaric oxygen therapy; HIF-1 α , hypoxia-inducible factor 1 alpha; NGN1, neurogenin 1; PHDs, prolyl hydroxylases; TCF, T-cell factor; VEGF, vascular endothelial growth factor.

Although temperature has an impact on survivability of ischemic cells, time is the factor that most directly and importantly impacts the reversibility of ischemia—the safe ischemic time. Independent of all other factors, the number of minutes that cardiac function is arrested, the amount of time that the hemoglobin concentration is below 6 to 7 g/dL, or the duration of apnea or asphyxia all directly correlate with morbidity and mortality. For cardiac arrest, evidence from assessment of the effect of duration of the arrest on survivability suggests that mortality increases by 8% to 10% for each minute for which there is no cardiac output.¹⁰ The most vital factor then in determining outcome is the timely restoration of normal cardiac, pulmonary, and hemodynamic function.

Cardiac Arrest

The National Library of Medicine in its Medical Subject Headings terms defines *heart arrest* as the cessation of effective cardiac function, which if not recognized and treated within minutes will lead to “sudden cardiac death” (SCD). The SCD in turn is the “unexpected rapid natural death due to cardiovascular collapse within one hour of the onset of symptoms usually caused by the worsening of existing heart disease.”

Thirty percent to 40% of patients who have an out-of-hospital cardiac arrest (OHCA) are found with ventricular tachycardia/ventricular fibrillation; ~20% of almost 12,000 patients admitted to central Massachusetts hospitals between 1986 and 2011 developed these same tachyarrhythmias.¹¹ Over a similar time frame though, the incidence of tachyarrhythmias has been decreasing.¹² Oftentimes, patients who have not had a myocardial ischemic event have a prolonged QT interval, which places them at increased risk for developing polymorphic ventricular tachycardia, for example, *torsade de pointes*, especially if they receive certain drugs that are also known to prolong the QT. Forty-seven mutations in genes that code for ion channels that generate the cardiac action potential have been identified in patients with the long QT syndrome.¹² More than 150 drugs have been reported to prolong the QT interval. Drugs that prolong the QT interval are thought to do so by modifying the activity of the same ion channels responsible for the long QT

syndrome. The effects of the different drugs range from mild to severe, with the latter having the greatest probability of precipitating *torsade de pointes*.¹³ The ability of a drug to precipitate a malignant tachyarrhythmia is related not just to the drug itself but also to the dose, drug-drug interactions, genetic factors, the sex of the patient, and the type and severity of preexisting cardiac disease.

The true incidence of the precipitating arrhythmia for an OHCA is not known because most sudden cardiac arrests occur out of hospital and typically several minutes pass before the rhythm can be assessed. The cardiac diseases that lead to the genesis of cardiac collapse are varied, and the association with SCD in some cases is not well understood. Similar to what has been found in some patients who have cardiovascular collapse from ventricular tachyarrhythmias, there are patients who develop ventricular fibrillation who do not have structural heart disease. One study identified inferolateral early repolarization in SCD patients who have no evidence of structural heart disease.¹⁴

For resuscitation to be successful, independent of the etiology of the cardiac collapse, CPR must be initiated as soon as possible. The best chance to improve outcome is the rapid return of spontaneous circulation (ROSC), which has led to a multiprong effort for OHCA.¹⁵ The foci have been on decreasing emergency medical services (EMS) response time, CPR training for the lay public, and increasing the number of automated external defibrillators in public places. Bystander initiation of BLS for a witnessed OHCA is associated with better outcomes than waiting for EMS to respond.¹⁶ The efficiency of BLS (eg, the quality of compressions) is critical,^{17,18} more so than ventilation.¹⁹ Next in the hierarchy is ACLS, supplied by EMS and emergency department personnel and by hospital personnel for in-hospital cardiac arrest. Once ROSC is achieved, more advanced technologies can be chosen, personalizing the resuscitation.¹⁵ Unfortunately, the average survival rate of OHCA of 7.6% did not change between 1980 and 2010.¹⁶ Predictors of increased survival for OHCA are EMS witnessed arrest, shockable rhythm, a cardiac as opposed to a noncardiac etiology, out-of-home versus in-home, and younger age.^{20,21} Better outcomes are also achieved if anesthesiologists are involved in prehospital care of patients, as they are in some European countries, who have sustained an OHCA.²²

For an arrest witnessed by a bystander trained in CPR, an EMS response time of ≤ 7.5 minutes is also associated with better outcomes.²³ For in-hospital cardiac arrest in those patients with a shockable rhythm, there is an inverse relationship between time to defibrillation and neurologic outcome; the goal should be to achieve defibrillation of ≤ 3 minutes.

Current ACLS guidelines deemphasize the importance of airway/breathing compared to return of circulation. The 2019 International Consensus on Cardiopulmonary Resuscitation suggested that bag-mask ventilation or ventilation through an advanced airway device be used during resuscitation from OHCA or in-hospital cardiac arrest, the choices depending on the skill of the personnel managing the airway. If a supraglottic device is used (in situations in which there is a low rate of success for tracheal intubation), no recommendations were made regarding the type of device that should be used.²⁴ Following ROSC, most patients will require tracheal intubation and mechanical ventilation.

For those patients with ROSC who are unresponsive, neurologic outcome is improved if hypothermia is induced for 24 hours. The 2015 guidelines of the International Liaison Committee on Resuscitation recommend targeted temperature management with a goal of 32°C to 36°C for patients with coma after ROSC from cardiac arrest.²⁵ A study from France published in 2019 demonstrated that patients in coma following ROSC after a cardiac arrest had improved neurologic outcome if targeted temperature management with a goal of 33°C was instituted for 24 hours.²⁶

Hemorrhagic Shock

In patients who sustain traumatic injury and die, hemorrhage accounts for the majority of deaths, oftentimes before patients arrive at a hospital. The same is true in combat where 67% of potentially preventable deaths are from hemorrhage. For those service members who were alive upon arrival at a combat support hospital in Afghanistan, severity of injury and hemorrhagic shock requiring a massive transfusion were significantly associated with mortality.²⁷

In both the civilian and military setting, mortality in the first several hours is also correlated with inadequate resuscitation²⁸ and the presence of coagulopathy.²⁹ A cascade of life-threatening conditions begins with severe hemorrhage, and many of these occur simultaneously creating a vicious cycle: (1) hemorrhage, (2) shock, (3) coagulopathy, (4) hypothermia, (5) hemorrhage. The goal for the anesthesiologist is to assess for and manage these problems simultaneously. Improvements in early hemorrhage control (damage control surgery³⁰), resuscitation, and the prevention and aggressive treatment of coagulopathy (damage control resuscitation³¹) appear to have the greatest potential to improve outcomes in severely injured trauma patients.

Pulmonary Arrest

Respiratory and cardiac arrest are distinct, but if untreated, one inevitably leads to the other. There are a multitude of etiologies of respiratory arrest, and respiratory arrest per se implies any process that inhibits the delivery of sufficient oxygen to the mitochondria to maintain aerobic metabolism. The respiratory centers are in the brainstem; they can be injured by penetrating injury (eg, a gunshot wound) or by increased intracranial pressure due to infection or an intraventricular hemorrhage. Even blunt trauma to the head of sufficient force can produce a similar result. Atkinson et al,³² using a mechanical blow to the head, demonstrated in a rodent model that as the force of the blow incrementally increased there came a point that the animal became completely apneic. A number of drugs can depress the respiratory centers, most notably the opioids, the sedatives, and the hypnotics (propofol, etomidate). These drugs can suppress ventilation or induce complete apnea even at low doses in patients with central sleep apnea^{33,34} or patients with chronic obstructive pulmonary disease (COPD) and hypercarbia, or in geriatric patients with comorbid conditions. Although it is true that opioids suppress ventilation, some have used this relationship to justify withholding opioids from patients with severe COPD at the end of their lives.³⁵ One study of over 2000 patients with severe COPD found a correlation between the dose of opioids and mortality, but at lower doses, the effect was not seen, and yet, lower doses did attenuate some of the patients' dyspnea.³⁶ More recent studies suggest that opioids continue to be used off-label to treat dyspnea in patients with COPD.^{37,38}

Whatever the cause, be it through a central nervous system mechanism or a peripheral mechanism such as glottic edema from anaphylactic shock or airway disruption from trauma or airway obstruction from a foreign body (eg, a piece of steak), death does not occur immediately. The hemoglobin in the circulating blood carries enough oxygen for maintenance of aerobic metabolism for 1 to 3 minutes. In addition, there is oxygen that has already entered the lungs. During normal breathing at end expiration, there is oxygen in the FRC that can be calculated as the FIO_2 times the volume of air in the FRC, which in turn is equal to the person's weight in kg times 15 mL/kg. For a 70-kg person breathing room air, the FRC would contain ~220 mL of oxygen ($[70 \text{ kg} \times 15 \text{ mL/kg}] \times 0.21$) enough to meet metabolic demand. At 3 to 4 minutes of complete apnea, evidence of tissue ischemia would become apparent, and, at >5 minutes, irreversible damage would occur, especially in the brain. Cardiac arrest would soon follow unless oxygenation and ventilation are immediately rapidly restored.

Other causes of hypoxic death are related to the neuromuscular system. A spinal cord transection above C4 would result in apnea that, if not recognized and treated, immediately will result in death simply because the phrenic nerves arise from C1 to C4. Likewise, in patients with amyotrophic lateral sclerosis, upper and lower motor neurons in the motor cortex, in the brainstem, and in the spinal cord self-destruct over time, leaving the patient unable to maintain respiratory effort. Neuromuscular blocking agents produce the same effect albeit more quickly.

Any process that increases the alveolar-to-arterial oxygen gradient can likewise interfere with the delivery of oxygen to tissues (eg, drowning) or acute respiratory distress syndrome.

Cyanide poisoning is the most well-known cause of inhibition of oxygen utilization within mitochondria by inhibiting of cytochrome c oxidase.

Using an alkaloid plant extract (curare) in which they dipped their arrows, the natives of Central and South America once killed their enemies.

All the causes of hypoxic death discussed so far come about from inhibition or destruction of the body's normal physiologic mechanisms. There are also environmental factors that play a role as well, the most important of which would be any factor that decreases the FIO_2 would interrupt aerobic metabolism. The best example for anesthesiologists would be a helium quench from a magnetic resonance imaging scanner that, if the proper safety valves in the room were not working correctly, would displace all the oxygen in the room.

Pharmacology

Cardiopulmonary Resuscitation

The primary goal when resuscitating a patient from cardiac arrest is ROSC, which is best achieved with effective chest compressions, and if the patient has a tachyarrhythmia, the delivery of electroshock therapy, as described in the preceding text. However, if these maneuvers are unsuccessful in restoring cardiac function, drug therapy is advocated because it has been shown to increase the rate of ROSC. Amiodarone, lidocaine, and epinephrine are three such drugs; vasopressin, sodium bicarbonate, fibrinolytics, and other vasoactive drugs have not been shown to increase the rate of ROSC and therefore their use is no longer advocated.

Epinephrine

Epinephrine is a catecholamine (vasoactive compound with a catechol—benzene ring with two hydroxyl groups [[Figure 47.2](#)] in its structure) for which dopamine is its precursor, and in turn epinephrine is the precursor for norepinephrine. Chromaffin cells in the adrenal medulla and the terminal boutons of certain nerves produce and release epinephrine, which gains its biologic activity by binding to α - and β -adrenergic receptors. Among its many effects, epinephrine activation of α -receptors produces vasoconstriction in the peripheral vasculature, whereas activation of β -receptors within the heart increases chronotropy, inotropy, dromotropy, and lusitropy. The majority of epinephrine produced is metabolized within the same cells in which it was synthesized simply because there is so much leakage of the catecholamine from the vesicles where it is stored in the cytoplasm.

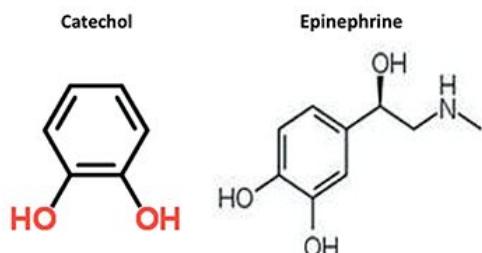

FIGURE 47.2 Molecular structure for the common catechol ring and for epinephrine.

When administered intravenously during a cardiac arrest, epinephrine is thought to increase the ROSC by binding to and activating α -adrenergic receptors. Activation of these receptors on the venules in the periphery would increase venous return to the heart and during chest compressions would increase cardiac output; on the arterial side, the vasoconstriction caused by α -receptor activation would constrict the peripheral arterial system. The increase in cardiac output with an increased systemic vascular resistance is hypothesized to improve coronary artery and carotid artery blood flow. By activating β -receptors within the heart, epinephrine should augment cardiac output even further, with additional benefit to the patient, but there are some who believe that epinephrine's effect on β -receptors is more detrimental than beneficial.

Epinephrine has been repeatedly demonstrated to improve ROSC when administered to patients in cardiac arrest but without an improvement in overall outcome. However, most of the studies of epinephrine have been observational in nature; in 2012, the only prospective randomized controlled study ever done until that time was stopped early because of difficulty enrolling patients into the placebo group.³⁹ During the intervening years, questions continued to arise about the role of epinephrine in cardiac arrest.^{40,41} Perkins et

al⁴² studied 8014 patients with OHCA who were randomized to either epinephrine (n = 4015) or placebo (n = 3999). The primary end point was 30-day survival, and a secondary end point was neurologic status. Patients administered epinephrine had better 30-day survival rates (3.2%) than those who received placebo (2.4%). More patients in the former group (31%) had devastating neurologic outcome with Rankin scores of 4 to 5, compared to the latter group (17.8%). The difference in survival rates was not enough to compensate for the difference in neurologic status, and in fact, the reverse was true.⁴² Unless the American Heart Association guidelines are changed, it is recommended that clinicians follow ACLS protocols when resuscitating patients who sustain a cardiac arrest. They are well established and well accepted by the medical and lay public communities.⁴³ The study highlights the fact that although the administration of epinephrine during CPR may increase the likelihood of ROSC, it may not improve neurologic outcome, but the same is true for every other drug that has been studied when administered during CPR.⁴⁴ However, the most recent guidelines of the American Heart Association recommend 1 mg of epinephrine administered intravenously or by intraosseous (IO) injection every 3 to 5 minutes. If these routes are not available, epinephrine can be given through the tracheal tube if one is present. The optimal dose is unknown, but typically, 2 to 2.5 times the intravenous dose is recommended. The dose should be diluted in 5 to 10 mL of sterile water or saline for tracheal tube administration.

The 2019 International Consensus on Cardiopulmonary Resuscitation guidelines for resuscitation include the strong recommendation that epinephrine continue to be used during CPR. For nonshockable rhythms, epinephrine should be administered as soon as possible. For shockable rhythms, epinephrine should be administered if ROSC is not achieved with initial defibrillation. The authors of the guidelines placed a great deal of credence in the potentially life-saving benefit of ROSC when epinephrine is administered during CPR. They acknowledge the downside of perhaps worse long-term neurologic outcomes and the cost to society of poor functional status. However, the latter should serve as a stimulus for studies to improve not just survivability but functional status as well.²⁴

Based on several studies, the most recent of which are several years old,⁴⁵ the guidelines continue to recommend against the administration of vasopressin for CPR protocols.²⁴

Amiodarone

Electric defibrillation is first-line treatment for ventricular fibrillation. Amiodarone is second-line pharmacologic treatment (after epinephrine) or in patients who have ventricular fibrillation refractory to electric defibrillation. Administered intravenously at a dose of 300 mg⁴⁶ or 5 mg/kg⁴⁷ amiodarone compared to lidocaine has been shown to be superior for ROSC in patients with ventricular fibrillation refractory to electric defibrillation. However, no study has yet demonstrated that long-term outcome in terms of morbidity or mortality is improved. However, the American Heart Association has recommended amiodarone to treat refractory ventricular fibrillation or pulseless ventricular tachycardia.⁴⁸

Following intravenous administration of amiodarone, it enters a central compartment, and from there, it undergoes extensive tissue redistribution. The distribution half-life of amiodarone out of the central compartment to these other tissues ($t_{1/2\alpha}$) may be as short as 4 hours. The terminal half-life ($t_{1/2\beta}$) is lengthy and also variable (9-77 days) because of prolonged release of amiodarone out of adipocytes due to the lipophilicity of the drug.^{49,50}

Hemodynamic effects of orally administered amiodarone are usually negligible; administered intravenously, there have been reports of hypotension, but the hypotension seen with intravenous amiodarone in the past was thought due to the vasoactive solvents (polysorbate and benzyl alcohol) in which it was compounded. When administered with a different diluent, rapid administration of amiodarone intravenously is not associated with hypotension.⁵¹ In terms of route administration, the intravenous administration of amiodarone may be preferable compared to the IO route. In one recent study of OHCA, survival to hospital admission was significantly better if either amiodarone or lidocaine was administered intravenously compared to IO, and more patients survived to hospital discharge when drugs were given IV compared to IO with slightly better neurologic outcome.⁵²

Effects of amiodarone on the thyroid gland and the liver are significant.^{53,54} The similarity between the chemical structures of amiodarone and thyroid hormone explain the former, and the latter is most likely due to direct injury to lipid bilayers of the hepatocyte cell membrane and inhibition of lysosomal function.⁵⁵ However, these adverse effects are seen in patients taking the drug in high doses for extended periods of time but not in patients who are administered one or two doses of the drug during sudden cardiac arrest.

Lidocaine may be considered as an alternative to amiodarone for ventricular fibrillation/pulseless ventricular tachycardia that is unresponsive to CPR and defibrillation.⁵⁶ A study published after the 2015 ACLS protocols were updated confirmed that neither lidocaine nor amiodarone significantly improved survival compared to placebo for OHCA, but there were subgroups of patients (eg, witnessed arrest) in whom outcomes were better if either drug was administered. Interestingly, patients who were administered amiodarone were more likely to require temporary pacing compared to those who received lidocaine or placebo.⁵⁷

Hemorrhage

The most critical intervention for someone who is bleeding is to stop the bleeding—either by applying a tourniquet to an extremity in the field or, if there is massive internal bleeding from a crush injury or ruptured aortic aneurysm, by transporting the patient as quickly as possible to a level I trauma hospital and from the emergency department to the operating room. The importance of surgical intervention as quickly as possible was underscored by Mattox and colleagues in a study of patients who were transported by emergency medical personnel and who were randomized to what at the time was conventional therapy of placing an intravenous cannula and initiating the infusion of crystalloid during transport to the hospital or to essentially no therapy, the “scoop and run” approach: emergency personnel evaluated the patient; treated the airway, breathing, and circulation; and then placed the patient in the ambulance with immediate transport back to the hospital. The latter group not only received less crystalloid but also had better survival than the conventionally treated group.⁵⁸

Other components of damage control resuscitation include maintaining normal temperature and pH, limiting intravenous crystalloid to maintain euvolemia, using a hemoglobin target of 7 to 8 g/dL to allow appropriate tissue oxygen delivery, and identifying patients at risk for developing acute traumatic coagulopathy. Multiple clinical studies have shown a benefit of a 1:1:1 ratio of packed red blood cells and the transfusion of platelets and fresh frozen plasma in severely injured and rapidly bleeding patients, as part of the damage control resuscitation. There are ongoing initiatives to determine if other practices can improve outcome in patients who sustain severe traumatic injury and develop acute coagulopathy of trauma.^{31,59} Prehospital administration of thawed plasma as the primary resuscitation fluid in one study demonstrated a lower 30-day mortality and lower median prothrombin time ratio than standard care resuscitation.⁶⁰ Of more importance though is the increasing use of whole blood in the prehospital⁶¹ and intrahospital⁶² management of trauma patients. In academic centers where whole blood is being transfused, either low titer O Rh-positive or O-negative blood is used simply because of the shortage of blood.⁶³

Tranexamic Acid

As with resuscitation from cardiac arrest, there is a limited role for drugs in improving outcome in patients who sustained traumatic injury with possibly one exception. In the CRASH-2 trial, such patients were randomized to a tranexamic acid group or control to examine the impact on death, vascular occlusive events, and transfusion requirement.⁶⁴ The group that was administered tranexamic acid early had a small but reduced risk of death (1.6% in all comers—a recent subgroup analysis suggested a 2.5% reduction) and was cost-effective, especially when given within an hour of admission. Beyond 3 hours, there appeared to be an increase in mortality. There has also been interest in using recombinant human factor VIIa and prothrombin complex concentrate in some trauma centers for coagulopathy, sometimes as salvage therapy. Further studies are necessary to determine the appropriate and effective utilization of these adjunct treatments.

Tranexamic acid, a synthetic analogue of the amino acid lysine (**Figure 47.3**), is an antifibrinolytic that has found widespread use following the removal of aprotinin from the market. By binding to specific sites on

plasminogen and plasmin, it inhibits the transformation of plasminogen to plasmin. Circulating plasmin degrades fibrin, an integral part of blood clots. Tranexamic acid's role in managing patients with traumatic injury has not yet been determined, but there are a number of level 1 trauma centers in the United States, that administer it routinely to their patients.

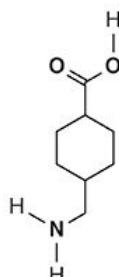

FIGURE 47.3 Molecular structure for tranexamic acid.

Oxygenation/Ventilation

As with patients with cardiac arrest in whom defibrillation in the first 3 minutes and CPR/defibrillation during the next 5 to 7 minutes achieves the best results, and as with patients with profound hemorrhage in whom immediate control of the bleeding and infusion of blood product has the biggest impact on outcome, for patients with pulmonary or respiratory arrest, immediate-assisted ventilation and oxygenation is the most likely intervention to increase the chances of survival. No drugs have been demonstrated in large prospective randomized trials to improve the chances of successful resuscitation. For pulmonary arrest, there are some exceptions (eg, for some causes of pulmonary arrest secondary to an opioid or less likely a benzodiazepine overdose), as the administration of naloxone for the former and flumazenil for the latter will antagonize the effects of the respective receptor's agonist, with an excessive dose (intentional, unintentional, or iatrogenic).

Likewise, for patients with cyanide toxicity and respiratory arrest at the cellular level, hydroxocobalamin is an antidote for cyanide toxicity that is effective with a high benefit-to-risk ratio and therefore safe in acute cyanide poisoning. Amyl nitrite and sodium nitrite are also effective because they promote the conversion of hemoglobin and cyanide ions to methemoglobin. Nitrites are not suitable for fire victims and those with poor cardiopulmonary reserve. Sodium thiosulfate is a sulfur donor; thiosulfate-cyanide transferase (rhodanese) converts cyanide ion to the less toxic thiocyanate.⁶⁵ These drugs are discussed elsewhere ([Chapter 20](#)).

heparin, 660–662, 661*f*
LMWHs, 662
maternal use of, 896*t*
oral, 664–668
direct factor Xa inhibitors, 665*t*, 666–667
direct thrombin inhibitors, 667
perioperative management of, 667–668
vitamin K antagonists, 664–666, 665*t*
platelet inhibitors, 668–670, 669*t*, 670*f*, 671*f*
thrombolytic drugs, 671
Anticonvulsants
benzodiazepines, 170, 170*f*
for bipolar disorders, 876
GABA agonists, 153
glutamate antagonists, 876
lithium and, 880*t*
nondepolarizing neuromuscular block and, 320
Antidepressants
adverse effects of, 855–858, 856*t*
glutamate antagonists, 876–877
MAO inhibitors, 861–864
serotonin and norepinephrine multimodal drugs, 860–861
serotonin multimodal drugs, 860
serotonin reuptake inhibitors, 855–860
serotonin syndrome, 219, 857–858, 858*t*
tricyclic antidepressants, 859–860, 864–867
Antidiuretic hormone, 53*t*, 369
Antiemesis
with antipsychotic drugs, 870–871
corticosteroids for, 787
GABA agonists, 153
with gastrointestinal prokinetics, 730
Antiepileptic drugs, 337–349, 339*t*
dosing of, 338, 339*t*
major, 339*t*–342*t*, 343–349
mechanism of action of, 338–342
pharmacokinetics of, 337–338, 342*t*
accelerated metabolism and, 338
protein binding and, 337–338
plasma concentrations of, 338
side effects of, 340*t*–341*t*, 343–349
status epilepticus, 349
Antiestrogens, 796, 796*f*, 829*t*, 834*t*, 847
Antifibrinolytic agents
aprotinin, 652

lysine analogs, 651–652
for massive transfusion coagulopathy, 680
Antihistamines, 719–727
airway and, 602
 H_1 -receptor antagonists, 719–722, 719*t*, 720*f*
 H_2 -receptor antagonists, 722–727, 722*f*, 723*t*–725*t*, 726*f*, 727*f*
for PONV, 709*t*, 712
Antihypertensive drugs, 501*t*
maternal use of, 895*t*
tricyclic antidepressants and, 866
Antiinflammatory effects
of cortisol, 761
of spinal anesthesia, 295–296
Antimetabolites, 829*t*, 831*t*–832*t*, 840–842
Antimicrobials
drug toxicity with, 811*t*–812*t*
in perioperative period, 814–821
selection of, 810–812
special patient groups for, 812–814
for surgical prophylaxis, 802–803, 803*t*–809*t*, 810*f*
Antineoplastic drugs. *See* Chemotherapeutic drugs
Antioxidant properties, of GABA agonists, 157–158
Antiplatelet drugs, maternal use of, 896*t*
Antiprogestins, 796, 797*f*
Antipruritic, GABA agonists, 153
Antipsychotic drugs
dopamine antagonists as, 869–873
drug interactions with, 873
levodopa and, 351
mechanism of action of, 869
metabolism of, 870
pharmacokinetics of, 870
side effects of, 871–873
Antiseptic prophylaxis, 821–824
Antithrombin, 632
Antitumor antibiotics, 829*t*, 833*t*, 842–845
Anxiolytics, 150
Aorta, 376*t*
Aortic insufficiency, 402, 403*f*
Aortic stenosis, 401–402
Aortocaval compression, maternal, 906
Apnea, with spinal anesthesia, 295
aPTT. *See* Activated partial thromboplastin time

Topical hemostatic agents, 656
Topoisomerase inhibitors, 829*t*, 832*t*–833*t*, 842–845, 843*f*, 844*f*, 845*t*
Torsades de pointes, 56, 521, 937
Total anesthetics, 115
opioids for, 234
Total body oxygen requirements, inhaled anesthetics and, 139
Total parenteral nutrition (TPN), 734
monitoring during, 738–739
preparations of solutions for, 739
side effects of, 737–738, 738*t*
Toxicity
of antimicrobials, 811*t*–812*t*
of antipsychotics, 873
of cannabinoids, 881
of cardiac glycosides, 463–464
of lidocaine, 266*f*
of lithium, 880, 880*t*
of methylxanthines, 355
of nitric oxide, 508
of nitrodilators, 510–511
of statins, 548, 548*t*
Trachea, structure of, 556–557, 557*f*, 558*f*, 559*f*
Train-of-four (TOF) stimulation, 316–317, 324, 324*f*, 331*f*
Transcortin, 761
Transdermal administration, 25
Transfusion-associated circulatory overload (TACO), 645–646, 646*t*
Transfusion-related acute inflammatory responses, 648
Transfusion-related acute lung injury (TRALI), 646–648, 646*f*, 647*t*
Transfusion therapy, 637
adverse effects of, 645–648, 646*f*, 646*t*, 647*t*
Transient neurologic symptoms (TNS), with local anesthetics, 286
Traube-Hering waves, 371
Trauma
endothelial dysfunction and, 675
hemostatic abnormalities with, 675
Trauma-induced coagulopathy, 674
Triangle of Koch, 391
Triazenes, 831*t*
Tricyclic antidepressants, 46, 856*t*, 859–860, 864–867
and autonomic nervous system, 80*t*
drug interactions with, 866
mechanism of action of, 864

overdose of, 866–867
pharmacokinetics of, 865–866
side effects of, 864–865, 864*t*
tolerance to, 865
Tricyclic serotonin reuptake inhibitors, 859–860
Triglycerides, 687, 700*f*, 701, 702, 702*t*
Triiodothyronine (T₃), 758–759, 758*f*, 779–782, 780*f*, 780*t*
TSH. *See* Thyroid-stimulating hormone
Tube feeding, 736
Tubular transport maximum (Tm), 418–419, 418*f*
Tubulin-binding drugs, 829*t*, 845–846
Tumescent liposuction, 297
T wave, 395
Two-pore potassium channels, inhaled anesthetics and, 114–115
TZDs. *See* Thiazolidinediones

U

Ulcerative colitis, 788
Unconsciousness, mechanisms of anesthesia-induced, by inhaled anesthetics, 115–116
Upper airway
in elderly patients, 927
gas flow of, 556, 556*f*
larynx, 553–555, 554*f*
oropharynx and nasopharynx, 553, 554*f*
pharyngeal innervation, 555–556
Urea, plasma concentration of, 423
Urinary retention, with neuraxial opioids, 236
Urine, transport to bladder, 419
Urodilatin, 421
Uterine smooth muscle, 313
Uteroplacental physiology, 910–911, 910*f*
oxygen transfer, 911, 911*f*
uterine blood flow, 911
U wave, 395

V

Vaccines, as chemotherapeutic drugs, 835*t*, 849
Valerian, 749*t*, 750
Valvular heart disease
aortic insufficiency, 402, 403*f*
aortic stenosis, 401–402
mitral regurgitation, 403, 404*f*
mitral stenosis, 402–403
Vanillylmandelic acid (VMA), 82
Vaporizers, 96
Vaptans. *See* Vasopressin receptor antagonists
Varicose veins, 366
Vasa recta, 419
Vascular compliance, 367

Vascular distensibility, 367
Vascular tone, endothelial function in, 359
Vasoactive intestinal peptide (VIP), 53*t*, 595
Vasoconstriction, 367
causes of, 84, 86, 91
cutaneous, 89
hypoxic pulmonary, 383–384, 384*f*, 579–580, 579*f*, 606–607
intraoperative, 90
reflex, 87, 90
Vasoconstrictors, with local anesthetics, 281, 281*f*
Vasodilators
nitric oxide and nitrovasodilators, 507–512, 508*f*
pulmonary, 604
sympatholytics for, 501–507, 501*t*, 503*f*
systemic hypertension, 500–501, 501*t*
Vasomotion, 377
Vasomotor center, 368
Vasomotor waves, 371
Vasopressin. *See* Antidiuretic hormone
Vasopressin receptor antagonists, 536*f*, 537*t*, 542–543
Vasopressors, pulmonary circulation and, 604
Veins, 360, 376*t*
Vena cava, 376*t*
Venoconstriction, 367
Venous circulation, 364–375
Venous return, regulation of, 371–375
Venous thromboembolism (VTE)
aging and, 927–928
prophylaxis against, 662
Venous valves, 365–366
Ventilation distribution, 574
perfusion matching with, 575, 576*f*, 577*f*, 578
Ventilation effects
of barbiturates, 175
of benzodiazepines, 166, 169, 169*f*
of GABA agonists, 160
of inhaled anesthetics, 127–130, 127*f*–131*f*, 128*t*
of neuraxial opioids, 236–237, 237*f*
of non- γ -aminobutyric acid sedative-hypnotics, 182
of opioids, 210–211, 226
Ventilatory depressant effects, of inhaled anesthetics, 129
Ventilatory response
to hydrogen ion concentration, 619–620
to hypoxia, local anesthetics and, 287
Ventilatory support, extracorporeal, 591
Ventricular fibrillation, 411, 411*f*
Ventricular function curves, 372–373, 372*f*
Ventricular tachycardia, 411, 411*f*
incessant, 521
Venules, 360, 375–376, 376*f*, 376*t*
Vessel-rich group tissues, 16

inhaled anesthetics and, 107
Vessels, of elderly patients, 923
VGSCs. *See* Voltage-gated sodium channels
Vinca alkaloids, 833*t*, 845–846
Vinyl halide nephrotoxicity, with inhaled anesthetics, 136, 136*f*
VIP. *See* Vasoactive intestinal peptide
Viral reactivation, neuraxial opioids and, 237
Visceral pain, 202, 203*f*
Vision, 72–74
field of, 73
Horner syndrome, 74
intraocular pressure, 72
lens, 72, 72*f*
pupil, 72, 72*f*
retina, 72–73, 72*f*
visual pathway, 73, 73*f*
Visual cortex, 60
Visual evoked potentials, 70
Vitamin A (retinol, retinoic acid), 740*t*, 745–746, 745*f*
Vitamin B₁ (thiamine), 739–741, 740*t*, 741*f*
Vitamin B₂ (riboflavin), 740*t*, 741–742, 741*f*
Vitamin B₃ (nicotinic acid, niacin), 740*t*, 741*f*, 742
Vitamin B₆ (pyridoxine), 740*t*, 741*f*, 742
Vitamin B₁₂ (cyanocobalamin, cobalamin), 740*t*, 741*f*, 743
Vitamin C (ascorbic acid), 740*t*, 741*f*, 744–745
Vitamin D (calciferol), 740*t*, 745*f*, 746–747
Vitamin E (α -tocopherol), 740*t*, 745*f*, 747
Vitamin K, 740*t*, 745*f*, 747–748
Vitamin K antagonists, 664–666, 665*t*
Vitamins, 739–748
fat-soluble, 740*t*, 745–748, 745*f*
water-soluble, 739–745, 740*t*, 741*f*
VMA. *See* Vanillylmandelic acid
Volatile anesthetics
airway and, 600–601, 600*t*
pulmonary circulation and, 603
Voltage-gated calcium channels, 53*f*, 59, 59*f*
neuronal, 250
Voltage-gated ion channels, 55–57
inhaled anesthetics and, 114
Voltage-gated sodium channels (VGSCs)
blocking of, 264, 266*f*
inhaled anesthetics and, 115
local anesthetics and, 273–274, 276*f*
non- γ -aminobutyric acid sedative-hypnotics and, 177
Vomiting, 75–76, 75*f*, 693. *See also* Postoperative nausea and vomiting (PONV)
opioids and, 212–213
with PCA, 250
von Willebrand factor, 644–645
VTE. *See* Venous thromboembolism

W

- Water-soluble vitamins, 739–745, 740*t*, 741*f*
- α waves, 68, 68*f*
- β waves, 68, 68*f*
- δ waves, 68–69, 68*f*
- θ waves, 68, 68*f*
- White matter, 64
- Whole blood viscoelastic tests, 633
- Wide complex ventricular rhythm, 521
- Withdrawal
 - of β-adrenergic receptor antagonists, 483
 - from opioids, 214, 214*t*, 229
- Work of breathing, 573–574

Z

- Zero-order processes, 25–26, 26*f*
- Zinc, in intravenous fluids, 447
- Zona fasciculata, 759
- Zona glomerulosa, 759
- Zona reticularis, 759
- Zymogens, 627
