This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on health care professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Health care professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made, and health care professionals should consult a variety of sources. When prescribing medication, health care professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

My coauthors and I dedicate this sixth edition of *Stoelting's Pharmacology & Physiology in Anesthetic Practice* to our dear colleague, coauthor, and friend, Dr. Mohamed A. Naguib, who passed away in 2020 at the age of 68 years.

Mohamed was a clinical anesthesiologist, a National Institutes of Health–funded basic scientist, and an entrepreneur who founded a company to develop new therapies for neuropathic pain based on his research. He was the mentor of record to many, including some of his coauthors in this edition. He was an unofficial mentor to countless others, including nearly the entire community of clinical pharmacologists in anesthesia.

You have likely read at least some of his more than 400 scientific papers and many books and book chapters. Mohamed's seven (!) chapters in the sixth edition of *Stoelting's Pharmacology & Physiology in Anesthetic Practice* reflect his academic rigor and clear writing. They also reflect his dedication to teaching; Mohamed was the first author to complete his chapters for this edition. His chapters in this edition reflect his academic breadth, ranging from analgesic pharmacology to neuromuscular physiology.

Those of you who were fortunate to know Mohamed will miss his enthusiasm for science, ready smile, and dry wit. I fondly recall discussing his elegant study of the mechanism that underlies anesthetic-induced cognitive dysfunction in neonatal rats. This is among my favorite papers in the anesthesiology literature. Mohamed demonstrated that the neurologic deficit in development induced by anesthesia in neonatal rats could be reversed with an enriched environment.

Sitting at a back table at a meeting on anesthetic mechanisms, Mohamed described how he created an enriched environment for a rat. How did he know what a baby rat would find entertaining? He leveraged his experience as a parent, creating a playroom for his baby rats. He placed a “play group” of six baby rats in a large space (preschool) and filled it with toys including running wheels and fun stuff for the rats to explore. Our discussion broke down into laughter about his baby rat playroom, with both of us concluding it might be more fun than the meeting we were attending. We were laughing so hard that we disrupted the speaker!

Oops . . .

That was the last time I saw Mohamed.

Mohamed's scholarship, intellectual rigor, and ability to clearly explain complex concepts are fully evident in this edition of *Stoelting's Pharmacology & Physiology in Anesthetic Practice*. We will miss this amazing clinician, scientist, teacher, and friend.

†Deceased.

My journey with *Pharmacology and Physiology in Anesthetic Practice* began in the early 1980s with what seemed an impossible dream, a single-author anesthesia textbook devoted to the *daily application of principles of pharmacology and physiology in the care of patients*. Many yellow tablets later (my computer skills were in their infancy); an understanding family, residents, and faculty in the Department of Anesthesia at Indiana University School of Medicine; and the unwavering support and encouragement of a special friend and publisher, the first edition of *Pharmacology and Physiology in Anesthetic Practice* appeared in the fall of 1986.

The acceptance of the textbook by students, trainees, and practitioners over the years has been incredibly rewarding to me personally and served as the stimulus to create revisions for the next three editions with Simon C. Hillier, MB, ChB, joining me as a coeditor for the fourth edition that appeared in 2006.

It is clearly time for a new edition and a new approach if *Pharmacology and Physiology in Anesthetic Practice* is going to continue to meet its original goal of *providing an in-depth but concise and current presentation of those aspects of pharmacology and physiology that are relevant either directly or indirectly to the perioperative anesthetic management of patients*.

In this regard, I could not be more pleased and honored that Drs. Pamela Flood, James P. Rathmell, and Richard D. Urman agreed to act as coeditors of this multi-authored sixth edition. Their unique expertise and access to recognized authorities in the wide and expanding areas of pharmacology and physiology that impact the perioperative care of patients is clearly evident in this edition.

On behalf of myself and all our past (and future) readers, I thank the new coeditors and their authors for keeping *Stoelting's Pharmacology & Physiology in Anesthetic Practice* current with the times and fulfilling the dream I had more than 30 years ago.

Robert K. Stoelting, MD

Robert Stoelting is among the best writers in our specialty. His signature textbook, *Pharmacology and Physiology in Anesthetic Practice*, resonated with residents and faculty, including us, because it was exceptionally well written. It has been the “go-to” reference since its first edition in 1986. Dr. Stoelting’s clear prose succinctly covered the drugs we were using in our daily practice. His explanations of physiology were intuitive and sensible. Every chapter in the earlier editions spoke with the same voice, reflecting the many years he invested in refining his single-authored textbook. Even though Dr. Hillier joined him as coauthor of the fourth edition, the text continued to resonate as a single voice.

When first approached about revising the textbook for the fifth edition, we turned down the project. It seemed impossible to reproduce the clarity of Dr. Stoelting’s work. However, the option for the publisher was to transform *Pharmacology and Physiology in Anesthetic Practice* into a conventional multi-authored textbook. Although it felt a bit like sacrilege to reduce one of the revered texts in our specialty to a “me too” multi-authored textbook, we agreed to take on the task.

The hybrid model developed for the fifth edition was undertaken by a small number of senior authors who were tasked with updating this classic text in their areas of expertise. This undertaking was daunting, but the model worked. We have maintained this structure for the sixth edition along with most of our authors.

We are proud to bring the sixth edition of *Stoelting’s Pharmacology & Physiology in Anesthetic Practice* to anesthesiology residents, clinicians, and investigators. We have tried to maintain the succinct elegance of Dr. Stoelting’s writing updated with the latest state-of-the-art knowledge and methods in anesthetic pharmacology and physiology.

Is everything in this book correct? No. The authors of each chapter have imperfect understanding; knowledge changes, and mistakes happen. Wikipedia brilliantly addresses this by allowing readers who catch errors to fix them. We can’t implement the “Wikipedia approach” in a textbook, but we can come close by inviting you, the reader compulsive enough to read the Preface, to bring any errors, corrections, or suggestions to our attention. We invite our readers to become “peer reviewers,” pointing us toward new information that should be included, out-of-date references, drugs no longer used, or missing content relevant to pharmacology and physiology in anesthesia practice. In this manner, readers will become collaborators for all future editions.

Finally, we have to acknowledge the efforts of our publishers, including Keith Donnellan, Ashley Fischer, Anthony Gonzalez, Tim Rinehart, and Harold Medina. No textbook comes to fruition without careful guidance, attention to detail, and occasional cajoling. In this case, they went full force on all three of us to maintain the gem that Bob Stoelting created.

PART I Basic Principles of Physiology and Pharmacology

Basic Principles of Physiology

Pamela Flood • Lisa Wise-Faberowski • Steven L. Shafer

This chapter reviews the basic principles of the composition of the body, and the structure of cells. Although very basic, these principles are essential for everything that follows.

Body Composition

Water is the medium in which all metabolic reactions occur. Water accounts for about 60% of the weight in an adult man and about 50% of the body weight in an adult woman ([Figure 1.1](#)).¹ In a neonate, total body water may represent 70% of body weight. Total body water is less in women and obese individuals, reflecting the decreased water content of adipose tissue. Advanced age is also associated with increased fat content and decreased total body water ([Table 1.1](#)). Body fluids can be divided into intracellular and extracellular fluid depending on their location relative to the cell membrane (see [Figure 1.1](#)).¹ Approximately two-thirds of the total body fluid in an adult are contained inside the estimated 100 trillion cells of the body. The fluid in these cells, despite individual differences in constituents, is collectively designated *intracellular fluid*. *Extracellular fluid*, one-third of fluid outside the cells, is divided into interstitial fluid and plasma (intravascular fluid) by the capillary membrane (see [Figure 1.1](#)).¹

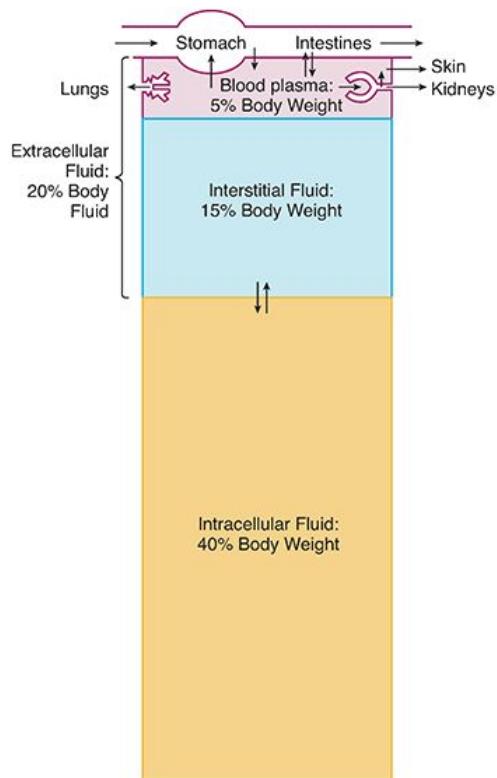

FIGURE 1.1 Body fluid compartments and the percentage of body weight represented by each compartment. The location relative to the capillary membrane divides extracellular fluid into plasma or interstitial fluid. Arrows represent fluid movement between compartments. *Reprinted with permission from Gamble JL. Chemical Anatomy, Physiology, and Pathology of Extracellular Fluid: A Lecture Syllabus. 6th*

ed. Cambridge, MA: Harvard University Press; 1954:9. Copyright © 1954 by the President and Fellows of Harvard College.

TABLE 1.1

Total body water by age and gender

Age (y)	Total body water	
	Men (%)	Women (%)
18-40	61	51
41-60	55	47
>60	52	46

Interstitial fluid is present in the spaces between cells. An estimated 99% of this fluid is held in the gel structure of the interstitial space. Plasma is the noncellular portion of blood. The average plasma volume is 3 L, a little over half of the blood volume of 5 L. Plasma is in dynamic equilibrium with the interstitial fluid through pores in the capillaries, the interstitial fluid serving as a reservoir from which water and electrolytes can be mobilized into the circulation. Loss of plasma volume from the intravascular space is minimized by colloid osmotic pressure exerted by the plasma proteins.

Other extracellular fluid that may be considered as part of the interstitial fluid includes cerebrospinal fluid, gastrointestinal fluid (because it is mostly resorbed), and fluid in potential spaces (pleural space, pericardial space, peritoneal cavity, synovial cavities). Excess amounts of fluid in the interstitial space manifest as peripheral edema.

The normal daily intake of water (drink and internal product of food metabolism) by an adult averages 2.5 L, of which about 1.5 L is excreted as urine, 100 mL is lost in sweat, and 100 mL is present in feces. Insensible water losses occur with respiration and diffusion through the skin. Inhaled air, saturated with water vapor (47 mm Hg at 37°C), is subsequently exhaled, accounting for an average daily water loss through the lungs of 300 to 400 mL. The water content of inhaled air decreases with decreases in ambient air temperature such that more endogenous water is required to achieve a saturated water vapor pressure at body temperature. As a result, insensible water loss from the lungs is greatest in cold environments and least in warm temperatures. The remaining 400 mL of insensible losses is by diffusion through the skin and is not perceived as sweat. Insensible water loss is limited by the mostly impermeable cornified layer of the skin. When the cornified layer is removed or interrupted, as after burn injury, the loss of water through the skin is greatly increased.

Blood Volume

Blood contains extracellular fluid, the plasma, and intracellular fluid, mostly held in erythrocytes. The body has multiple systems to maintain intravascular fluid volume, including renin-angiotensin system, and arginine vasopressin (antidiuretic hormone), that increase fluid resorption in the kidney and evoke changes in the renal tubules that lead to restoration of intravascular fluid volume (see [Chapter 16](#)).

The average blood volume of an adult is 5 L, compromising about 3 L of plasma and 2 L of erythrocytes. These volumes vary with age, weight, and gender. For example, in nonobese individuals, the blood volume varies in direct proportion to the body weight, averaging 70 mL/kg for lean men and women. The greater the ratio of fat to body weight, however, the less is the blood volume in milliliter per kilogram because adipose tissue has a decreased vascular supply. The hematocrit or packed cell volume is approximately the erythrocyte fraction blood. The normal hematocrit is about 45% for men and postmenopausal women and about 38% for menstruating women, with a range of approximately ±5%.

Constituents of Body Fluid Compartments

The constituents of intracellular and extracellular fluid are identical, but the quantity of each substance varies among the compartments ([Figure 1.2](#)).² The most striking differences are the low protein content in interstitial fluid compared with intracellular fluid and plasma and the fact that sodium and chloride ions are

largely extracellular, whereas most of the potassium ions (approximately 90%) are intracellular. This unequal distribution of ions results in establishment of a potential (voltage) difference across cell membranes.

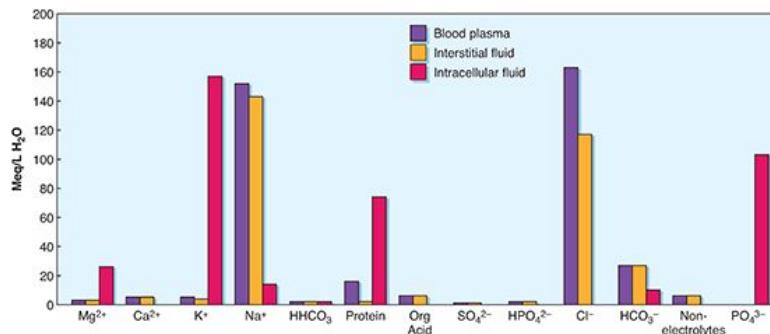

FIGURE 1.2 Electrolyte composition of body fluid compartments.

The constituents of extracellular fluid are carefully regulated by the kidneys so that cells are bathed in an osmotically neutral fluid containing the proper concentrations of electrolytes and nutrients. The normal amount of sodium and potassium in the body is about 58 mEq/kg and 45 mEq/kg, respectively. Trauma is associated with progressive loss of potassium through the kidneys. For example, a patient undergoing surgery excretes about 100 mEq of potassium in the first 48 hours postoperatively and, after this period, about 25 mEq daily. Plasma potassium concentrations are not good indicators of total body potassium content because most potassium is intracellular. There is a correlation, however, between the potassium and hydrogen ion content of plasma, the two increasing and decreasing together. In metabolic acidosis, there is net efflux of potassium out of the cells to compensate for the hydrogen ion influx and preserve the resting potential. As metabolic acidosis is treated, the plasma potassium will fall from that measured in the acidotic state.

Osmosis

Osmosis is the movement of water (solvent molecules) across a semipermeable membrane from a compartment in which the nondiffusible solute (ion) concentration is lower to a compartment in which the solute concentration is higher ([Figure 1.3](#)).³ The lipid bilayer that surrounds all cells is freely permeable to water but is impermeable to ions. As a result, water rapidly moves across the cell membrane to establish osmotic equilibration, which happens almost instantly.

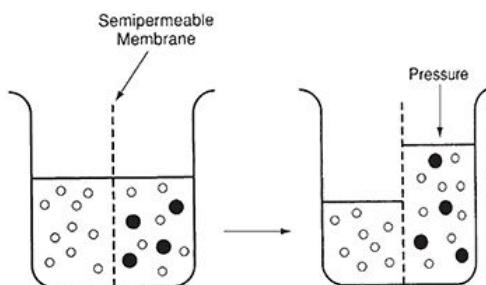

FIGURE 1.3 Diagrammatic representation of osmosis depicting water molecules (open circles) and solute molecules (solid circles) separated by a semipermeable membrane. Water molecules move across the semipermeable membrane to the area of higher concentration of solute molecules. Osmotic pressure is the pressure that would have to be applied to prevent continued movement of water molecules. *Republished with permission of McGraw Hill LLC from Ganong WF. Review of Medical Physiology. 21st ed. New York, NY: Lange Medical Books/McGraw-Hill; 2003; permission conveyed through Copyright Clearance Center, Inc.*

Cells control their size by controlling intracellular osmotic pressure. The maintenance of a normal cell volume and pressure depends on sodium-potassium adenosine triphosphatase (ATPase) (sodium-potassium exchange pump), which maintains the intracellular-extracellular ionic balance by removing three sodium ions

from the cell for every two potassium ions brought into the cell. The sodium-potassium pump also maintains the transmembrane electrical potential and the sodium and potassium concentration gradients that power many cellular processes, including neuronal conduction.

The osmotic pressure exerted by nondiffusible particles in a solution is determined by the number of particles in the solution (with each ion counting as 1 unit) and not the type of particles (molecular weight) (see [Figure 1.3](#)).³ Thus, a 1-mol solution of glucose or albumin and 0.5-mol solution of sodium chloride exert the same osmotic pressure because the sodium chloride exists as independent sodium and chloride ions, each having a concentration of 0.5 mol.

Osmole is the unit used to express osmotic pressure in solutes, but the denominator for osmolality is kilogram of water. *Osmolarity* is the correct terminology when osmole concentrations are expressed in liters of body fluid (eg, plasma) rather than kilograms of water. Because it is much easier to express body fluids in liters of fluid rather than kilograms of free water, almost all physiology calculations are based on osmolarity. Plasma osmolarity is important in evaluating dehydration, overhydration, and electrolyte abnormalities.

Normal plasma has an osmolarity of about 290 mOsm/L. All but about 20 mOsm of the 290 mOsm in each liter of plasma are contributed by sodium ions and their accompanying anions, principally chloride and bicarbonate. Proteins normally contribute <1 mOsm/L. The major nonelectrolytes of plasma are glucose and urea, and these substances can contribute significantly to plasma osmolarity when hyperglycemia or uremia is present, as suggested by the standard calculation of plasma osmolarity:

$$\text{Plasma osmolarity} = 2 (\text{Na}^+) + 0.055 (\text{glucose}) + 0.36 (\text{blood urea nitrogen}).$$

Tonicity of Fluids

Packed erythrocytes must be suspended in **isotonic** solutions to avoid damaging the cells ([Figure 1.4](#)).⁴ A 0.9% solution of sodium chloride is isotonic and remains so because there is no net movement of the osmotically active particles in the solution into cells, and the particles are not metabolized. A solution of 5% glucose in water is initially isotonic when infused, but glucose is metabolized, so the net effect is that of infusing a hypotonic solution. Lactated Ringer solution plus 5% glucose is initially hypertonic (about 560 mOsm/L), but as glucose is metabolized, the solution becomes less hypertonic.

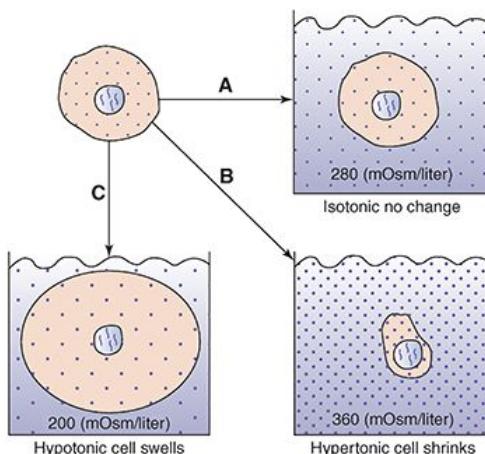

FIGURE 1.4 Effects of isotonic (A), hypertonic (B), and hypotonic (C) solutions on cell volume. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Fluid Management

The goal of fluid management is to maintain normovolemia characterized by hemodynamic stability. Crystalloids consist of water, electrolytes, and occasionally glucose that freely distribute along a concentration gradient between the two extracellular spaces. After 20 to 30 minutes, an estimated 75% to

80% of an isotonic saline or a lactate-containing solution will have distributed outside the confines of the circulation, thus limiting the efficacy of these solutions in treating hypovolemia. The major goal of fluid resuscitation is to maintain microcirculatory perfusion to preserve the delivery of oxygen and glucose to the tissues. Measurement of systemic blood pressure or central venous pressure does not provide an accurate picture of specific organ micro perfusion. Indeed, microperfusion of individual organs is tightly regulated in most situations to prioritize tissue perfusion to the brain with other organs delegated to secondary status. A variety of techniques have been developed to measure microcirculation, the most common being sublingual with handheld microscopy.⁵

Hypotonic intravenous fluids equilibrate with extracellular fluid, causing it to become hypotonic with respect to intracellular fluid. When this occurs, osmosis rapidly increases intracellular water, causing cellular swelling. Increased intracellular fluid volume is particularly undesirable in patients with increased intracranial pressure or an intracranial mass. Protection from excessive fluid accumulation in the interstitial compartment is mediated by lymphatic flow, which can increase as much as tenfold but can be overwhelmed. The lymphatic system can be obstructed by surgery as after extensive axillary resection for breast cancer and tumor invasion causing distal tissue edema.

Hypertonic saline solutions (7.5% sodium chloride) have been useful for rapid intravascular fluid repletion during resuscitation as during hemorrhagic and septic shock. Hypertonic saline solutions compare favorably with mannitol for lowering intracranial pressure.⁶ The primary effect of hypertonic saline solutions (increase systemic blood pressure and decrease intracranial pressure) most likely reflects increased intravascular fluid volume because of fluid shifts and movement of water away from uninjured region of the brain. In a secondary analysis of the data from the Resuscitation Outcomes Consortium Hypertonic Saline Trial Shock Study and Traumatic Brain Injury Study, the effect of hypertonic saline alone was compared with that of hypertonic saline plus mannitol on renal function after acute brain injury.⁷ The combination was not superior to treatment with hypertonic saline alone. The use of hypertonic saline solutions is viewed as short-term treatment as hypertonicity and hypernatremia are likely with sustained administration.

Albumin should remain within the intracellular space longer than crystalloids in the setting of an intact vascular endothelial and blood-brain barrier. However, the vascular endothelium is commonly damaged by trauma, hyperglycemia, and sepsis, obviating this advantage.⁸ While the administration of albumin makes sense, no randomized controlled trial has demonstrated long-term benefit over other solutions except perhaps in septic shock.⁹

Dehydration

Loss of water by gastrointestinal or renal routes or by diaphoresis is associated with an initial deficit in extracellular fluid volume. Intracellular water partly repletes this loss through osmosis, keeping the osmolarities in both compartments equal despite decreased absolute volume (dehydration) of both compartments. The ratio of extracellular fluid to intracellular fluid is greater in infants than adults, but the absolute volume of extracellular fluid is obviously less in infants. This is why dehydration develops more rapidly and is often more severe in the very young. Clinical signs of dehydration are likely when about 5% to 10% (severe dehydration) of total body water has been lost in a brief period of time. Physiologic mechanisms can usually compensate for acute loss of 15% to 25% of the intravascular fluid volume, whereas a greater loss places the patient at risk for hemodynamic decompensation.

Cell Structure and Function

The basic living unit of the body is the cell. It is estimated that the entire body consists of 38 trillion cells, 85% of which are (amazingly) erythrocytes. We cohabit our bodies with an approximately equal number of bacterial cells, which fortunately only contribute about 0.2 kg to our total mass.¹⁰ Each organ is a mass of cells held together by intracellular supporting structures.

All mammalian cells literally burn nutrients (ie, carbohydrates, lipids, proteins) using intracellular oxygen to release energy necessary for cellular function. Almost every cell is within 25 to 50 microns of a capillary, assuring prompt diffusion of oxygen to cells. All cells exist in nearly the same composition of

extracellular fluid. Our organs (lungs, kidneys, gastrointestinal tract) function to maintain a constant composition (homeostasis) of extracellular fluid.

Cell Anatomy

The principal components of cells include the nucleus (except for mature red blood cells) and the cytoplasm, which contains structures known as *organelles* (Figure 1.5).¹¹ The nucleus is separated from the cytoplasm by the nuclear membrane, and the cytoplasm is separated from surrounding fluids by a cell membrane. Organelles are also enclosed by membranes. All cellular membranes are lipid bilayers.

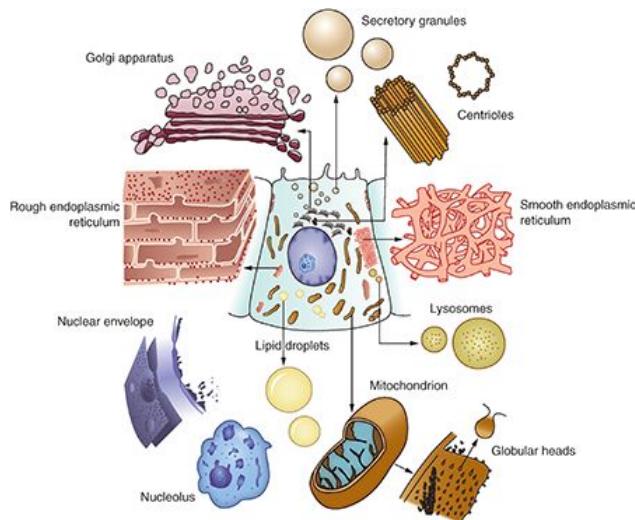

FIGURE 1.5 Schematic diagram of a hypothetical cell (center) and its organelles. Republished with permission of McGraw Hill LLC from Junqueira LC, Carneiro J, Kelley RO. Basic Histology. 7th ed. Norwalk, CT: Appleton & Lange, 1992; permission conveyed through Copyright Clearance Center, Inc.

Cell Membrane

The lipid bilayer acts as a permeability barrier, allowing the cell to maintain a cytoplasmic composition different from extracellular fluid. Proteins and phospholipids are the most abundant constituents of cell membranes (Table 1.2). The lipid bilayer is interspersed with large globular proteins (Figure 1.6).¹² Lipid bilayers are readily permeable to water, both through passive diffusion and through aquaporins, specialized proteins in the membrane that function as water channels described in the following text. Lipid bilayers are nearly impermeable to water-soluble substances, such as ions and glucose. Ions and charged water-soluble molecules require specialized channel and transport pumps to enter the intracellular environments. Conversely, fat-soluble substances (eg, steroids) and gases readily cross hydrophobic cell membranes.

Abbreviation: ATPase, adenosine triphosphatase.

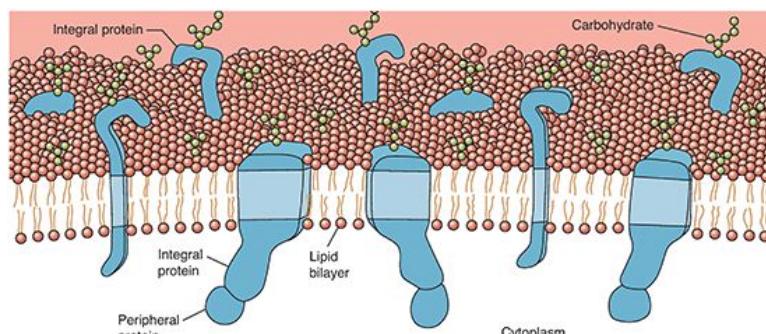

FIGURE 1.6 The cell membrane is a two molecule-thick lipid bilayer containing protein molecules that extend through the bilayer.

There are several types of proteins in the cell membrane (see [Table 1.2](#)). In addition to structural proteins (microtubules), there are transport proteins (eg, sodium-potassium ATPase) that function as pumps, actively transporting ions across cell membranes. Other proteins function as passive channels for ions that can be opened or closed by changes in the conformation of the protein. There are proteins that function as receptors to bind ligands (hormones or neurotransmitters), thus initiating physiologic changes inside cells. Another group of proteins function as enzymes (adenylate cyclase), catalyzing reactions at the surface of cell membranes. The protein structure of cell membranes, especially the enzyme content, varies from cell to cell.

Transfer of Molecules Through Cell Membranes

Diffusion

Oxygen, carbon dioxide, and nitrogen move through cell membranes by diffusion through the lipid bilayer. Because diffusion is relatively slow over macroscopic distances, organisms have developed circulatory systems to deliver nutrients within reasonable diffusion ranges of cells ([Table 1.3](#)). Water is also able to diffuse through cells as described earlier, although not as freely as the gases.

TABLE 1.3
Predicted relationship between diffusion distance and time

Diffusion distance (mm)	Time required for diffusion
0.001	0.5 ms
0.01	50 ms
0.1	5 s
1	498 s
10	14 h

Poorly lipid-soluble substances, such as glucose and amino acids, may pass through lipid bilayers by facilitated diffusion. For example, glucose combines with a carrier to form a complex that is lipid soluble. This lipid-soluble complex can diffuse to the interior of the cell membrane where glucose is released into the cytoplasm. The carrier then moves back to the exterior of the cell membrane, where it becomes available to transport more glucose from the extracellular fluid ([Figure 1.7](#)).⁴ As such, the carrier renders glucose soluble in cell membranes that otherwise would prevent its passage. Insulin greatly speeds facilitated diffusion of glucose and some amino acids across cell membranes.

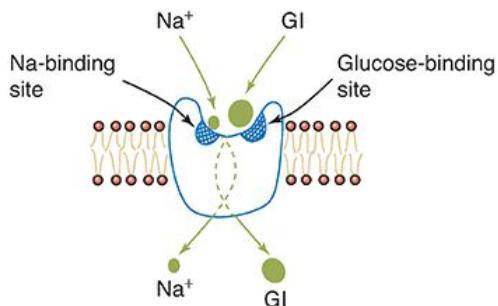

FIGURE 1.7 Glucose (Gl) can combine with a sodium (Na) cotransport carrier system at the outside surface of the cell membrane to facilitate diffusion (carrier-mediated diffusion) of Gl across the cell membrane. At the inside surface of the cell membrane, Gl is released to the interior of the cell and the carrier again becomes available for reuse. *Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.*

Endocytosis and Exocytosis

Endocytosis and exocytosis transfer molecules such as nutrients across cell membranes without the molecule actually passing through a cell membranes. The uptake of particulate matter (bacteria, damaged cells) by cells is phagocytosis, whereas uptake of materials in solution in the extracellular fluid is pinocytosis ([Figure 1.8](#)).¹³ The process of phagocytosis is initiated when antibodies attach to damaged tissue and foreign substances (opsonization), facilitating binding to specialized proteins on the cell surface. Fusion of phagocytic or pinocytic vesicles with lysosomes allows intracellular digestion of materials to proceed. Neurotransmitters are ejected from cells by exocytosis from specialized presynaptic vesicles activated by an action potential. This process requires calcium ions and resembles endocytosis in reverse.

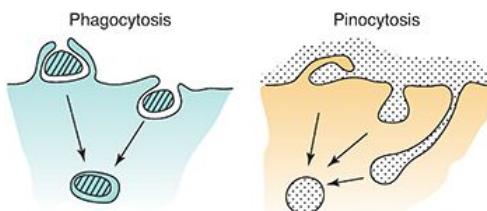

FIGURE 1.8 Schematic depiction of phagocytosis (ingestion of solid particles) and pinocytosis (ingestion of dissolved particles). *From Berne RM, Levy MN, Koeppen BM, et al. Physiology. 5th ed. St Louis, MO: Mosby; 2004. Reprinted with permission from Bruce M. Koeppen, MD.*

Sodium-Potassium Adenosine Triphosphatase

As mentioned previously, sodium-potassium ATPase, also known as the sodium-potassium pump, is an adenosine triphosphate (ATP)-dependent sodium and potassium transporter on the cell membrane that ejects three sodium ions from the cell in exchange for the import of two potassium ions ([Figure 1.9](#)).⁴ This action maintains oncotic equilibration across the cell membrane, reducing the number of intracellular ions to balance the large number of protein and other intracellular constituents. It also is responsible for creating the transmembrane electrical potential, creating a net positive charge on the outside of the cell from the excess of positive sodium ions outside compared to number of positive potassium ions inside of the cell. Lastly, it creates the sodium gradients responsible for propagation of the action potential and the potassium gradient that rapidly restores the resting membrane potential after conduction of an action potential. In the brain, the sodium-potassium pump accounts for nearly 50% of energy consumption.¹⁴

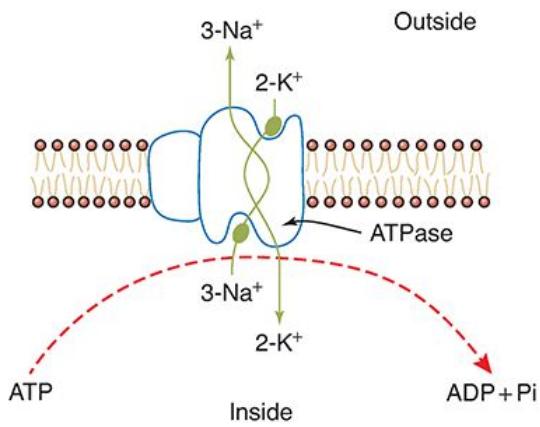

FIGURE 1.9 Sodium (Na)-potassium (K) adenosine triphosphatase (ATPase) is an enzyme present in all cells that catalyzes the conversion of adenosine triphosphate (ATP) to adenosine diphosphate (ADP). The resulting energy is used by the active transport carrier system (sodium pump) that is responsible for the outward movement of three sodium ions across the cell membrane for every two potassium ions that pass inward. Abbreviation: Pi, inorganic phosphate. *Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.*

Other ion transporters include hydrogen-potassium ATPases in the gastric mucosa and renal tubules, the transporter that exchanges protons for potassium ions. Calcium ATPases are responsible for maintaining very low cytoplasmic concentrations of calcium, either by ejecting it from the cell (plasma membrane calcium ATPase) or sequestering calcium in the endoplasmic reticulum via the sarcoplasmic/endoplasmic reticulum calcium ATPase.¹⁵

Ion Channels

Ion channels are transmembrane proteins that generate electrical signals the brain, nerves, heart, and skeletal muscles (**Figure 1.10**).¹⁶ Ion channels use the energy stored in the chemical and electrical gradients created by sodium-potassium ATPase to rapidly initiate changes in transmembrane potential, causing conduction of an action potential.

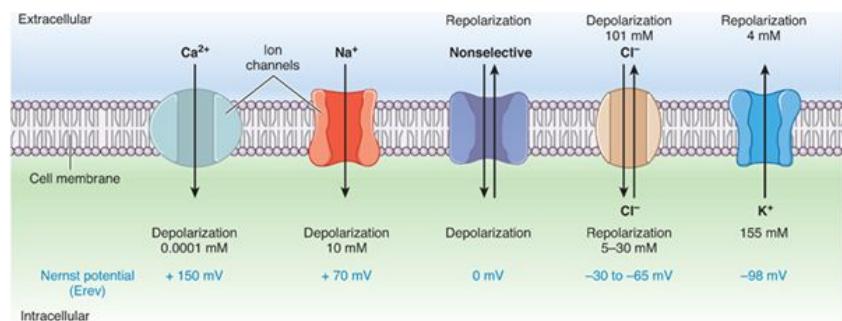

FIGURE 1.10 Ion channels that traverse the lipid bilayer to allow ion transport in response to a ligand or change in membrane potential. Sodium and calcium flow into the cell to facilitate depolarization while chloride and potassium have net outward flow to allow for repolarization. Non-selective channels carry multiple ions but favor repolarization at the cell's resting potential.

Because of their charge, most ions are relatively insoluble in cell membranes. Ions pass through cell membranes primarily through “ion channels” in transmembrane proteins. Ion channels are intermolecular spaces that extend through the entire cell membrane. Some channels are highly specific with respect to ions allowed to pass (sodium, potassium), whereas other channels allow all ions below a certain size to pass (**Table 1.4**). Neurotransmitter receptors such as those for γ -aminobutyric acid, glycine, glutamate, and others are activated upon the binding of the transmitter to open or close the channel to their specific anion or cation.

Movement of the ion alters the resting potential of the cell to facilitate or suppress the generation of an action potential.

TABLE 1.4

Diameters of ions, molecules, and channels

	Diameter (nm) ^a
Channel (average)	0.80
Water	0.30
Sodium (hydrated)	0.51
Potassium (hydrated)	0.40
Chloride (hydrated)	0.39
Glucose	0.86

^a1 nm = 10 Å.

Genes encoding the protein ion channels may be defective, leading to diseases such as cystic fibrosis (chloride channel defects), long Q-T interval syndrome (mutant potassium or [less commonly] sodium channels), hereditary nephrolithiasis (chloride channel), hereditary myopathies including myotonia congenital (chloride channel), and malignant hyperthermia (eg, the ryanodine receptor, the primary receptor releasing calcium from the sarcoplasmic reticulum)¹⁷ or the α_1 subunit of the dihydropyridine receptor encoded by the CACNA1S gene.¹⁸ The CACNA1S encoded calcium. Many drugs target ion channels, including common intravenous and inhalational anesthetics. Although details on the physiologic underpinning of most drugs is understood, the mechanism that underlies the action of inhalational anesthetics remains a well-studied mystery.^{19,20} Ion channels are discussed further in detail in [Chapter 3](#). Their interactions with general anesthetics are discussed in [Chapter 4](#).

Protein-Mediated Transport

Protein-mediated transport is responsible for movement of specific substrates across cell membranes. Indeed, carrier molecules are enzymes (specifically ATPases) that catalyze the hydrolysis of ATP. The most important of the ATPases is sodium-potassium ATPase, commonly called the sodium pump, which pumps sodium and potassium against their chemical gradients. Substances that are actively transported through cell membranes against a concentration gradient include ions (sodium, potassium, calcium, hydrogen, chloride, and magnesium), iodide (thyroid gland), carbohydrates, and amino acids.

P-glycoprotein is the primary transmembrane transporter, particularly for transporting drugs across the blood–brain barrier. Notably, the transport of morphine out of the CNS significantly slows the rate of rise and activity of morphine in the CNS.²¹ The ABC transporters (of which P-glycoprotein is a member) can be upregulated by long-term exposure to substrates including morphine and oxycodone contributing to tolerance.²² Virtually all transport of molecules against concentration gradients requires the assistance of proteins, which utilize energy provided by ATP to pump the molecule against the concentration gradient.

Sodium Ion Cotransport

Despite the widespread presence of sodium-potassium ATPase, the active transport of sodium ions in some tissues is coupled to the transport of other substances. For example, a carrier system present in the gastrointestinal tract and renal tubules will transport sodium ions only in combination with a glucose molecule. As such, glucose is returned to the circulation, thus preventing its excretion. Sodium ion cotransport of amino acids is an active transport mechanism that supplements facilitated diffusion of amino acids into cells. Epithelial cells lining the gastrointestinal tract and renal tubules are able to reabsorb amino acids into the circulation by this mechanism, thus preventing their excretion.

Other substances, including insulin, steroids, and growth hormone, influence amino acid transport by the sodium ion cotransport mechanism. For example, estradiol facilitates transport of amino acids into the musculature of the uterus, which promotes uterine and metamorphosis during pregnancy.

Aquaporins

Aquaporins are protein channels that permit water to freely flux across cell membranes.²³ In the absence of aquaporins, diffusion of water might not be sufficiently rapid for some physiologic processes. Genetic defects in aquaporins are responsible for several clinical diseases, including some cases of congenital cataracts²⁴ and nephrogenic diabetes insipidus.²⁵

Nucleus

The nucleus is mostly made up of the 46 chromosomes, except the nucleus of the egg cell, which contains 23. Each chromosome consists of a molecule of DNA covered with proteins including histones that tightly regulate DNA transcription. The nucleus is surrounded by a membrane that separates its contents from the cytoplasm. Nuclear pores allow transport of larger molecules, including RNA, and DNA, and proteins to pass between the nucleus and the cytoplasm.

The nucleolus is a non-membrane-bound structure within the nucleus responsible for the synthesis of ribosomes. Centrioles are present in the cytoplasm near the nucleus and coordinate the movement of chromosomes during cell division ([Figure 1.11](#)).

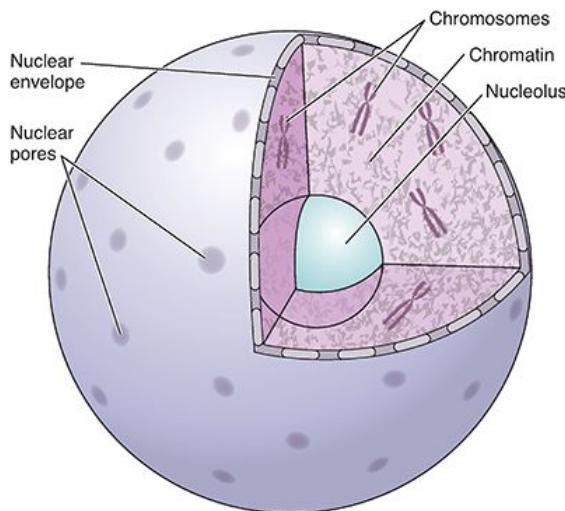

FIGURE 1.11 Contents of the cellular nucleus.

Structure and Function of DNA and RNA

The DNA consists of two complementary nucleotide chains composed of adenine, guanine, thymine, and cytosine ([Figure 1.12](#)).²⁶ The genetic message is determined by the sequence of nucleotides. The DNA is transcribed to RNA, which transfers the genetic message to the site of protein synthesis (ribosomes) in cytoplasm. All 3.2 billion base pairs of the human genome has been sequenced.²⁷ The protein encoding genes account for only 1% to 2% of our DNA. Our genome differs from that of chimpanzees by just 1%.²⁸ This explains so much!

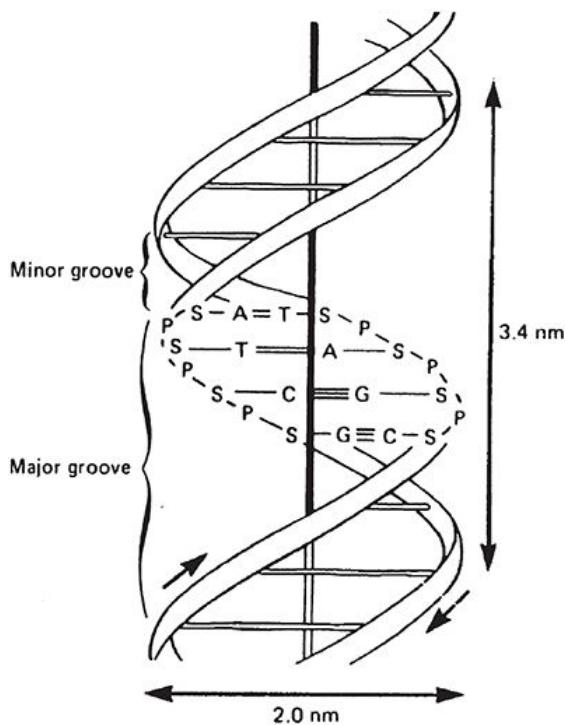

FIGURE 1.12 Double helical structure of DNA with adenine (A) bonding to thymine (T) and cytosine (C) to guanine (G). Republished with permission from Murray RK. Harper's Biochemistry. 23rd ed. Norwalk, CT: Appleton & Lange; 1990. Copyright © 1990 by Appleton & Lange.

The vast majority of our DNA consists of regulatory sequences, non-protein encoding RNA sequences (ribosomal RNA, transfer RNA and small nucleolar RNA), introns, and a considerable amount of DNA previously termed *junk* because it has no known function. Noncoding genes are transcribed to RNA but not translated to protein. There are short RNA sequences termed *microRNA* and long noncoding sequences called pseudogenes that can be transcribed from hundreds of base pairs. The physiologic functions are still being identified by include modulation of gene expression, protein function, and preservation of genomic stability in germ line cells.²⁹

Cytoplasm

The cytoplasm consists of water, electrolytes, and proteins including enzymes, lipids, and carbohydrates. About 70% to 80% of the cell volume is water. Cellular chemicals are dissolved in the water, and these substances can diffuse to all parts of the cell in this fluid medium. Proteins are, next to water, the most abundant substance in most cells, accounting for 10% to 20% of the cell mass. The cytoplasm contains numerous organelles with specific roles in cellular function.

Mitochondria

Mitochondria are the power-generating units of cells. They contain both the enzymes and substrates of the tricarboxylic acid cycle (Krebs cycle) and the electron transport chain. As a result, oxidative phosphorylation and synthesis of ATP are localized to mitochondria. The ATP leaves the mitochondria and diffuses throughout the cell, providing energy for cellular functions. Mitochondria consist of two lipid bilayers: the outer bilayer in contact with the cytoplasm and the inner layer that houses most of the biochemical machinery and the mitochondrial DNA. The space between these two membranes functions as a reservoir for protons created during electron transport. It is the movement of these protons back to the matrix, through the inner membrane, that drives the conversion of adenosine diphosphate to ATP, the primary form of intercellular energy, by ATP synthase.³⁰

Increased need for ATP in the cell leads to an increase in the number of mitochondria. A number of diseases are known to be based on aberrant mitochondrial function.³¹ The common element of mitochondrial diseases is aberrant cellular energetics. Mitochondria are exclusively inherited from the mother because sperm have no mitochondria. However, of the approximately 1,500 proteins responsible for mitochondrial function, only 13 are encoded by mitochondrial DNA. The balance is encoded in the nuclear DNA. Thus, the vast majority of mitochondrial diseases follow standard models of genetic inheritance.

Endoplasmic Reticulum

The endoplasmic reticulum is a complex lipid bilayer that wraps and folds creating tubules and vesicles in the cytoplasm. Ribosomes, composed mainly of RNA, attach to the outer portions of many parts of the endoplasmic reticulum membranes, serving as the sites for protein synthesis. The portion of the membrane containing these ribosomes is known as the *rough endoplasmic reticulum*. The part of the membrane that lacks ribosomes is the *smooth endoplasmic reticulum*. This smooth portion of the endoplasmic reticulum membrane functions in the synthesis of lipids, metabolism of carbohydrates, and other enzymatic processes. The sarcoplasmic reticulum is found in muscle cells, where it serves as a reservoir for calcium required for activation of the contractile apparatus.

Lysosomes

Lysosomes are lipid membrane enclosed organelles scattered throughout the cytoplasm. They function as an intracellular digestive system. Lysosomes are filled with digestive (hydrolytic) enzymes. When cells are damaged or die, these digestive enzymes cause autolysis of the remnants. Bactericidal substances in the lysosome kill phagocytized bacteria before they can cause cellular damage. These bactericidal substances include (1) lysozyme, which dissolves the cell membranes of bacteria; (2) lysoferrin, which binds iron and other metals that are essential for bacterial growth; (3) acid that has a pH of <4; and (4) hydrogen peroxide, which can disrupt some bacterial metabolic systems.

Lysosomal storage diseases are genetic disorders caused by inherited genetic defect in lysosomal function, resulting in accumulation of incompletely degraded macromolecules. There are more than 50 known lysosomal storage diseases, including Tay-Sachs, Gaucher, Fabry, and Niemann-Pick diseases.³²

Golgi Apparatus

The Golgi apparatus is a collection of membrane-enclosed sacs that are responsible for storing proteins and lipids as well as performing postsynthetic modifications including glycosylation and phosphorylation. Proteins synthesized in the rough endoplasmic reticulum are transported to the Golgi apparatus, where they are stored in highly concentrated packets (secretory vesicles) for subsequent release into the cell's cytoplasm, or transport to the surface for extracellular release via exocytosis. Exocytic vesicles continuously release their content, whereas secretory vesicles store the packaged material until a triggering signal is received. Neurotransmitter release is a highly relevant (to anesthesia) example of regulated secretion. The Golgi apparatus is also responsible for creating lysosomes.

Basic Principles of Pharmacology

Pamela Flood • Steven L. Shafer

This chapter combines Dr. Stoelting's original elegant description of pharmacology with mathematical underpinnings first presented by Dr. Shafer¹ in 1997 and most recently in *Miller's Anesthesia*.^{2,3} The combination of approaches sets a foundation for the pharmacology presented in the subsequent chapters. It also explains the fundamental principles of drug behavior and drug interaction that govern our daily practice of anesthesia.

Receptor Theory

A drug that *activates* a receptor by binding to that receptor is called an **agonist**. Most agonists bind through a combination of ionic, hydrogen, and van der Waals interactions (the sum of the attractive or repulsive forces between molecules), making them reversible. Rarely, an agonist will bind covalently to the receptor, rendering the interaction irreversible. Receptors are often envisioned as proteins that are either unbound or are bound to the agonist ligand. When the receptor is bound to the agonist ligand, the effect of the drug is produced. When the receptor is not bound, there is no effect. The receptor state is seen as binary: It is either unbound, resulting in one conformation, or it is bound, resulting in another conformation. Agonists are often portrayed as simply activating a receptor (**Figure 2.1**). In this view, the magnitude of the drug effect reflects the total number of receptors that are bound. In this simplistic view, the “most” drug effect occurs when every receptor is bound.

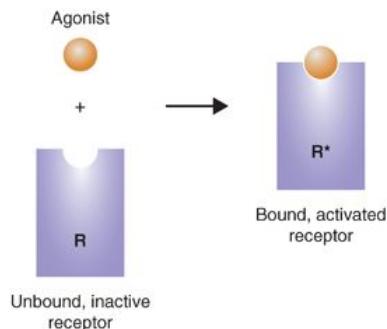

FIGURE 2.1 The interaction of a receptor with an agonist may be portrayed as a binary bound versus unbound receptor. The unbound receptor is portrayed as inactive. When the receptor is bound to the agonist ligand, it becomes the activated, R^* , and mediates the drug effect. This view is too simplistic, but it permits understanding of basic agonist behavior.

This simple view helps to understand the action of an antagonist (**Figure 2.2**). An **antagonist** is a drug that binds to the receptor without activating the receptor. Antagonists typically bind with ionic, hydrogen, and van der Waals interactions, rendering them reversible. Antagonists block the action of agonists simply by getting in the way of the agonist, preventing the agonist from binding to the receptor and producing the drug effect. **Competitive antagonism** is present when increasing concentrations of the antagonist progressively inhibit the response to the agonist. This causes a rightward displacement of the agonist dose-response (or concentration-response) relationship. **Noncompetitive antagonism** is present when, after administration of an antagonist, even high concentrations of agonist cannot completely overcome the antagonism. In this instance, either the agonist is bound irreversibly (and probably covalently) to the receptor site or it binds to a different site on the molecule and the interaction is allosteric (occurring at another site that fundamentally alters the activity of the receptor). Noncompetitive antagonism causes both a rightward shift of the dose-

response relationship as well as a decreased maximum efficacy of the concentration versus response relationship.

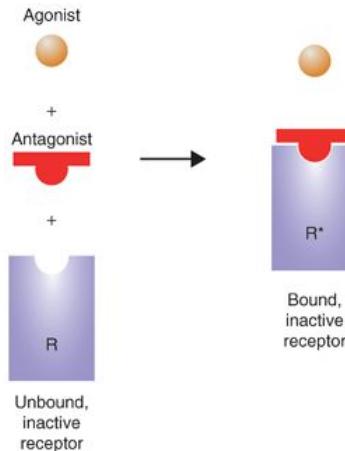

FIGURE 2.2 The simple view of receptor activation also explains the action of antagonist. In this case, the antagonist (red) binds to the receptor, but the binding does not cause activation. However, the binding of the antagonist blocks the agonist from binding, and thus blocks agonist drug effect. If the binding is reversible, this is competitive antagonism. If it is not reversible, then it is noncompetitive antagonism.

Although this simple view of activated and inactivated receptors explains agonists and antagonists, it has a more difficult time with **partial agonists** and **inverse agonists** (Figure 2.3). A partial agonist is a drug that binds to a receptor (usually at the agonist site) where it activates the receptor but not as much as a full agonist. Even at supramaximal doses, a partial agonist cannot cause the full drug effect. Partial agonists may also have antagonist activity in which case they are also called **agonist-antagonists**. When a partial agonist is administered with a full agonist, it decreases the effect of the full agonist. For example, butorphanol acts as a partial agonist at the μ -opioid receptor. Given alone, butorphanol is a modestly efficacious analgesic. Given along with fentanyl, it will partly reverse the fentanyl analgesia. Individuals using high doses of full agonist opioids withdraw after receiving buprenorphine. Inverse agonists bind at the same site as the agonist (and likely compete with it), but they produce the opposite effect of the agonist. Inverse agonists “turn off” the constitutive activity of the receptor. The simple view of receptors as bound or unbound does not explain partial agonists or inverse agonists.

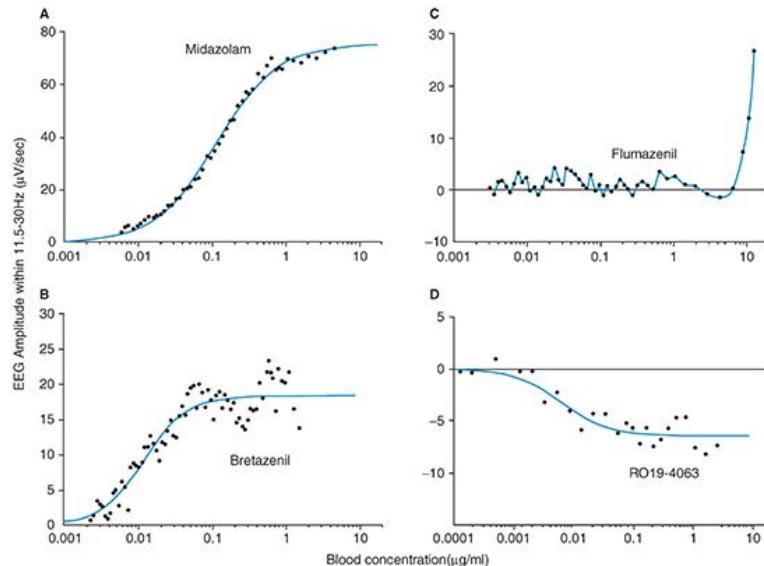

FIGURE 2.3 The concentration versus electroencephalogram (EEG) response relationship for four benzodiazepine ligands: midazolam (full agonist), bretazenil (partial agonist), flumazenil (competitive antagonist), and RO 19-4063 (inverse agonist). *Reprinted from Shafer SL. Principles of pharmacokinetics and pharmacodynamics. In: Longnecker DE, Tinker JH, Morgan GE, eds. Principles and Practice of Anesthesiology. 2nd ed. St Louis, MO: Mosby-Year Book; 1997:1159, based on Mandema JW, Kuck MT, Danhof M. In vivo modeling of the pharmacodynamic interaction between benzodiazepines which differ in intrinsic efficacy. J Pharmacol Exp Ther. 1992;261(1):56-61. Copyright © 1997 Elsevier. With permission.*

It turns out that receptors have many natural conformations, and they naturally fluctuate between these different conformations (**Figure 2.4**). Some of the conformations are associated with the pharmacologic effect, and some are not. In the example shown, the receptor only has two states: an inactive state and an active state that produces the same effect as if an agonist were bound to the receptor, although at a reduced level because the receptor only spends 20% of its time in this activated state.

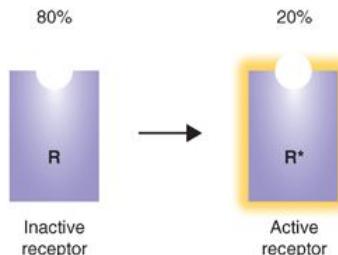

FIGURE 2.4 Receptors have multiple states, and they switch spontaneously between them. In this case, the receptor has just two states. It spends 80% of the time in the inactive state and 20% of the time in the active state in the absence of any ligand.

In this view, ligands do not cause the receptor shape to change. That happens spontaneously. However, ligands change the ratio of active to inactive states by (thermodynamically) favoring one of the states. **Figure 2.5** shows the receptor as seen in **Figure 2.4** in the presence of an agonist, a partial agonist, an antagonist, and an inverse agonist. Presence of the full agonist causes the conformation of the active state to be strongly favored, causing the receptors to be in this state nearly 100% of the time. The partial agonist is not as effective in stabilizing the receptor in the active state, so the bound receptor only spends 50% of its time in this state. The antagonist does not favor either state; it just gets in the way of binding (as before; see **Figure 2.2**). The inverse agonist favors the inactive state, reversing the baseline receptor activity.

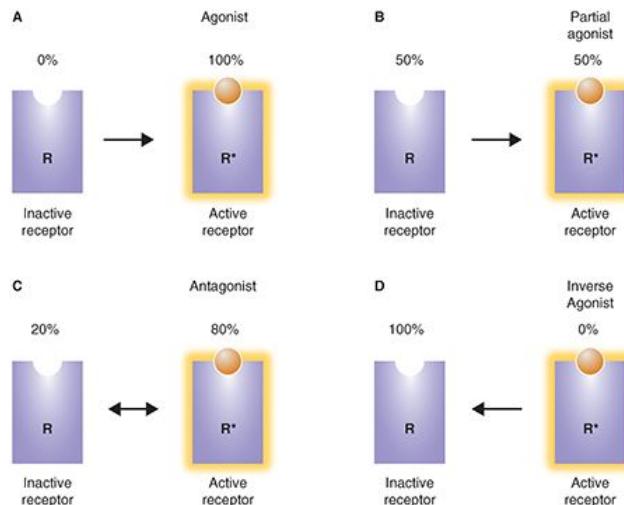

FIGURE 2.5 The action of agonists (A), partial agonists (B), antagonists (C), and inverse agonists (D) can be interpreted as changing the balance between the active and inactive forms of the receptor. In this case, in

the absence of agonist, the receptor is in the activated state 20% of the time. This percentage changes based on nature of the ligand bound to the receptor.

Using this information, we can now interpret the action of several ligands for the benzodiazepine receptor (see [Figure 2.3](#)). The actions include full agonism (midazolam), partial agonism (bretazenil), competitive antagonism (flumazenil), and inverse agonism (RO 19-4063). This range of actions can be explained by considering receptor states. Assume that the γ -aminobutyric acid (GABA) receptor has several conformations, one of which is particularly sensitive to endogenous GABA. Typically, there are some GABA receptors in this more sensitive conformation. As a full agonist, midazolam causes nearly all of the GABA receptors to be in the confirmation with increased sensitivity to GABA. Bretazenil does the same thing but not as well. Even when every benzodiazepine receptor is occupied by bretazenil, fewer GABA receptors are in the more sensitive confirmation. Bretazenil simply does not favor that conformation as well as midazolam. When flumazenil is in the binding pocket, it does not change the relative probabilities of the receptor being in any conformation. Flumazenil just gets in the way of other drugs that would otherwise bind to the pocket. RO 19-4063 actually decreases the number of GABA receptors in the more sensitive conformation. Usually, some of them are in this more sensitive conformation, but that number is decreased by the inverse agonist RO 19-4063 (which was never developed as a drug because endogenous benzodiazepines, although anticipated, have not been described). The notion of receptors having multiple conformations with distinct activity, and drugs acting through favoring particular conformations, helps to understand the action of agonists, partial agonists, antagonists, and inverse agonists.

Receptor Action

The number for receptors in cell membranes is dynamic and increases (upregulates) or decreases (downregulates) in response to specific stimuli. For example, a patient with pheochromocytoma has an excess of circulating catecholamines. In response, there is a decrease in the numbers of β -adrenergic receptors in cell membranes in an attempt to maintain homeostasis. Likewise, prolonged treatment of asthma with a β -agonist may result in tachyphylaxis (decreased response to the same dose of β -agonist, often indistinguishable from **tolerance**) because of the decrease in β -adrenergic receptors. Conversely, lower motor neuron injury causes an increase in the number of nicotinic acetylcholine receptors in the neuromuscular junction, leading to an exaggerated response to succinylcholine. Changing receptor numbers is one of many mechanisms that contribute to variability in response to drugs.

Receptor Types

Receptors for drug action can be classified by location. Many of the receptors thought to be the most critical for anesthetic action are located in the lipid bilayer of cell membranes. For example, opioids, intravenous sedative hypnotics, benzodiazepines, β -blockers, catecholamines, and muscle relaxants (most of which are antagonists) all interact with membrane-bound receptors. Some receptors are intracellular proteins. Drugs such as caffeine, insulin, steroids, theophylline, and milrinone interact with intracellular proteins. Circulating proteins can also be drug targets. The coagulation cascade comprises an ensemble of circulating proteins, many of which are therapeutic targets for modifying coagulation.

There are also drugs that do not interact with proteins at all. Stomach antacids such as sodium citrate simply work by changing gastric pH. Chelating drugs work by binding divalent cations. Iodine kills bacteria by osmotic pressure (intracellular desiccation, which is why it is best to let iodine prep solutions dry), and intravenous sodium bicarbonate changes plasma pH. The mechanism of action of these drugs does not involve receptors per se, and hence, these drugs will not be further considered in this section.

Proteins are small machines whose cogs, cams, and wheels catalyze enzymatic reactions, permit ions to traverse cell membranes, exert mechanical force, or the myriad of other protein-based activities. When a drug binds to a receptor, it changes the activity of the machine, typically by enhancing its activity (eg, propofol increases the sensitivity of the GABA_A receptor to GABA, the endogenous ligand), decreasing its activity (ketamine decreases the activity of the N-methyl-D-aspartate [NMDA] receptor), or triggering a chain

reaction (opioid binding to the μ -opioid receptor activates an inhibitory G protein that decreases adenylyl cyclase activity). The protein's response to binding of the drug is responsible for the drug effect.

Pharmacokinetics

Pharmacokinetics is the quantitative study of the absorption, distribution, metabolism, and excretion of injected and inhaled drugs and their metabolites. *Pharmacokinetics describes what the body does to the drug.* Pharmacodynamics is the quantitative study of the body's response to a drug. *Pharmacodynamics describes what the drug does to the body.* This section introduces the basic principles of pharmacokinetics. The next section discusses the basic principles of pharmacodynamics.

Pharmacokinetics determines the concentration of a drug in the plasma or at the site of drug effect. Pharmacokinetic variability is a significant component of patient-to-patient variability in drug response. Pharmacokinetic variability may result from genetic modifications in metabolism; interactions with other drugs; or diseases of the liver, kidneys, or other organs of metabolism.⁴

The basic principles of pharmacokinetics are absorption, metabolism, distribution, and elimination. These processes are fundamental to all drugs. They can be described in basic physiologic terms or using mathematical models. Each serves a purpose. Physiology can be used to predict how changes in organ function will affect the disposition of drugs. Mathematical models can be used to calculate the concentration of drug in the blood or tissue following any arbitrary dose at any arbitrary time. We initially tackle the physiologic principles that govern distribution, metabolism, elimination, and absorption, in that order. We then turn to the mathematical models.

Distribution

Intravenously administered drugs mix with body tissues and are immediately diluted from the concentrated injectate in the syringe to the more dilute concentration measured in the plasma or tissue. This initial distribution (within 1 minute) after bolus injection is considered mixing within the “central compartment” (**Figure 2.6**). The central compartment is physically composed of those elements of the body that dilute the drug within the first minute after injection: the venous blood volume of the arm, the volume of the great vessels, the heart, the lung, and the upper aorta, and whatever uptake of drug occurs in the first passage through the lungs. Many of these volumes are fixed regardless of the drug that is given. The lungs are different. Drugs that are highly fat soluble may be avidly taken up in the first passage through the lung, reducing the concentration measured in the arterial blood. This results in an apparent increase in size of the central compartment. For example, first-pass pulmonary uptake of the initial dose of lidocaine, propranolol, meperidine, fentanyl, sufentanil, and alfentanil exceeds 65% of the dose.⁵

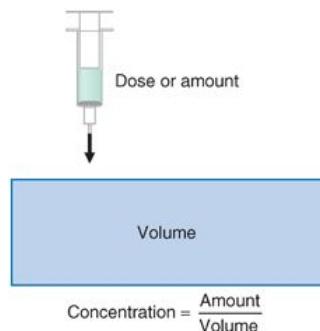

FIGURE 2.6 The central volume is the volume that intravenously injected drug initially mixes into. Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, et al, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514, with permission. Copyright © 2010 Elsevier. With permission.

The body is a complex space, and mixing within the myriad body fluids and tissues is an ongoing process. The central compartment is the small initial mixing volume. Several minutes later, the drug will fully

mix with the entire blood volume. However, it may take hours or even days for the drug to fully mix with all bodily tissues because some tissues have very low perfusion.

In the process of mixing, molecules are drawn to other molecules, some with specific binding sites. A drug that is polar will be drawn to water, where the polar water molecules find a low-energy state by associating with the charged aspects of the molecule. A drug that is nonpolar has a higher affinity for fat, where van der Waals binding provides numerous weak binding sites. Many anesthetic drugs are highly fat soluble and poorly soluble in water. High fat solubility means that the molecule will have a large volume of distribution because it will be preferentially taken up by fat, diluting the concentration in the plasma. The extreme example of this is propofol, which is almost inseparable from fat. The capacity of body fat to hold propofol is so vast that in some studies, the total volume of distribution of propofol has been reported as exceeding 5,000 L. Of course, nobody has a total volume of 5,000 L! It is important to understand that those 5,000 L refer to imaginary liters of plasma required to dilute the initial dose of propofol to achieve the measured concentration. Because propofol is so fat soluble, a large amount of propofol is held in the body's fatty tissues, with just a tiny fraction measured in the plasma.

Following bolus injection, the drug initially goes to the tissues that receive the bulk of arterial blood flow: the brain, heart, kidneys, and liver. These tissues are often called the **vessel-rich group**. The rapid blood flow to these highly perfused tissues ensures that the tissue drug concentration rapidly equilibrates with arterial blood. However, for highly lipid-soluble drugs, the capacity of the fat to hold the drug greatly exceeds the capacity of highly perfused tissues. Initially, the fat compartment is almost invisible because the blood supply to fat is quite limited. However, with time, the fat gradually absorbs more and more drug, sequestering it away from the highly perfused tissues. This redistribution of drug from the highly perfused tissue to the fat accounts for a substantial part of the offset of drug effect following a bolus of an intravenous anesthetic or fat-soluble opioid (eg, fentanyl). Muscles play an intermediate role in this process, having (at rest) blood flow that is intermediate between highly perfused tissues and fat, and also having intermediate solubility for lipophilic drugs.

Protein Binding

Most drugs are bound to some extent to plasma proteins, primarily albumin, α_1 -acid glycoprotein, and lipoproteins.⁶ Most acidic drugs bind to albumin, whereas basic drugs bind to α_1 -acid glycoprotein. Protein binding effects both the distribution of drugs (because only the free or unbound fraction can readily cross cell membranes) and the apparent potency of drugs, again because it is the free fraction that determines the concentration of bound drug on the receptor.

The extent of protein binding parallels the lipid solubility of the drug. This is because drugs that are hydrophobic are more likely to bind to proteins in the plasma and to lipids in the fat. For intravenous anesthetic drugs, which tend to be quite potent, the number of available protein binding sites in the plasma vastly exceeds the number of sites actually bound. As a result, the fraction bound is not dependent on the concentration of the anesthetic and only dependent on the protein concentration.

Binding of drugs to plasma albumin is nonselective, and drugs with similar physicochemical characteristics may compete with each other and with endogenous substances for the same protein binding sites. For example, sulfonamides can displace unconjugated bilirubin from binding sites on albumin, leading to the risk of bilirubin encephalopathy in the neonate.

Age, hepatic disease, renal failure, and pregnancy can decrease plasma protein concentration. Alterations in protein binding are important only for drugs that are highly protein bound (eg, >90%). For such drugs, the free fraction changes as an inverse proportion with a change in protein concentration. If the free fraction is 2% in the normal state, then in a patient with 50% decrease in plasma proteins, the free fraction will increase to 4%, a 100% increase.

Theoretically, an increase in free fraction of a drug may increase the pharmacologic effect of the drug, but in practice, it is far from certain that there will be any change in pharmacologic effect at all. The reason is that it is the unbound fraction that equilibrates throughout the body, including with the receptor. Plasma proteins only account for a small portion of the total binding sites for drug in the body. Because the free drug **concentration** in the plasma and tissues represents partitioning with all binding sites, not just the plasma

binding sites, the actual free drug concentration that drives drug on and off receptors may change fairly little with changes in plasma protein concentration.

Metabolism

Metabolism converts pharmacologically active, lipid-soluble drugs into water-soluble and usually pharmacologically inactive metabolites. However, this is not always the case. For example, diazepam and propranolol may be metabolized to active compounds. Morphine-6-glucuronide, a metabolite of morphine, is a more potent opioid than morphine itself. In some instances, an inactive parent compound (prodrug) is metabolized to an active drug. This is the case with codeine, which is an exceedingly weak opioid. Codeine is metabolized to morphine, which is responsible for the analgesic effects of codeine.

Pathways of Metabolism

The four basic pathways of metabolism are (1) oxidation, (2) reduction, (3) hydrolysis, and (4) conjugation. Traditionally, metabolism has been divided into phase I and phase II reactions. Phase I reactions include oxidation, reduction, and hydrolysis, which increase the drug's polarity prior to the phase II reactions. Phase II reactions are conjugation reactions that covalently link the drug or metabolites with a highly polar molecule (carbohydrate or an amino acid) that renders the conjugate more water-soluble for subsequent excretion.

Hepatic microsomal enzymes are responsible for the metabolism of most drugs. Other sites of drug metabolism include the plasma (Hofmann elimination, ester hydrolysis), lungs, kidneys, and gastrointestinal tract and placenta (tissue esterases). Hepatic microsomal enzymes, which participate in the metabolism of many drugs, are located principally in hepatic smooth endoplasmic reticulum. These microsomal enzymes are also present in the kidneys, gastrointestinal tract, and adrenal cortex. Microsomes are vesicle-like artifacts reformed from pieces of the endoplasmic reticulum bilayer sliced apart as cells are cut up in a blender. Microsomal enzymes are those enzymes that are concentrated in these vesicle-like artifacts.

Phase I Enzymes

Enzymes responsible for phase I reactions include cytochrome P450 (CYP) enzymes, non-CYP enzymes, and flavin-containing monooxygenase enzymes. The CYP enzyme system is a large family of membrane-bound proteins containing a heme cofactor that catalyzes the metabolism of compounds. The P450 enzymes are predominantly hepatic microsomal enzymes, although there are also mitochondrial P450 enzymes. The designation CYP is derived from their characteristic absorption peak at 450 nm when heme is combined with carbon monoxide. The CYP system is also known as the mixed function oxidase system because it involves both oxidation and reduction steps; the most common reaction catalyzed by CYP is the monooxygenase reaction, for example, insertion of one atom of oxygen into an organic substrate while the other oxygen atom is reduced to water. The CYP functions as the terminal oxidase in the electron transport chain.

Individual CYP enzymes have evolved from a common protein.⁷ The CYP enzymes, often called **CYPs**, that share more than 40% sequence homology are grouped in a family designated by a number (eg, “CYP2”), those that share more than 55% homology are grouped in a subfamily designated by a letter (eg, “CYP2A”), and individual CYP enzymes are identified by a third number (eg, “CYP2A6”). Ten isoforms of CYP are responsible for the oxidative metabolism of most drugs. The preponderance of CYP activity for anesthetic drugs is generated by CYP3A4, which is the most abundantly expressed P450 isoform, comprising 20% to 60% of total P450 activity. The P450 3A4 metabolizes more than one-half of all currently available drugs, including opioids (alfentanil, sufentanil, fentanyl), benzodiazepines, local anesthetics (lidocaine, ropivacaine), immunosuppressants (cyclosporine), and antihistamines (terfenadine).

Drugs can alter the activity of these enzymes through induction and inhibition. Induction occurs through increased expression of the enzymes. For example, phenobarbital induces microsomal enzymes and thus can render drugs less effective through increased metabolism. Conversely, other drugs directly inhibit enzymes, increasing the exposure to their substrates. Famously, grapefruit juice (not exactly a drug) inhibits CYP 3A4, possibly increasing the concentration of anesthetics and other drugs.

Oxidation

CYP enzymes are crucial for oxidation reactions. These enzymes require an electron donor in the form of reduced nicotinamide adenine dinucleotide and molecular oxygen for their activity. The molecule of oxygen is split, with one atom of oxygen oxidizing each molecule of drug and the other oxygen atom being incorporated into a molecule of water. Examples of oxidative metabolism of drugs catalyzed by CYP enzymes include hydroxylation, deamination, desulfuration, dealkylation, and dehalogenation. Demethylation of morphine to normorphine is an example of oxidative dealkylation. Dehalogenation involves oxidation of a carbon-hydrogen bond to form an intermediate metabolite that is unstable and spontaneously loses a halogen atom. Halogenated volatile anesthetics are susceptible to dehalogenation, leading to release of bromide, chloride, and fluoride ions. Aliphatic oxidation is oxidation of a side chain. For example, oxidation of the side chain of thiopental converts the highly lipid-soluble parent drug to the more water-soluble carboxylic acid derivative. Thiopental also undergoes desulfuration to pentobarbital by an oxidative step.

Epoxide intermediates in the oxidative metabolism of drugs are capable of covalent binding with macromolecules and may be responsible for some drug-induced organ toxicity, such as hepatic dysfunction. Normally, these highly reactive intermediates have such a transient existence that they exert no biologic action. When enzyme induction occurs, however, large amounts of reactive intermediates may be produced, leading to organ damage. This is especially likely to occur if the antioxidant glutathione, which is in limited supply in the liver, is depleted by the reactive intermediates.

Reduction

The CYP enzymes are also essential for reduction reactions. Under conditions of low oxygen partial pressures, CYP enzymes transfer electrons directly to a substrate such as halothane rather than to oxygen. This electron gain imparted to the substrate occurs only when insufficient amounts of oxygen are present to compete for electrons.

Conjugation

Conjugation with glucuronic acid involves CYP enzymes. Glucuronic acid is synthesized from glucose and added to lipid-soluble drugs to render them water-soluble. The resulting water-soluble glucuronide conjugates are then excreted in bile and urine. In premature infants, reduced microsomal enzyme activity interferes with conjugation, leading to neonatal hyperbilirubinemia and the risk of bilirubin encephalopathy. The reduced conjugation ability of the neonate increases the effect and potential toxicity of drugs that are normally inactivated by conjugation with glucuronic acid.

Hydrolysis

Enzymes responsible for hydrolysis of drugs, usually at an ester bond, do not involve the CYP enzymes system. Hydrolysis often occurs outside of the liver. For example, remifentanil, succinylcholine, esmolol, and the ester local anesthetics are cleared in the plasma and tissues via ester hydrolysis.

Phase II Enzymes

Phase II enzymes include glucuronosyltransferases, glutathione-S-transferases, *N*-acetyl-transferases, and sulfotransferases. Uridine diphosphate glucuronosyltransferase catalyzes the covalent addition of glucuronic acid to a variety of endogenous and exogenous compounds, rendering them more water-soluble. Glucuronidation is an important metabolic pathway for several drugs used during anesthesia, including propofol, morphine (yielding morphine-3-glucuronide and the pharmacologically active morphine-6-glucuronide), and midazolam (yielding the pharmacologically active α_1 -hydroxymidazolam). Glutathione-S-transferase enzymes are primarily a defensive system for detoxification and protection against oxidative stress. *N*-Acetylation catalyzed by *N*-acetyl-transferase is a common phase II reaction for metabolism of heterocyclic aromatic amines (particularly serotonin) and arylamines, including the inactivation of isoniazid.

Hepatic Clearance

The rate of metabolism for most anesthetic drugs is proportional to drug concentration, rendering the clearance of the drug constant (ie, independent of dose). This is a fundamental assumption for anesthetic pharmacokinetics. Exploring this assumption will provide insight into the critical role of clearance in governing the metabolism of drugs.

Although the metabolic capacity of the body is large, it is not possible that metabolism is *always* proportional to drug concentration because the liver does not have infinite metabolic capacity. At some rate of drug flow into the liver, the organ will be metabolizing drug as fast as the metabolic enzymes in the organ allow. At this point, metabolism can no longer be proportional to concentration because the metabolic capacity of the organ has been exceeded.

Understanding metabolism starts with a simple mass balance: The rate at which drug flows *out* of the liver must be the same as the rate at which drug flows *into* the liver minus the rate at which the liver metabolizes drug. The rate at which drug flows into the liver is liver blood flow, Q , times the concentration of drug flowing in, C_{inflow} . The rate at which drug flows out of the liver is liver blood flow, Q , times the concentration of drug flowing out, $C_{outflow}$. The rate of hepatic metabolism by the liver, R , is the difference between the drug concentration flowing into the liver and the drug concentration flowing out of the liver, times the rate of liver blood flow:

$$\text{Rate of drug metabolism} = R = Q(C_{inflow} - C_{outflow})$$

Equation 2.1

This relationship is illustrated in [Figure 2.7](#).

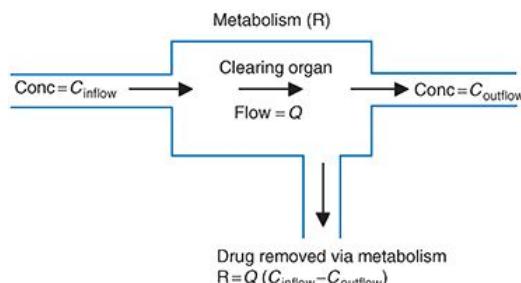

FIGURE 2.7 The relationship between drug rate of metabolism can be computed as the rate of liver blood flow times the difference between the inflowing and outflowing drug concentrations. This is a common approach to analyzing metabolism or tissue uptake across an organ in mass-balance pharmacokinetic studies. *Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514. Copyright © 2010 Elsevier. With permission.*

Metabolism can be saturated because the liver does not have infinite metabolic capacity. A common equation used for this saturation processes is as follows:

$$\text{Response} = \frac{C}{C_{50} + C}$$

Equation 2.2

“Response” in [Equation 2.2](#) varies from 0 to 1, depending on the value of C . In this context, Response is the fraction of maximal metabolic rate. Response = 0 means no metabolism, and response = 1 means metabolism at the maximal possible rate. C refers to whatever is driving the response. In this chapter, C means drug concentration. When C is 0, the response is 0. If C is greater than 0 but much less than C_{50} , the denominator

is approximately C_{50} and the response is nearly proportional to C : $\text{Response} \approx \frac{C}{C_{50}}$. If we increase C even further to exactly C_{50} , then the response is $\frac{C_{50}}{C_{50} + C_{50}} = 0.5$, which is simply 0.5. That is where the name “ C_{50} ” comes from:

It is the concentration associated with 50% response. As C becomes much greater than C_{50} , the equation

approaches $\frac{C}{C}$, which is 1. The shape of this relationship is shown in [Figure 2.8](#). The relationship is nearly linear at low concentrations, but at high concentrations, the response saturates at 1.

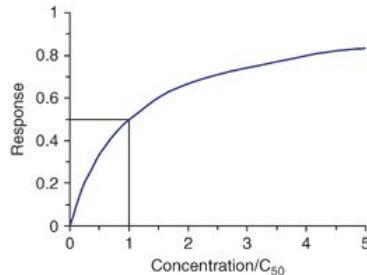

FIGURE 2.8 The shape of the saturation equation. Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514. Copyright © 2010 Elsevier. With permission.

To understand hepatic clearance, we must understand the relationship between hepatic metabolism and drug concentration. But what concentration determines the rate of metabolism: the concentration flowing into the liver, the average concentration within the liver, or the concentration flowing out of the liver? All have been used, but the most common views the rate of metabolism as a function of the concentration flowing *out* of the liver, C_{outflow} . The rationale for using C_{outflow} is the same as the rationale for using end tidal anesthetic concentration to assess the steady state concentration in the lungs.

We can expand our equation of metabolism to include the observation that the rate of metabolism, R , approaches saturation at the maximum metabolic rate, V_m , as a function of C_{outflow} :

$$\begin{aligned} \text{Rate of drug metabolism} = R &= Q(C_{\text{inflow}} - C_{\text{outflow}}) = \\ &V_m \frac{C_{\text{outflow}}}{K_m + C_{\text{outflow}}} \end{aligned} \quad \text{Equation 2.3}$$

The saturation equation appears at the end of the [Equation 2.3](#) equation. The V_m is the maximum possible

metabolic rate. The saturation part of this equation, $\frac{C_{\text{outflow}}}{K_m + C_{\text{outflow}}}$, determines fraction of the maximum metabolic rate. K_m , the "Michaelis constant," is the outflow concentration at which the metabolic rate is 50% of the maximum rate (V_m). This relationship is shown in [Figure 2.9](#). The x -axis is the outflow concentration, C_{outflow} , as a fraction K_m . The y -axis is the rate of drug metabolism as a fraction of V_m . By normalizing the x - and y -axis in this manner, the relationship shown in [Figure 2.9](#) is true for all values of V_m and K_m . As long as the outflow concentration is less than one-half of K_m (true for almost all anesthetic drugs), there is a nearly proportional change in metabolic rate with a proportional change in outflow concentration. Another interpretation is that metabolism will be proportional to concentration as long as the metabolic rate is less than one-third of the maximum metabolic capacity.

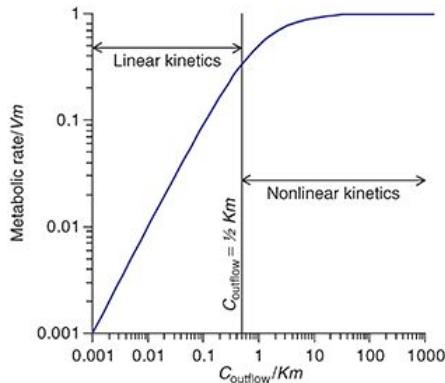

FIGURE 2.9 The relationship between concentration, here shown as a fraction of the Michaelis constant (K_m), and drug metabolism, here shown as a fraction of the maximum rate (V_m). Metabolism increases proportionally with concentration as long as the outflow concentration is less than half K_m , which corresponds to a metabolic rate that is roughly one-third of the maximal rate. Metabolism is proportional to concentration, meaning that clearance is constant, for typical doses of all intravenous drugs used in anesthesia. *Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514. Copyright © 2010 Elsevier. With permission.*

So far, we have talked about the rate of metabolism and not about hepatic clearance. If the liver could completely extract the drug from the afferent flow, then clearance would equal liver blood flow, Q . However, the liver cannot remove every last drug molecule. There is always some drug in the effluent plasma. The

fraction of inflowing drug extracted by the liver is $\frac{C_{inflow} - C_{outflow}}{C_{inflow}}$. This is called the **extraction ratio**. Clearance is the amount of blood completely cleared of drug per unit time. We can calculate clearance as the liver blood flow times the extraction ratio:

$$\text{Clearance} = Q \times ER = Q \left(\frac{C_{inflow} - C_{outflow}}{C_{inflow}} \right)$$

Equation 2.4

With this basic understanding of clearance, let us divide each part of [Equation 2.3](#) by C_{inflow} :

$$\begin{aligned} \frac{\text{Rate of drug metabolism}}{C_{inflow}} &= \frac{R}{C_{inflow}} = \\ Q \left(\frac{C_{inflow} - C_{outflow}}{C_{inflow}} \right) &= \frac{C_{outflow}}{C_{inflow}} \left(\frac{V_m}{K_m + C_{outflow}} \right) \end{aligned}$$

Equation 2.5

The third term in the above equation is clearance as defined in [Equation 2.4](#): Q times the extraction ratio. Thus, each term in [Equation 2.4](#) must be clearance. Let us consider them in order.

$$\text{Clearance} = \frac{\text{Rate of drug metabolism}}{C_{inflow}}$$

The first term tells us that $\frac{\text{Rate of drug metabolism}}{C_{inflow}}$. This indicates that clearance is a proportionality constant that relates inflowing (eg, arterial) concentration to the rate of metabolism. If we want to maintain a given steady-state arterial drug concentration, we must infuse drug at the same rate that it is being metabolized. With this understanding, we can rearrange the equation to say the following: Infusion rate = metabolic rate = Clearance $\times C_{inflow}$. Thus, the infusion rate to maintain a given arterial concentration (C_{inflow}) is the clearance times the desired concentration.

The third and fourth terms

$$\text{Clearance} = Q \left(\frac{C_{\text{inflow}} - C_{\text{outflow}}}{C_{\text{inflow}}} \right)$$

and

$$\text{Clearance} = \frac{C_{\text{outflow}}}{C_{\text{inflow}}} \left(\frac{V_m}{K_m + C_{\text{outflow}}} \right)$$

$$\frac{C_{\text{inflow}} - C_{\text{outflow}}}{C_{\text{inflow}}}$$

are particularly interesting when taken together. Remembering that $\frac{C_{\text{inflow}} - C_{\text{outflow}}}{C_{\text{inflow}}}$ is the extraction ratio, these equations relate clearance to liver blood flow and the extraction ratio, as shown in [Figure 2.10](#).⁸ For drugs with an extraction ratio of nearly 1 (eg, propofol), a change in liver blood flow produces a nearly proportional change in clearance. For drugs with a low extraction ratio (eg, alfentanil), clearance is nearly independent of the rate of liver blood flow. This makes intuitive sense. If nearly 100% of the drug is extracted by the liver, then the liver has tremendous metabolic capacity for the drug. In this case, flow of drug to the liver is what limits the metabolic rate. Metabolism is “flow limited.” The reduction in liver blood flow that accompanies anesthesia can be expected to reduce clearance. However, moderate changes in hepatic metabolic function per se will have little impact on clearance because hepatic metabolic capacity is overwhelmingly in excess of demand.

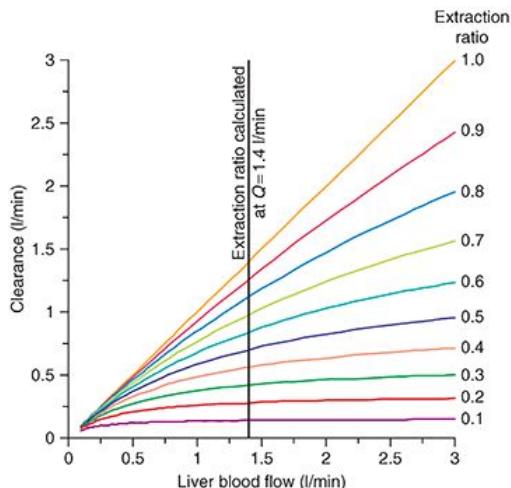

FIGURE 2.10 The relationship between liver blood flow (Q), clearance, and extraction ratio. For drugs with a high extraction ratio, clearance is nearly identical to liver blood flow. For drugs with a low extraction ratio, changes in liver blood flow have almost no effect on clearance. *Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514.*

Copyright © 2010 Elsevier. With permission.

Conversely, for drugs with an extraction ratio considerably less than 1, clearance is limited by the capacity of the liver to take up and metabolize the drug. This is called “capacity-limited” clearance. When clearance is capacity limited, changes in liver blood flow (as might be caused by the anesthetic state itself) have little influence on the clearance because the liver can only handle a fraction of the drug flowing through it. It does not matter if liver blood flow is doubled, or cut in half, because the liver’s enzymatic capacity is “maxed out” regardless of the amount of drug flowing through it.

When clearance is flow limited, it is generally unaffected by modest changes in hepatic capacity. However, when clearance is capacity limited, changes in liver metabolic capacity produce nearly proportional changes in clearance rate. For these drugs, clearance can be significantly decreased by hepatic disease or increased by enzymatic induction. This relationship can be seen in [Figure 2.11](#).

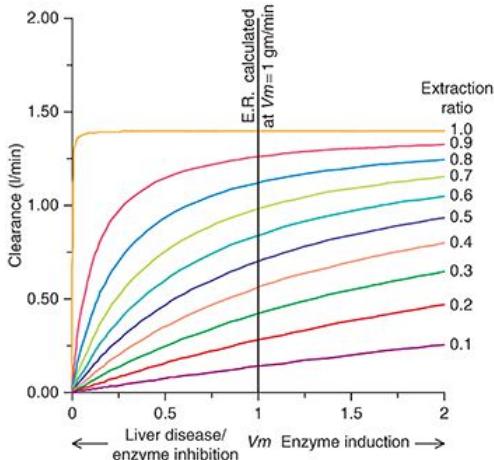

FIGURE 2.11 Changes in maximum metabolic velocity (V_m) have little effect on drugs with a high extraction ratio (ER) but cause a nearly proportional decrease in clearance for drugs with a low extraction ratio. Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514. Copyright © 2010 Elsevier. With permission.

[Figure 2.11](#) allows us to also see how extraction ratio helps identify flow-limited from capacity-limited drugs. The vertical line at $V_m = 1$ shows the extraction ratio for each line (labeled to the left), based on a liver blood flow of 1.4 L per minute. Changes in V_m , as might be caused by liver disease (reduced V_m) or enzymatic induction (increased V_m) have little effect on drugs with a high extraction ratio. However, drugs with a low extraction ratio have a nearly linear change in clearance with a change in intrinsic metabolic capacity (V_m).

V_m and K_m are usually not known and condensed into a single term, $\frac{V_m}{K_m}$. This term summarizes the hepatic metabolic capacity and is called **intrinsic clearance**. Because $\text{clearance} = \frac{C_{\text{outflow}}}{C_{\text{inflow}}} \left(\frac{V_m}{K_m + C_{\text{outflow}}} \right)$, consider what happens if hepatic blood flow increases to infinity (this is a thought experiment—do not try this at home). At super high hepatic blood flow, C_{outflow} becomes indistinguishable from C_{inflow} because the finite hepatic capacity only metabolizes an infinitesimal fraction of the drug flowing through the liver. As a result, clearance becomes $\frac{V_m}{K_m + C_{\text{outflow}}} = \frac{V_m}{K_m}$. This is clearance when blood flow is infinitely fast. There must be a linear portion, where metabolism is proportional to concentration. We can solve for clearance in the “linear range” by solving for $C_{\text{inflow}} = C_{\text{outflow}} = 0$, $\frac{V_m}{K_m}$. This is the intrinsic clearance, Cl_{int} . It can be demonstrated algebraically from the definition of Cl_{int} that in the linear range (ie, when $K_m \gg C_{\text{outflow}}$), Cl_{int} is related to the extraction ratio and hepatic blood flow:

$$ER = \frac{Cl_{int}}{Q + Cl_{int}}$$

Equation 2.6

This relationship between intrinsic clearance and extraction ratio is shown in [Figure 2.12](#), calculated at a hepatic blood flow of 1,400 mL per minute. It shows that the intrinsic clearance for drugs like propofol with an extraction ratio of approximately 1 is enormous, somewhere around 100 L per minute!

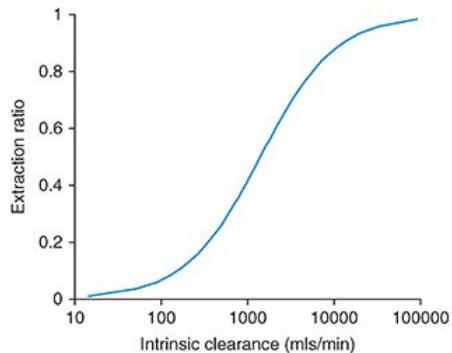

FIGURE 2.12 The extraction ratio as a function of the intrinsic calculated for a liver blood flow of 1,400 mL per minute. *Reprinted from Shafer SL, Flood P, Schwinn DA. Basic principles of pharmacology. In: Miller RD, Eriksson LI, Fleisher LA, Wiener-Kronish JP, Young WL, eds. Miller's Anesthesia. Vol 1. 7th ed. Philadelphia, PA: Churchill Livingstone; 2010:479-514. Copyright © 2010 Elsevier. With permission.*

Finally, we can combine [Equation 2.6](#) with [Equation 2.5](#) to solve for the relationship between hepatic clearance and Cl_{int} :

$$\text{Hepatic Clearance} = \frac{Q Cl_{int}}{Q + Cl_{int}}$$

Equation 2.7

In general, true hepatic clearance and extraction ratio are more useful concepts for anesthetic drugs than the intrinsic clearance. However, intrinsic clearance is introduced here because it is occasionally used in pharmacokinetic analyses of drugs used during anesthesia.

So far, we have focused on linear pharmacokinetics, that is, the pharmacokinetics of drugs whose metabolic rate at clinical doses is less than $Vm/3$. The clearance of such drugs is generally expressed as a constant (eg, propofol clearance = 1.6 L per minute). Some drugs, such as phenytoin, exhibit saturable pharmacokinetics (ie, have such low Vm that typical doses exceed the linear portion of [Figure 2.9](#)). The clearance of drugs with saturable metabolism is a function of drug concentration, rather than a constant flow (ie, volume per unit time). There are almost no drugs with saturable clearance in anesthesia, so they will not be discussed in greater detail. However, the clearance for these drugs as a function of concentration can be calculated from [Equations 2.5](#) and [2.7](#).

Renal Clearance

Renal excretion of drugs involves (1) glomerular filtration, (2) active tubular secretion, and (3) passive tubular reabsorption. The amount of drug that enters the renal tubular lumen depends on the fraction of drug bound to protein and the glomerular filtration rate (GFR). Renal tubular secretion involves active transport processes, which may be selective for certain drugs and metabolites, including protein-bound compounds. Reabsorption from renal tubules removes drug that has entered tubules by glomerular filtration and tubular secretion. This reabsorption is most prominent for lipid-soluble drugs that can easily cross cell membranes of renal tubular epithelial cells to enter pericapillary fluid. Indeed, a highly lipid-soluble drug, such as thiopental, is almost completely reabsorbed such that little or no unchanged drug is excreted in the urine. Conversely, production of less lipid-soluble metabolites limits renal tubule reabsorption and facilitates excretion in the urine.

The rate of reabsorption from renal tubules is influenced by factors such as pH and rate of urine flow in the renal tubules. Passive reabsorption of weak bases and acids is altered by urine pH, which influences the fraction of drug that exists in the ionized form. For example, weak acids are excreted more rapidly in alkaline urine. This occurs because alkalinization of the urine results in more ionized drug that cannot easily cross renal tubular epithelial cells, resulting in less passive reabsorption.

Renal blood flow is inversely correlated with age, as is creatinine clearance, which is closely related to GFR because creatinine is water-soluble and not resorbed in the tubules. Creatinine clearance can be predicted from age and weight according to the equation of Cockcroft and Gault⁹:

Men:

$$\text{Creatinine Clearance (mL/min)} = \frac{[140 - \text{age(years)}] \times \text{weight(kgs)}}{72 \times \text{serum creatinine (mg\%)}}$$

Women:

85% of the above equation.

Equation 2.8

[Equation 2.8](#) shows that age is an independent predictor of creatinine clearance. Elderly patients with normal serum creatinine have about half the GFR than younger patients. This can be seen graphically in [Figure 2.13](#).

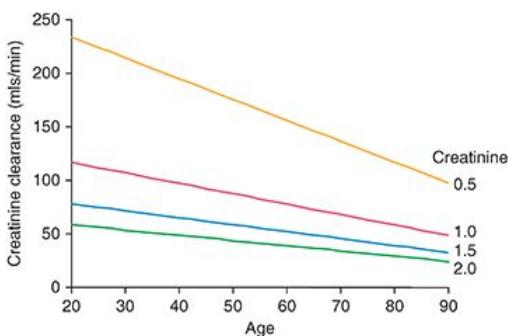

FIGURE 2.13 Creatinine clearance as a function of age and serum creatinine based on the equation of Cockcroft and Gault. *Derived from Cockcroft DW, Gault MH. Prediction of creatinine clearance from serum creatinine. Nephron. 1976;16:31-41.*

Absorption

Classically, pharmacokinetics is taught as “absorption, distribution, metabolism, and elimination.” Because most anesthetic drugs are administered intravenously, and inhaled anesthetic pharmacokinetics are discussed elsewhere, this order has been changed in this textbook to put absorption at the end of the list. Absorption is not particularly relevant for most anesthetic drugs.

Ionization

Most drugs are weak acids or bases that are present in both ionized and nonionized forms in solution. The nonionized molecule is usually lipid soluble and can diffuse across cell membranes including the blood–brain barrier, renal tubular epithelium, gastrointestinal epithelium, placenta, and hepatocytes ([Table 2.1](#)). As a result, it is usually the nonionized form of the drug that is pharmacologically active, undergoes reabsorption across renal tubules, is absorbed from the gastrointestinal tract, and is susceptible to hepatic metabolism. Conversely, the ionized fraction is poorly lipid soluble and cannot penetrate lipid cell membranes easily (see [Table 2.1](#)). A high degree of ionization thus impairs absorption of drug from the gastrointestinal tract, limits access to drug-metabolizing enzymes in the hepatocytes, and facilitates excretion of unchanged drug, as reabsorption across the renal tubular epithelium is unlikely.

TABLE 2.1

Characteristics of nonionized and ionized drug molecules

	Nonionized	Ionized
Pharmacologic effect	Active	Inactive

	Lipids	Water
Cross lipid barriers (gastrointestinal tract, blood–brain barrier, placenta)	Yes	No
Renal excretion	No	Yes
Hepatic metabolism	Yes	No

Determinants of Degree of Ionization

The degree of drug ionization is a function of its dissociation constant (pK) and the pH of the surrounding fluid. When the pK and the pH are identical, 50% of the drug exists in both the ionized and nonionized form. Small changes in pH can result in large changes in the extent of ionization, especially if the pH and pK values are similar. Acidic drugs, such as barbiturates, tend to be highly ionized at an alkaline pH, whereas basic drugs, such as opioids and local anesthetics, are highly ionized at an acid pH. Acidic drugs are usually supplied in a basic solution to make them more soluble in water and basic drugs are usually supplied in an acidic solution for the same reason, unless the pH affects drug stability, as is the case for most ester local anesthetics.

Ion Trapping

Because it is the nonionized drug that equilibrates across lipid membranes, a concentration difference of total drug can develop on two sides of a membrane that separates fluids with different pHs¹⁰ because the ionized concentrations will reflect the local equilibration between ionized and nonionized forms based on the pH. This is an important consideration because one fraction of the drug may be more pharmacologically active than the other fraction.

Systemic administration of a weak base, such as an opioid, can result in accumulation of ionized drug (ion trapping) in the acid environment of the stomach. A similar phenomenon occurs in the transfer of basic drugs, such as local anesthetics, across the placenta from mother to fetus because the fetal pH is lower than maternal pH. The lipid-soluble nonionized fraction of local anesthetic crosses the placenta and is converted to the poorly lipid-soluble ionized fraction in the more acidic environment of the fetus. The ionized fraction in the fetus cannot easily cross the placenta to the maternal circulation and thus is effectively trapped in the fetus. At the same time, conversion of the nonionized to ionized fraction maintains a gradient for continued passage of local anesthetic into the fetus. The resulting accumulation of local anesthetic in the fetus is accentuated by the acidosis that accompanies fetal distress.

The kidneys are the most important organs for the elimination of unchanged drugs or their metabolites. Water-soluble compounds are excreted more efficiently by the kidneys than are compounds with high lipid solubility. This emphasizes the important role of metabolism in converting lipid-soluble drugs to water-soluble metabolites. Drug elimination by the kidneys is correlated with endogenous creatinine clearance or serum creatinine concentration. The magnitude of change in these indices provides an estimate of the necessary change adjustment in drug dosage. Although age and many diseases are associated with a decrease in creatinine clearance and requirement for decreased dosing, pregnancy is associated with an increase in creatinine clearance and higher dose requirements for some drugs.

Ion trapping and extraction ratio featured, somewhat unexpectedly, in the trial of Conrad Murray for the death of Michael Jackson. The initial defense strategy was to blame Michael Jackson for his death, claiming that he drank a mixture of propofol and lidocaine when Conrad Murray stepped out of the room. We already know why the propofol claim is bogus. As discussed earlier, the extraction ratio for propofol is nearly 1. The extraction ratio does not care if the propofol enters the liver from the hepatic artery or portal vein. The liver will just as happily remove all the propofol from the portal vein as from the hepatic artery. As a result, any propofol that is swallowed will be metabolized in the liver before ever reaching the systemic circulation.

The defense also observed that the concentration of lidocaine in Michael Jackson's stomach was 22.9 $\mu\text{g}/\text{mL}$, far exceeding the concentration of lidocaine in Michael Jackson's blood of 0.8 $\mu\text{g}/\text{mL}$. Surely this was evidence that Michael Jackson drank a mixture of lidocaine and propofol! Nope. It is just ion trapping, nothing more.

We can quantitate the extent of ion trapping using the Henderson-Hasselbalch equation:

$$pH = pK_a + \log_{10} \left(\frac{[A^-]}{[HA]} \right)$$

Equation 2.9

This assumes that the dissociating moiety is an acid that releases a proton. However, lidocaine is a proton receptor, requiring we use the form of the Henderson-Hasselbalch equation adapted for bases:

$$pOH = pK_b + \log_{10} \left(\frac{[BH^+]}{[B]} \right)$$

Equation 2.10

where pOH is the negative logarithm (base 10) of the hydroxide ion concentration, pK_b is the base dissociation constant (readily calculated as $14 - pK_a$), $[B]$ is the concentration of the base (uncharged lidocaine), and $[BH^+]$ is the concentration of the conjugate acid (protonated lidocaine). We can rearrange the second equation to calculate the ratio of $[BH^+] / [B]$ as $10^{pOH - pK_b}$.

The pH of blood is 7.4, the pH of the stomach is 1 to 3.5, and the pK_a of lidocaine is 8.01. Therefore, the pOH of blood is 6.6, the pOH of the stomach is 10.5 to 13, and the pK_b of lidocaine is 5.99.

[Figure 2.14](#) was presented in pretrial testimony to explain the mathematics of ion trapping. The left shows blood, where the total lidocaine was measured on autopsy as 0.84 µg/mL. From the Henderson-Hasselbalch equation, we can calculate that the uncharged moiety was 0.17 µg/mL and the balance was charged. Because the uncharged moiety establishes equilibrium across gastric epithelium, we expect the lidocaine concentration in the stomach to be the same, 0.17 µg/mL. Knowing this, and the gastric pH, we can calculate the charged lidocaine concentration at equilibrium would have been 5,357 µg/mL, about 200 times higher than actually measured on autopsy. Of course, the system was not in equilibrium at the time of autopsy, which is why the stomach concentration was only 22.9 µg/mL, not 5,357 µg/mL. However, all that we know about Michael Jackson is that charged lidocaine accumulated in his stomach, exactly as expected from ion trapping.

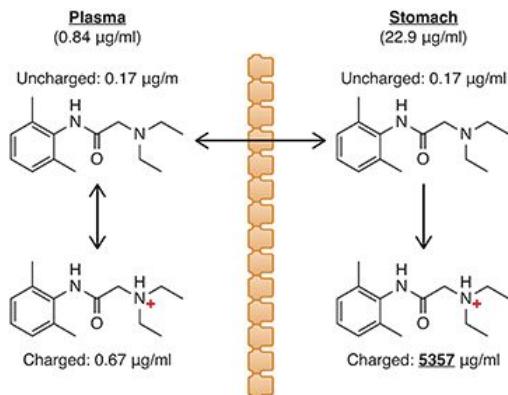

FIGURE 2.14 Ion trapping can result in significant sequestration of drugs based on local pH. The molecule shown is lidocaine, which has a nitrogen group that can accept protons in an acidic environment. Only neutrally charged lidocaine equilibrates across membranes. The figure is taken from the trial of Conrad Murray for the death of Michael Jackson. The defense claimed that the measured lidocaine concentration in the stomach, 22 µg/mL, proved that Mr. Jackson drank a mixture of lidocaine and propofol. However, the measured concentration can be entirely explained by ion trapping, which was not even close to the equilibrium concentration of 5,357 µg/mL.

Route of Administration and Systemic Absorption of Drugs

Drugs administered by intravenous injection or inhalation reach the systemic circulation almost instantly. However, for drugs not administered by these two routes, there is an initial delay between administering the

drug (eg, swallowing a pill or applying a patch) and appearance of the drug in the systemic circulation. The rate of systemic absorption determines the magnitude of the drug effect and duration of action. Changes in the rate of systemic absorption rate may require adjusting the dose or time interval between repeated drug doses.

Systemic absorption, regardless of the route of drug administration, depends on the drug's solubility. Local conditions at the site of absorption alter solubility, particularly in the gastrointestinal tract. Blood flow to the site of absorption also affects the rate of systemic transfer. For example, increased blood flow evoked by rubbing or applying heat at the subcutaneous or intramuscular injection site enhances systemic absorption, whereas decreased blood flow due to vasoconstriction impedes drug absorption. Finally, the area of the absorbing surface available for drug absorption is an important determinant of drug entry into the circulation.

Oral Administration

Oral administration of a drug is often the most convenient and inexpensive route of administration. Disadvantages of the oral route include (1) emesis caused by irritation of the gastrointestinal mucosa by the drug, (2) destruction of the drug by digestive enzymes or acidic gastric fluid, and (3) irregularities in absorption in the presence of food or other drugs. Furthermore, drugs may be metabolized by enzymes or bacteria in the gastrointestinal tract before systemic absorption can occur.

With oral administration, the onset of drug effect is largely determined by the rate and extent of absorption from the gastrointestinal tract. The principal site of most drug absorption after oral administration is the small intestine due to the large surface area of this portion of the gastrointestinal tract. Changes in the pH of gastrointestinal fluid that favor the presence of a drug in its nonionized (lipid-soluble) fraction thus favor systemic absorption. Some absorption occurs in the stomach, where the fluid is obviously acidic, enhancing the absorption of weak acids such as aspirin. However, most drug absorption occurs in the alkaline environment of the small intestine. The alkalinity enhances absorption of weak bases such as opioids, but even weak acids are mostly absorbed in the small intestine because of the large surface area.

First-Pass Hepatic Effect

Drugs absorbed from the gastrointestinal tract enter the portal venous blood and thus pass through the liver before entering the systemic circulation for delivery to tissue receptors. This is known as the **first-pass hepatic metabolism**. For drugs that undergo extensive hepatic extraction and metabolism (propranolol, lidocaine), it is the reason for large differences in the pharmacologic effect between oral and intravenous doses. As mentioned earlier, it is also the reason that propofol exerts no pharmacologic effect when swallowed—none gets past the liver.

Sublingual, Buccal, and Nasal Administration

The sublingual or buccal route of administration permits a rapid onset of drug effect because this blood bypasses the liver, preventing first-pass metabolism for the initial dose. Drugs absorbed from the oral cavity flow into the superior vena cava. Evidence of the value of bypassing the first-pass hepatic effect is the efficacy of sublingual nitroglycerin. Sublingual nitroglycerin works quickly, while oral nitroglycerin tablets are ineffective because of extensive first-pass hepatic metabolism. It is also why oral transmucosal fentanyl citrate results in a rapid rise in fentanyl concentration for “breakthrough” cancer pain where rapid onset of pain relief is clinically important. Oral fentanyl has an extraction ratio of about 50%, which greatly limits the utility of oral administration. Buccal administration is an alternative to sublingual placement of a drug; it is better tolerated and less likely to stimulate salivation. Buccal buprenorphine is an example of effective buccal administration.

The nasal mucosa also provides an effective absorption surface for certain drugs. For example, in 2019, the US Food and Drug Administration approved nasally administered s-ketamine for treatment resistant depression. Nasally administered naloxone is now widely available to emergency medical technicians for treatment of opioid overdose. The nasal route affords very rapid reversal of opioid overdose.

Transdermal Administration

Transdermal administration of drugs provides sustained therapeutic plasma concentrations of the drug and decreases the likelihood of loss of therapeutic efficacy due to peaks and valleys associated with conventional intermittent drug injections. This route of administration is devoid of the complexity of continuous infusion techniques, and the low incidence of side effects (because of the small doses used) contributes to high patient compliance. Characteristics of drugs that favor predictable transdermal absorption include (1) combined water and lipid solubility, (2) molecular weight of <1,000, (3) pH 5 to 9 in a saturated aqueous solution, (4) absence of histamine-releasing effects, and (5) daily dose requirements of <10 mg. Scopolamine, fentanyl, clonidine, estrogen, progesterone, and nitroglycerin can be delivered with commercially approved transdermal systems. For some drugs, such as scopolamine and nitroglycerine, the sustained plasma concentrations provided by transdermal absorption result in tolerance and loss of therapeutic effect.

The rate-limiting step in transdermal absorption of drugs is diffusion across the stratum corneum of the epidermis. Initial absorption occurs along sweat ducts and hair follicles that function as diffusion shunts. Differences in the thickness and chemistry of the stratum corneum are reflected in the skin's permeability to drug absorption. For example, skin may be 10 to 20 micron thick on the back and abdomen compared with 400 to 600 micron on the palmar surfaces of the hands. This explains part of the variability in transdermal delivery. This is the reason that scopolamine patches are placed behind the ear. It has nothing to do with the proximity to the semicircular canals. The postauricular zone, because of its thin epidermal layer and somewhat higher temperature, is the only region of skin sufficiently permeable for predictable and sustained absorption of scopolamine.

The stratum corneum sloughs and regenerates over about 7 days, placing an upper limit on the adhesion duration of transdermal delivery systems. Contact dermatitis at the site of transdermal patch applications occurs in a significant number of patients and is another reason to limit the duration of patch placement.

Rectal Administration

Drugs administered into the proximal rectum are absorbed into the superior hemorrhoidal veins and subsequently transported via the portal venous system to the liver. Thus, rectally administered drugs undergo the same first pass metabolism as orally administered drugs. However, if the drugs are placed more distal (eg, closer to the anus), then they may be absorbed directly into the systemic circulation, bypassing the liver. This is one of the reasons that rectal drug delivery is exceptionally unpredictable. Furthermore, drugs may cause irritation of the rectal mucosa. Patients have limited enthusiasm for this route of drug delivery.

Pharmacokinetic Models

In the following section, several common, useful pharmacokinetic models are derived. Although it is not necessary for every clinician to be able to derive these models, a consideration of where they come from takes them out of the "black box" and allows consideration of their representative parts.

Zero- and First-Order Processes

The consumption of oxygen and production of carbon dioxide are processes that happen at a constant rate.

These are called **zero-order processes**. The rate of change (dx/dt) for a zero-order process is $\frac{dx}{dt} = k$. This says the rate of change is constant. If x represents an amount of drug and t represents time, then the units of k are amount/time. If we want to know the value of x at time t , $x(t)$, we can compute it as the integral of this equation from time 0 to time t : $x(t) = x_0 + k \cdot t$, where x_0 is the value of x at time 0. This is the equation of a straight line with a slope of k and an intercept of x_0 .

Many processes occur at a rate proportional to the amount. For example, the interest payment on a loan is proportional to the outstanding balance. The rate at which water drains from a bathtub is proportional to amount (height) of water in the tub. These are examples of first-order processes. The rate of change in a first-

order process is only slightly more complex than for a zero-order process, $\frac{dx}{dt} = k \cdot x$. In this equation, x has units of amount, so the units of k are 1/time. The value of x at time t , $x(t)$, can be computed as the integral from time 0 to time t : $x(t) = x_0 e^{kt}$, where x_0 is the value of x at time 0. If $k > 0$, $x(t)$ increases exponentially to

infinity. If $k < 0$, $x(t)$ decreases exponentially to 0. In pharmacokinetics, k is negative because concentrations decrease over time. For clarity, the minus sign is usually explicit, so k is expressed as a positive number. Thus, the identical equation for pharmacokinetics, with the minus sign explicitly written, is

$$x(t) = x_0 e^{-kt}$$

Equation 2.11

Figure 2.15A shows the exponential relationship between x and time. X continuously decreases over time. Taking the natural logarithm of both sides of $x(t) = x_0 e^{-kt}$ gives

$$\begin{aligned}\ln[x(t)] &= \ln(x_0 \cdot e^{-kt}) \\ &= \ln(x_0) + \ln(e^{-kt}) \\ &= \ln(x_0) - k \cdot t\end{aligned}$$

Equation 2.12

This is the equation of a straight line, as shown in **Figure 2.15B**, where the vertical axis is $\ln[x(t)]$, the horizontal axis is t , the intercept is $\ln(x_0)$, and the slope of the line is $-k$. How long will it take for x to go from some value, x_1 , to half that value, $x_{1/2}$? Because k is the slope of a straight line relating $\ln(x)$ to time, it follows that

$$k = \frac{\Delta \ln(x)}{\Delta t} = \frac{\ln(x) - \ln\left(\frac{x}{2}\right)}{t_{1/2}} = \frac{\ln\left(\frac{x}{\left(\frac{x}{2}\right)}\right)}{t_{1/2}} = \frac{\ln(2)}{t_{1/2}} \approx \frac{0.693}{t_{1/2}}$$

Equation 2.13

where $t_{1/2}$ is the “half-life,” the time required for a 50% decrease in x . The natural log of 2 is close enough to 0.693 to be considered an equality in subsequent equations here.

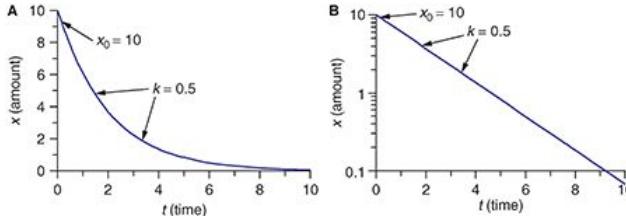

FIGURE 2.15 Exponential decay curve, as given by $x(t) = x_0 e^{-kt}$, plotted on standard axis (A) and a logarithmic axis (B).

Thus, the relationship of the slope (or “rate constant”), k , to half-life, $t_{1/2}$ is $k = \frac{0.693}{t_{1/2}}$. If we measure the time it takes for x to fall by 50%, $t_{1/2}$, then we know the rate constant, k . Conversely, if we know k , the rate constant, we can easily calculate the time it will take for x to fall by 50% as

$$t_{1/2} = \frac{0.693}{k}$$

Equation 2.14

Physiologic Pharmacokinetic Models

It is possible to analyze volumes and clearances for each organ in the body and construct models of pharmacokinetics by assembling the organ models into physiologically and anatomically accurate models of the entire animal. **Figure 2.16** shows such a model for thiopental in rats.¹¹ However, models that work with individual tissues are mathematically cumbersome and do not offer a better prediction of plasma drug

concentration than models that lump the tissues into a few compartments. If the goal is to determine how to give drugs in order to obtain therapeutic plasma drug concentrations, then all that is needed is to mathematically relate dose to plasma concentration. For this purpose, “compartmental” models are usually adequate.

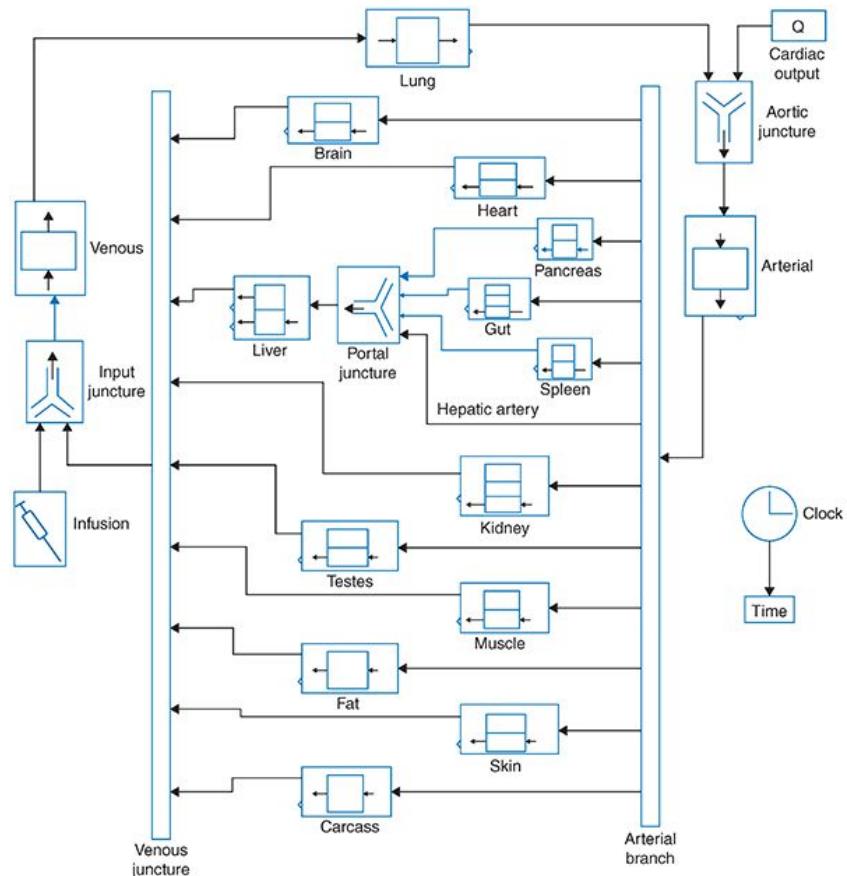

FIGURE 2.16 Physiologic model for thiopental in rats. The pharmacokinetics of distribution into each organ has been individually determined. The components of the model are linked by zero-order (flow) and first-order (diffusion) processes. Reprinted by permission from Springer: Ebling WF, Wada DR, Stanski DR. From piecewise to full physiologic pharmacokinetic modeling: applied to thiopental disposition in the rat. J Pharmacokinetic Biopharm. 1994;22(4):259-292. Copyright © 1994 Plenum Publishing Corporation.

Compartmental Pharmacokinetic Models

Compartmental models are built on the same basic concepts as physiologic models. The “one-compartment model” ([Figure 2.17A](#)) contains a single volume and a single clearance, as though we were buckets of fluid. For anesthetic drugs, we resemble several buckets connected by pipes. These are usually modeled using two- or three-compartment models ([Figure 2.17B,C](#)). The volume to the left in the two-compartment model and in the center of the three-compartment model is the central volume. This is the volume where we inject our intravenous drugs and also the volume we measure when we draw blood samples. The other volumes are peripheral volumes of distribution. The sum of the all volumes is the volume of distribution at steady state, Vd_{ss} . The clearance for drugs permanently removed from the central compartment is the “systemic clearance,” so named because it is the process that clears drug from the entire system. The clearances between the central compartment and the peripheral compartments are the “intercompartmental” clearances. Although the concept of compartments yields useful mathematics for planning dosing, when experimental animals were flash frozen at different times following administration of anesthetic drugs, and characterized

using physiologic models, none of the compartments identified in two and three compartment models could be anatomically identified.¹² Other than clearance, none of the parameters of compartment models readily translates into any anatomic structure or physiologic process.

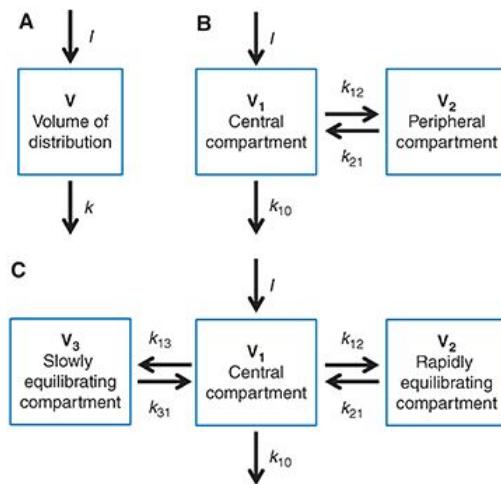

FIGURE 2.17 Standard one- (A), two- (B), and three-compartment (C) mammillary pharmacokinetic models. I represents any input into the system (eg, bolus or infusion). The volumes are represented by V and the rate constants by k . The subscripts on rate constants indicate the direction of flow, noted as $k_{\text{from to}}$.

One-Compartment Model

Bolus Pharmacokinetics

Returning to the one-compartment bucket, let us call the amount of drug poured into the bucket x_0 (x at time 0).

Remembering that the definition of concentration is amount divided by volume, by definition concentration immediately following a bolus dose, C_0 is:

$$C_0 = x_0/V$$

Equation 2.15

where x_0 is the amount at time 0 (i.e., the amount of the bolus dose) and V is the volume of the compartment. We can rearrange equation 2.15 to calculate the bolus dose for any desired target concentration, C_T :

$$\text{Dose} = C_T \times V$$

Equation 2.16

Let us assume that the fluid is being drained through a pipe at a constant rate, which we will call **clearance**, Cl . What is the rate, dx/dt , that drug x is leaving the bucket? It is the concentration of drug times the rate of flow through the pipe:

$$\frac{dx}{dt} = \text{Concentration} \cdot Cl = \frac{x}{V} \cdot Cl = x \cdot \frac{Cl}{V}$$

Equation 2.17

We will come back to this equation many times.

Because Cl/V is a constant, and the rate $x \times Cl/V$ is obviously proportional to x , $\frac{dx}{dt}$ is a first-order process. We know that a first order process can be expressed as $\frac{dx}{dt} = k x$. Since $\frac{dx}{dt} = x \frac{Cl}{V} = k x$, it follows that $k = \frac{Cl}{V}$. This can be rearranged to yield a fundamental identity of linear pharmacokinetics:

$$Cl = k \times V$$

Equation 2.18

What does this identity tell us about the relationship between half-life, volume, and clearance? Rearranging the above equation as $k = \frac{Cl}{V}$ and remembering that $t_{1/2} = \frac{0.693}{k}$, we can conclude that half-life is proportional to volume and inversely proportional to clearance.

$$t_{1/2} = 0.693 \frac{V}{Cl}$$

Equation 2.19

Consider two alternative models, one with a large volume and a small clearance ([Figure 2.18A](#)), and one with a small volume and a large clearance ([Figure 2.18B](#)). It is (hopefully) intuitively obvious that following bolus injection, concentrations will fall more quickly (shorter half-life) with the larger clearance and smaller volume as predicted by [Equation 2.16](#) and shown in [figure 2.18B](#).

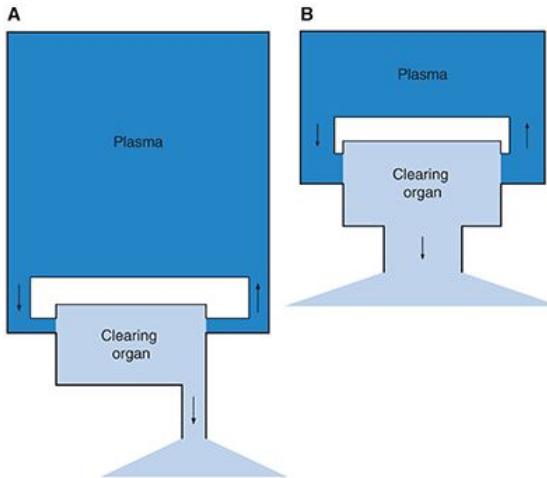

FIGURE 2.18 The relationship between volume and clearance and half-life can be envisioned by considering two settings: a big volume and a small clearance (A) and a small volume with a big clearance (B). Drug will be eliminated faster in the latter case.

Because this is a first-order process, let us calculate the concentration of drug that remains in the bucket as drug is being cleared following bolus injection. Using the equation that describes first-order processes, $x(t) = x_0 e^{-kt}$, $x(t)$ is the amount of drug at time t , x_0 is the amount of drug right after bolus injection, and k is the rate constant (Cl/V). If we divide both sides by V , and remember that x/V is the definition of concentration, we get the equation that relates concentration following an intravenous bolus to time and initial concentration:

$$C(t) = C_0 e^{-kt}$$

Equation 2.20

This equation defines the “concentration over time” curve for a one-compartment model after a bolus of drug and has the log linear shape seen in [Figure 2.15B](#).

In a typical experiment, we start with the concentrations, as seen in [Figure 2.15](#), and calculate clearance in one of two ways. First, we can calculate V by rearranging the definition of concentration, $V = \text{dose}/\text{initial concentration} = \text{dose}/C_0$. If you know the dose and you measure C_0 in the experiment, you can calculate V . If you then fit the log (C) line versus time line to a straight line, you can directly measure the slope, $-k$. You can then calculate clearance as $k \cdot V$.

A more general solution is to consider the integral of the concentration over time curve, $C(t) = C_0 e^{-kt}$, known in pharmacokinetics as the area under the curve, or AUC:

$$\begin{aligned} AUC &= \int_0^{\infty} C_0 e^{-kt} dt \\ &= \int_0^{\infty} \frac{x_0}{V} \left(e^{-\frac{Cl}{V}t} \right) dt \text{ (substituting for } C_0 \text{ and } k) \\ &= \frac{x_0}{V} \times \frac{V}{Cl} \text{ (evaluating the above integral)} \\ &= \frac{x_0}{Cl} \end{aligned}$$

Equation 2.21

We can rearrange the right side and the last term on the left side to solve for clearance, Cl :

$$Cl = \frac{x_0}{AUC}$$

Equation 2.22

Because x_0 is the dose of drug, clearance equals the dose divided by the AUC. This fundamental property of *linear* pharmacokinetic models applies to one-compartment models, to multicompartment models, and to any type of intravenous drug dosing (provided the *total* dose administered is used as the numerator). It directly follows that AUC is proportional to dose for linear models (ie, models where Cl is constant).

The term *linear pharmacokinetics* has been used multiple times, starting with [Figure 2.9](#) showing that in the “linear” portion, metabolism was clearly proportional to concentrations. Now that the basic concepts have been introduced, we can define “linear” more precisely. If metabolism is proportional to concentration, as

seen in [Figure 2.9](#), then metabolism, defined as $\frac{dx}{dt}$ is therefore a first-order process defined by a rate constant $k = \frac{Cl}{V}$. Since k is constant, and V is constant, then clearance, Cl , must also be constant. In other words, clearance does not change with dose, concentration, time, or anything else. When clearance is constant, the pharmacokinetics are said to be “linear” because a linear (eg, proportional) increase in dose results in a linear (eg, proportional) increase in concentration. More intuitively stated, if you double the dose, you double the concentration. It also means that if you give a dose now, and another dose in an hour, the concentrations after the second dose what you would expect from the second dose alone, “linearly” added to the residual concentrations from the first dose. This is also called the principle of superposition.

Occasionally the term *linear* is confusing because the curves of concentration over time are typically exponentially increasing or decreasing rather than straight lines. That is not what linear implies because concentrations over time are virtually never straight lines. Linear pharmacokinetics are “linear” with respect to *dose*, but never with respect to time.

Infusion Pharmacokinetics

If you give an infusion at a rate of I (for *Input*), the plasma concentration will rise as long as the rate of drug going into the body, I , exceeds the rate at which drug leaves the body, $C \cdot Cl$, where C is the drug concentration. Once, $I = C \cdot Cl$, drug is going in and coming out at the same rate, and the body is at steady

state. We can calculate the concentration at steady state by observing that the rate of drug going in must equal the rate of drug coming out. At steady state, the drug concentration is C_{ss} . Based on [Equation 2.17](#), drug is leaving the system at the rate $C_{ss} \cdot Cl$. Because at steady state, the infusion rate equals the metabolic rate, the infusion rate, I , must therefore equal the metabolic rate, $C_{ss} \cdot Cl$.

This can be rearranged to give the concentration of drug at steady state during an infusion:

$$C_{ss} = \frac{I}{Cl}$$

Equation 2.23

Thus, the steady-state concentration during an infusion is the rate of drug input divided by the clearance. It follows that if we want to calculate the infusion rate that will achieve a given target concentration, C_T , at steady state, then the infusion rate must be $C_T \cdot Cl$.

$C_{ss} \cdot \frac{I}{Cl}$ is similar in form to the equation describing the concentration following a bolus injection: $C_0 = \frac{x_0}{V}$ as shown in [equation 2.15](#). Thus, volume is a scalar relating bolus dose to initial concentration, and clearance is a scalar relating infusion rate to steady-state concentration. It follows that the initial concentration following a bolus is independent of the clearance, and the steady-state concentration during a continuous infusion is independent of the volume.

During an infusion, the rate of change in the amount of drug, x , is rate of inflow, I , minus the rate of outflow, $k \cdot x$, which is represented as $\frac{dx}{dt} = I - kx$. We can calculate x at any time t as the integral from time 0 to time t . Assuming that we are starting with no drug in the body (ie, $x_0 = 0$), the result is $x(t) = \frac{I}{k}(1 - e^{-kt})$. If we divide both sides by volume, V , and remember that $Cl = k \cdot V$, we can solve this equation for concentration: $C(t) = \frac{I}{Cl}(1 - e^{-kt})$. This is the equation for concentration during an infusion in a one-compartment model.

As $t \rightarrow \infty$, $e^{-kt} \rightarrow 0$, the equation $x(t) = \frac{I}{k}(1 - e^{-kt})$ reduces to $x_{ss} = \frac{I}{k}$. During an infusion, the amount in the body approaches x_{ss} (steady state) asymptotically, only reaching it at infinity. However, we can calculate how

long it takes to get to half of the steady-state amount, $\frac{x_{ss}}{2}$. If $x_{ss} = \frac{I}{k}$, then $\frac{x_{ss}}{2} = \frac{I}{2k}$. Because $\frac{I}{2k}$ is the amount of drug when we are halfway to steady state, we can substitute that for the amount of drug in our formula, $x(t) = \frac{I}{k}(1 - e^{-kt})$, giving us $\frac{I}{2k} = \frac{I}{k}(1 - e^{-kt})$, and solve that for t . The solution is $t_{1/2} = \frac{\ln(2)}{k}$. This is the time to rise to half of the steady state concentration. Recall that $t_{1/2}$, the half time to decrease to 0 following a bolus

injection, was $\frac{\ln(2)}{k}$. We again have a parallel between boluses and infusions. Following a bolus, it takes 1 half-life to reduce the concentrations by half, and during an infusion, it takes 1 half-life to increase the concentration halfway to steady state. Similarly, it takes 2 half-lives to reach 75%, 3 half-lives to reach 87.5%, and 5 half-lives to reach 97% of the steady-state concentration. By 4 to 5 half-lives, we typically consider the patient to be at steady state, although the concentrations only asymptotically approach the steady-state value.

Absorption Pharmacokinetics

When drugs are given intravenously, every molecule reaches the systemic circulation. When drugs are given by a different route, such as orally, transdermally, or intramuscularly, the drug must first reach the systemic circulation. Oral drugs may be only partly absorbed. What is absorbed then has to get past the liver (“first-pass hepatic metabolism”) before reaching the systemic circulation. Transdermally applied drugs may be rubbed off, removed with soap or alcohol, or be sloughed off with the stratum corneum without being

absorbed. The dose of drug that eventually reaches the systemic circulation with alternative routes of drug delivery is the administered dose times f , the fraction “bioavailable.”

Alternative routes of drug delivery are often modeled by assuming the drug is absorbed from a reservoir or depot, usually modeled as an additional compartment with a monoexponential rate of transfer to the systemic circulation, $A(t) = f \cdot D_{\text{oral}} \cdot k_a \cdot e^{-k_a t}$, where $A(t)$ is the absorption rate at time t , f is the fraction bioavailable, D_{oral} is the dose taken orally (or intramuscularly, applied to the skin, etc). The k_a is the absorption rate constant. Because the integral of $e^{-k_a t}$ is 1, the total amount of drug absorbed is $f \cdot D_{\text{oral}}$. To compute the concentrations over time, we first reduce the problem to differential equations and integrate. The differential equation for the amount, x , with oral absorption into a one-compartment disposition model is

$$\frac{dx}{dt} = \text{inflow} - \text{outflow} = A(t) - k \cdot x = \\ f \cdot D_{\text{oral}} \cdot k_a \cdot e^{-k_a t} - k \cdot x$$

Equation 2.24

This is simply the rate of absorption at time t , $A(t)$, minus the rate of exit, $k \cdot x$. The amount of drug, x , in the compartment at time t is the integral of this from 0 to time t :

$$x(t) = \frac{D_{\text{oral}} f k_a}{k - k_a} (e^{-k_a t} - e^{-kt})$$

Equation 2.25

This equation describes the amount of drug in the systemic circulation following first-order absorption from a depot, such as the stomach, an intramuscular injection, the skin, or even an epidural dose. To describe the concentrations, rather than amounts of drug, it is necessary to divide both sides by V , the volume of distribution.

Multicompartment Models

The previous section used one-compartment model to introduce concepts of rate constants and half-lives and relate them to the physiologic concepts of volume and clearance. Unfortunately, none of the drugs used in anesthesia can be accurately characterized by one-compartment models because anesthetic drugs distribute extensively into peripheral tissues. To describe the pharmacokinetics of intravenous anesthetics, we must extend the one-compartment model to account for this distribution.

The plasma concentrations over time following an intravenous bolus resemble the curve in [Figure 2.19](#). In contrast to [Figure 2.15](#), [Figure 2.19](#) is not a straight line even though it is plotted on a log y-axis. This curve has the characteristics common to most drugs when given by intravenous bolus. First, the concentrations continuously decrease over time. Second, the rate of decline is initially steep but becomes less steep over time until we get to a portion that is “log-linear.”

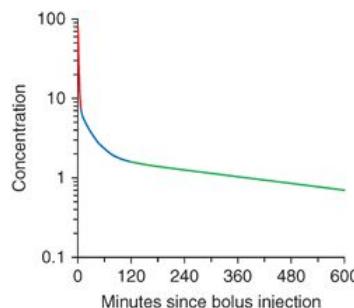

FIGURE 2.19 Typical time course of plasma concentration following bolus injection of an intravenous drug, with a rapid phase (red), an intermediate phase (blue), and a slow log-linear phase (green). The simulation was performed with the pharmacokinetics of fentanyl. *Reprinted with permission from Scott JC,*

Stanski DR. Decreased fentanyl and alfentanil dose requirements with age. A simultaneous pharmacokinetic and pharmacodynamics evaluation. J Pharmacol Exp Ther. 1987;240(1):159-166. Copyright © 1987 by The American Society for Pharmacology and Experimental Therapeutics.

Many anesthetic drugs appear to have three distinct phases, as suggested by [Figure 2.19](#). There is a “rapid distribution” phase (red in [Figure 2.19](#)) that begins immediately after bolus injection. Very rapid movement of the drug from the plasma to the rapidly equilibrating tissues characterizes this phase. Often, there is a second “slow distribution” phase (blue in [Figure 2.19](#)) that is characterized by movement of drug into more slowly equilibrating tissues and return of drug to the plasma from the most rapidly equilibrating tissues. The terminal phase (green in [Figure 2.19](#)) is a straight line when plotted on a semilogarithmic graph. The distinguishing characteristic of the terminal elimination phase is that the plasma concentration is lower than the tissue concentrations, and the relative proportion of drug in the plasma and peripheral volumes of distribution remains constant. During this “terminal phase,” drug returns from the rapid and slow distribution volumes to the plasma and is permanently removed from the plasma by metabolism or excretion.

The presence of three distinct phases following bolus injection is a defining characteristic of a mammillary model with three compartments. (A mammillary model consists of a central compartment with peripheral compartments connecting to it. There are no interconnections among other compartments.) It is possible to develop “hydraulic” models, as shown in [Figure 2.20](#), for intravenous drugs.¹³ In this model, there are three tanks, corresponding (from left to right) with the slowly equilibrating peripheral compartment, the central compartment (the plasma, into which drug is injected), and the rapidly equilibrating peripheral compartment. The horizontal pipes represent intercompartmental clearance or (for the pipe draining onto the page) metabolic clearance. The volumes of each tank correspond with the volumes of the compartments for fentanyl. The cross-sectional areas of the pipes correlate with fentanyl systemic and intercompartmental clearances. The height of water in each tank corresponds to drug concentration.

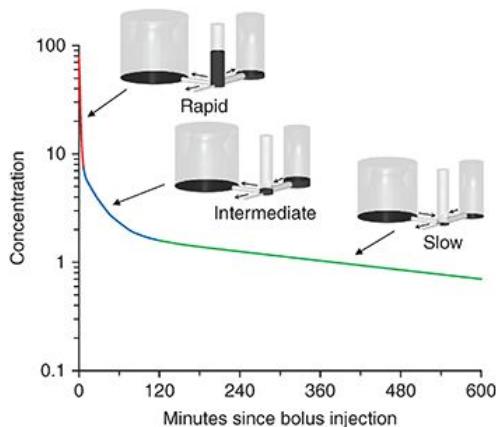

FIGURE 2.20 Hydraulic equivalent of the model in [Figure 2.19](#). Adapted with permission from Youngs EJ, Shafer SL. Basic pharmacokinetic and pharmacodynamic principles. In: White PF, ed. Textbook of Intravenous Anesthesia. Baltimore, MD: Lippincott Williams & Wilkins; 1997:10.

We can follow the processes that decrease drug concentration over time following bolus injection. Initially, drug flows from the central compartment to both peripheral compartments and is eliminated via the drain pipe through metabolic clearance. Because there are three places for drug to go, the central compartment concentration decreases very rapidly. At the transition between the red and the blue lines, there is a change in the role of the most rapidly equilibrating compartment. At this transition, the central compartment concentration falls below the concentration in the rapidly equilibrating compartment, and the direction of flow between them is reversed. After this transition (blue line), drug in the plasma only has two places to go: the slowly equilibrating compartment or out the drain pipe. These processes are partly offset by the return of drug to the plasma from the rapidly equilibrating compartment, which slows the decrease in plasma concentration. Once the concentration in the central compartment falls below both the rapidly and

slowly equilibrating compartments (*green line*), then the only method of decreasing the plasma concentration is clearance out the drain pipe. Drug accumulated in the rapidly and slowly equilibrating compartments acts as an enormous drag on the system, and the little drain pipe now is working against the entire body store of drug.

Curves that continuously decrease over time, with a continuously increasing slope (ie, curves that look like [Figures 2.19](#) and [2.20](#)), can be described by a sum of negative exponentials, as shown in [Figure 2.21](#), which shows how three single exponential curves are added together to get a sum of exponentials that describes the plasma concentrations over time after bolus injection:

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$$

Equation 2.26

where t is the time since the bolus; $C(t)$ is the drug concentration following a bolus dose; and A , α , B , β , C , and γ are parameters of a pharmacokinetic model. A , B , and C are called **coefficients**, whereas α , β , and γ are called **exponents**. Following a bolus injection, all six of the parameters (A , α , B , β , C , and γ) will be greater than 0.

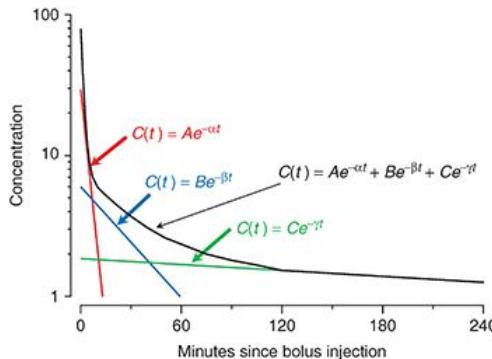

FIGURE 2.21 The polyexponential equation that describes the decline in plasma concentration for most intravenous anesthetics is the algebraic sum of the exponential terms that represent rapid phase shown in red, intermediate phase shown in blue and slow phase shown in green.

The main reason that polyexponential equations are used is that they work. These equations describe reasonably accurately the plasma concentrations observed after bolus injection, except for the misspecification in the first few minutes mentioned previously.

Polyexponential equations permit us to use the one-compartment ideas just developed, with some generalization of the concepts. $C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$ says that the concentrations over time are the algebraic sum of three separate functions, $Ae^{-\alpha t}$, $Be^{-\beta t}$, and $Ce^{-\gamma t}$. Typically, $\alpha > \beta > \gamma$ by about 1 order of magnitude. At time 0 ($t = 0$), [Equation 2.22](#) reduces to $C_0 = A + B + C$. In other words, the sum of the coefficients A , B , and C equals the concentration immediately following a bolus. It thus follows that $A + B + C = \text{bolus amount} / V_1$.

Constructing pharmacokinetic models represents a trade-off between accurately describing the data, having confidence in the results, and mathematical tractability. Adding exponents to the model usually provides a better description of the observed concentrations. However, adding more exponent terms usually decreases our confidence in how well we know each coefficient and exponential and *greatly* increases the mathematical burden of the models. This is why most pharmacokinetic models are limited to two or three exponents.

Polyexponential models can be mathematically transformed from the admittedly unintuitive exponential form $C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$ to a more easily visualized compartmental form, as shown in [Figures 2.17](#) and [2.20](#). Micro-rate constants, expressed as k_{ij} , define the rate of drug transfer from compartment i to

compartment j. Compartment 0 is the compartment outside the model, so k_{10} is the micro-rate constant for irreversible removal of drug from the central compartment (analogous to k for a one-compartment model).

The intercompartmental micro-rate constants (k_{12} , k_{21} , etc) describe the movement of drug between the central and peripheral compartments. Each peripheral compartment has two micro-rate constants, one for drug entry and one for drug exit. The micro-rate constants for the two- and three-compartment models can be seen in [Figure 2.17](#). The differential equations describing the rate of change for the amount of drug in compartments 1, 2, and 3 follow directly from the micro-rate constants. For the two-compartment model, the differential equations for each compartment are as follows:

$$\begin{aligned}\frac{dx_1}{dt} &= I + x_2 k_{21} - x_1 k_{10} - x_1 k_{12} \\ \frac{dx_2}{dt} &= x_1 k_{12} - x_2 k_{21}\end{aligned}$$

Equation 2.27

where I is the rate of drug input. For the three-compartment model, the differential equations for each compartment are as follows:

$$\begin{aligned}\frac{dx_1}{dt} &= I + x_3 k_{31} + x_2 k_{21} - x_1 k_{10} - x_1 k_{12} - x_1 k_{13} \\ \frac{dx_2}{dt} &= x_1 k_{12} - x_2 k_{21} \\ \frac{dx_3}{dt} &= x_1 k_{13} - x_3 k_{31}\end{aligned}$$

Equation 2.28

For the one-compartment model, k was both the rate constant and the exponent. For multicompartment models, the relationships are more complex. The interconversion between the micro-rate constants and the exponents becomes exceedingly complex as more exponents are added because every exponent is a function of every micro-rate constant and vice versa. Individuals interested in such interconversions can find them in the Excel spreadsheet “convert.xls,” which can be downloaded from <https://github.com/StevenLShafer/Pharmacokinetics/blob/master/convert.xls>. This is useful because publications on pharmacokinetics may use one or another system, and it is difficult to compare without converting the exponents to micro-rate constants.

The Time Course of Drug Effect

The plasma is not the site of drug effect for anesthetic drugs. There is a time lag between plasma drug concentration and effect site drug concentration. Consider the different rate of onset for fentanyl and alfentanil. [Figure 2.21](#) is from work by Stanski and colleagues.^{14,15} The black bar in [Figure 2.22A](#) shows the duration of a fentanyl infusion.¹⁴ Rapid arterial samples document the rise in fentanyl concentration. The time course of electroencephalogram effect (spectral edge) lags 2 to 3 minutes behind the rapid rise in arterial concentration. This lag is called **hysteresis**. The plasma concentration peaks at the moment the infusion is turned off. Following the peak plasma concentration (and the Disney logo that appears at peak plasma concentration), the plasma fentanyl concentration rapidly decreases. However, the offset of fentanyl drug effect lags well behind the decrease in plasma concentration. [Figure 2.22B](#) shows the same study design in a patient receiving alfentanil. Because of alfentanil’s rapid blood–brain equilibration, there is less hysteresis (delay) with alfentanil than with fentanyl.

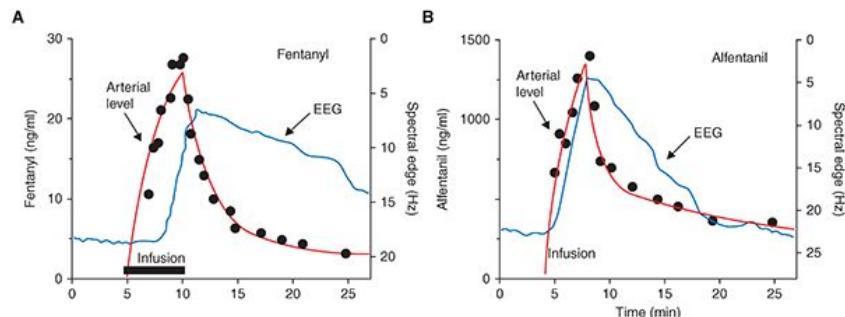

FIGURE 2.22 Fentanyl and alfentanil arterial concentrations (circles) and electroencephalographic (EEG) response (irregular line) to an intravenous infusion. Alfentanil shows a less time lag between the rise and fall of arterial concentration and the rise and fall of EEG response than fentanyl because it equilibrates with the brain more quickly. *Reprinted with permission from Scott JC, Ponganis KV, Stanski DR. EEG quantitation of narcotic effect: the comparative pharmacodynamics of fentanyl and alfentanil. Anesthesiology. 1985;62(3):234-241. Copyright © 1985 American Society of Anesthesiologists, Inc.*

The relationship between the plasma and the site of drug effect is modeled with an “effect site” model, as shown in [Figure 2.23](#).¹⁶ The site of drug effect is connected to the plasma by a first-order process. The equation that relates effect site concentration to plasma concentration is

$$\frac{dCe}{dt} = k_{e0} \cdot Cp - k_{e0} \cdot Ce$$

Equation 2.29

where Ce is the effect site concentration and Cp is the plasma drug concentration. k_{e0} is the rate constant for elimination of drug from the effect site. It is most easily understood in terms of its reciprocal, $0.693/k_{e0}$, the half-time for equilibration between the plasma and the site of drug effect.

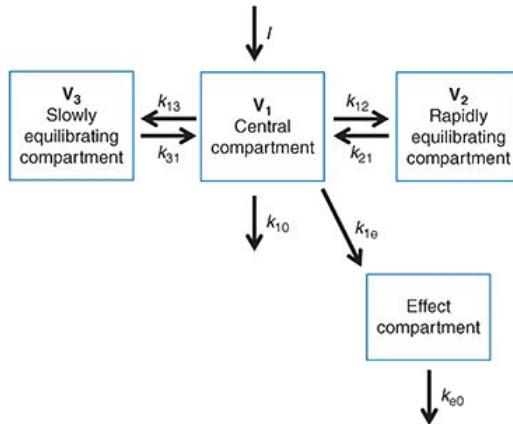

FIGURE 2.23 The three-compartment model from [Figure 2.16](#) with an added effect site to account for the equilibration delay between the plasma concentration and the observed drug effect. The effect site has a negligible volume. As a result, the only parameter that affects the delay is k_{e0} .

[Figure 2.24](#) shows the plasma and effect site concentrations predicted by the model (see [Figure 2.22](#)) for fentanyl and alfentanil. The plasma concentrations (*black lines*) are not very different. However, the effect site concentrations (*red lines*) show that alfentanil equilibrates more quickly. There are two consequences. First, the peak effect is sooner (obviously). Second, the rapid equilibration of alfentanil allows the brain to “see” the initial high plasma concentrations, producing a relatively greater rise in effect site concentrations than observed with fentanyl. This permits alfentanil to deliver relatively more “bang” for a bolus.

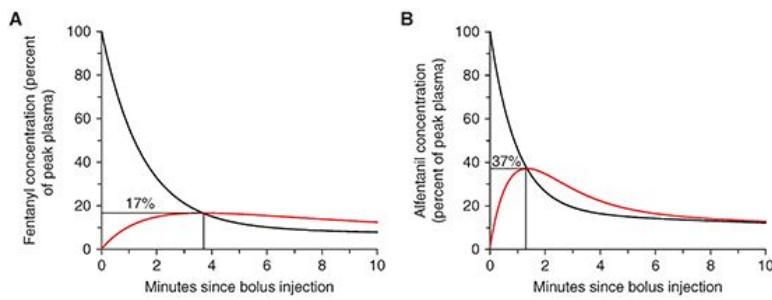

FIGURE 2.24 Plasma (black line) and effect site (red line) concentrations following a bolus dose of fentanyl (A) or alfentanil (B). Adapted with permission from Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics, and rational opioid selection. *Anesthesiology*. 1991;74(1):53-63. Copyright © 1991 American Society of Anesthesiologists, Inc.

The constant k_{e0} has a large influence on the rate of rise of drug effect, the rate of offset of drug effect, the time to peak effect,¹⁷ and the dose that is required to produce the desired drug effect.

Dose Calculations

Bolus Dosing

We noted previously that we can rearrange the definition of concentration to find the amount of drug required to produce any desired target concentration for a known volume, amount = $C_T \times$ volume. Many introductory pharmacokinetic texts suggest using this formula to calculate the loading bolus required to achieve a given concentration. The problem with applying this concept to the anesthetic drugs is that there are several volumes: V_1 (central compartment); V_2 and V_3 (the peripheral compartments); and Vd_{ss} , the sum of the individual volumes. V_1 is usually much smaller than Vd_{ss} , and so it is tempting to say that the loading dose should be something between $C_T \times V_1$ and $C_T \times Vd_{ss}$.

That proves to be a useless suggestion. Consider the initial dose of fentanyl. The C_{50} for fentanyl to attenuate hemodynamic response to intubation (when combined with an intravenous hypnotic) is approximately 2 ng/mL. The V_1 and Vd_{ss} for fentanyl are 13 L and 360 L, respectively. The dose of fentanyl thus ranges from a low of 26 µg (based on the V_1 of 13 L) to a high 720 µg (based on the Vd_{ss} of 360 L). A fentanyl bolus of 26 µg achieves the desired concentration in the plasma for an initial instant (Figure 2.25). Unfortunately, the plasma levels almost instantly decrease below the desired target, and the effect site levels are never close to the desired target. A fentanyl bolus of 720 µg, not surprisingly, produces an enormous overshoot in the plasma levels that persists for hours. It is absurd to use equations to calculate the fentanyl dose if the resulting recommendation is “pick a dose between 26 and 720 µg.”

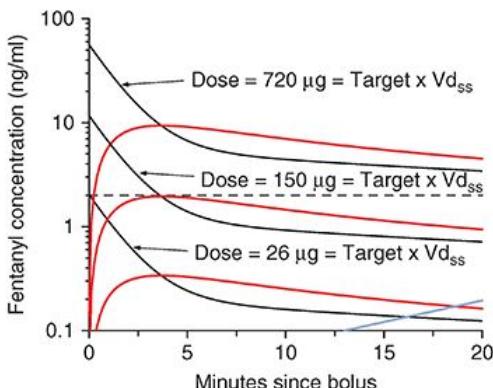

FIGURE 2.25 The volume of the central compartment of fentanyl is 13 L. The volume of distribution at steady state is 360 L. For a target concentration of 2 µg/L (dotted line), the dose calculated on V_1 , 26 µg, results in a substantial undershoot. The dose calculated using Vd_{ss} , 720 µg, produces a profound overshoot.

Only a dose based on $Vd_{peak\ effect}$, 150 µg, produces the desired concentration in the effect site. The black lines show plasma concentration over time. Red lines show effect site concentration over time.

Conventional approaches to calculate a bolus dose are designed to produce a specific *plasma* concentration. This makes little sense because the plasma is not the site of drug effect. By knowing the k_{e0} (the rate constant for elimination of drug from the effect site) of an intravenous anesthetic, we can design a dosing regimen that yields the desired concentration *at the site of drug effect*. If we do not want to overdose the patient, we should select the bolus that produces the desired peak concentration in the effect site.

The decline in plasma concentration after the bolus, up to the time of peak effect, can be thought of as a dilution of the bolus into a larger volume than the volume of the central compartment. One interesting characteristic of the equilibration between the plasma and the effect site is that at the time of peak effect, the plasma and the effect site concentrations are the same (if they were not the same, then it would not be the peak because there would be a gradient driving drug in or out of the effect site). This introduces the concept of Vd_{pe} , the apparent volume of distribution at the time of peak effect.¹⁸ The size of this volume can be readily calculated from the observation that the plasma and effect site concentrations are the same at the time of peak effect:

$$Vd_{pe} = \frac{\text{bolus amount}}{C_{pe}}$$

Equation 2.30

where C_{pe} is the plasma concentration at the time of peak effect. We can arrange this equation to calculate the dose that provides the desired peak effect site concentration: bolus dose = $C_T \times Vd_{pe}$. For example, the Vd_{pe} for fentanyl is 75 L. Producing a peak fentanyl effect site concentration of 2 ng/mL requires 150 µg for the typical patient, which produces a peak effect in 3.6 minutes. This is a much more reasonable dosing guideline than the previous recommendation of picking a dose between 26 and 760 µg. **Table 2.2** lists V_1 and Vd_{pe} for fentanyl, alfentanil, sufentanil, remifentanil, propofol, thiopental, and midazolam. **Table 2.3** lists the time to peak effect and the $t_{1/2} k_{e0}$ (half-life at the site of drug effect) of the commonly used intravenous anesthetics. Of course, individuals may differ from the typical patient. The individual characteristics that drive the differences may be known (age, weight, renal or hepatic dysfunction) in which case they can be built into the pharmacokinetic model if they are found to be significant. On the other hand, they may be unknown, in which case pharmacodynamic monitoring is required to fine tune dosing.

TABLE 2.2
Volume of distribution at the time of peak effect^a

Drug	V_1 (L)	Vd_{pe} (L)
Fentanyl	12.7	75
Alfentanil	2.19	5.9
Sufentanil	17.8	89
Remifentanil	5.0	17
Propofol	6.7	37
Thiopental	5.6	14.6
Midazolam	3.4	31

Abbreviations: V_1 , volume of the central compartment; Vd_{pe} , apparent volume of distribution at the time of peak effect.

^b $t_{1/2} k_{e0} = 0.693/k_{e0}$, the effect site half-life, where k_{e0} is the rate constant for elimination of drug from the site of drug effect and $t_{1/2} k_{e0}$ is the time required for the concentration at the site of drug effect to fall to half of its value.

Maintenance Infusion Rate

As explained previously, to maintain a given target concentration, C_T , drug must be delivered at the same rate that drug is exiting the body. Thus, the maintenance infusion rate at steady state is maintenance infusion rate = $C_T \times Cl$. However, this equation only applies after peripheral tissues have fully equilibrated with the plasma, which may require many hours. At all other times, this maintenance infusion rate underestimates the infusion rate to maintain a target concentration.

In some situations, this simple rate calculation may be acceptable. For example, if an infusion at this rate is used after a bolus based on Vd_{pe} (apparent volume of distribution at time of peak effect), and the drug has a long delay between the bolus and peak effect, then much of the distribution of drug into the tissues may have occurred by the time of peak effect site concentration. In this case, the maintenance infusion rate calculated as clearance times target concentration may be satisfactory because Vd_{pe} is sufficiently higher than V_1 to account for the distribution of drug into peripheral tissues. Unfortunately, most drugs used in anesthesia have sufficiently rapid plasma-effect site equilibration that Vd_{pe} does not adequately encompass the distribution process, making this approach unsuitable.

The pharmacokinetically sound approach should account for tissue distribution. Initially, the infusion rate is higher than $C_T \cdot Cl$ because it is necessary to replace the drug that gets taken up by peripheral tissues. However, the net flow of drug into peripheral tissues decreases over time. Therefore, the infusion rate required to maintain any desired concentration must also decrease over time. Following bolus injection, the equation to maintain the desired concentration is:

$$\text{Maintenance infusion rate} = C_T \times V_1 \times (k_{10} + k_{12}e^{-k_{21}t} + k_{13}e^{-k_{31}t})$$

Equation 2.31

This equation indicates that a high infusion rate is initially required to maintain C_T . Over time, the infusion rate gradually decreases ([Figure 2.26](#)). At equilibrium ($t = \infty$), the infusion rate decreases to $C_T V_1 k_{10}$, which is the same as $C_T \times Cl$.

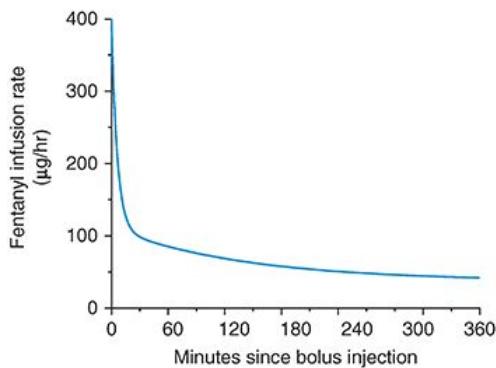

FIGURE 2.26 Fentanyl infusion rate to maintain a plasma concentration of 1 μg per hour. The rate starts off quite high because fentanyl is avidly taken up by body fat. The necessary infusion rate decreases as the fat equilibrates with the plasma.

No anesthetic in history has ever been so boring as to merit mentally solving such an equation while administration of an anesthetic. Fortunately, there are simple techniques that can be used in place of solving such a complex expression.

[Figure 2.27](#) is a nomogram in which the [Equation 2.14](#) has been solved, showing the infusion rates over time necessary to maintain any desired concentration of fentanyl, alfentanil, sufentanil, and propofol. This nomogram is complex, and we don't use it even though one of us (SLS) created this nomogram. The point in including it is to show how infusion rates must be turned down over time as drug accumulates. The y -axis represents the target concentration, C_T . The suggested target initial concentrations (shown in red) are based on the work of Vuyk and colleagues¹⁹ and appropriately scaled for fentanyl and sufentanil. The x -axis is the time since the beginning of the anesthetic. The intersections of the target concentration line and the diagonal lines indicates the infusion rate appropriate at each point in time. For example, to maintain a fentanyl concentration of 1.0 ng/mL, the appropriate rates are 3.0 $\mu\text{g}/\text{kg}/\text{hour}$ at 15 minutes, 2.4 $\mu\text{g}/\text{kg}/\text{hour}$ at 30 minutes, 1.8 $\mu\text{g}/\text{kg}/\text{hour}$ at 60 minutes, 2.1 $\mu\text{g}/\text{kg}/\text{hour}$ at 120 minutes, and 0.9 $\mu\text{g}/\text{kg}/\text{hour}$ at 180 minutes.

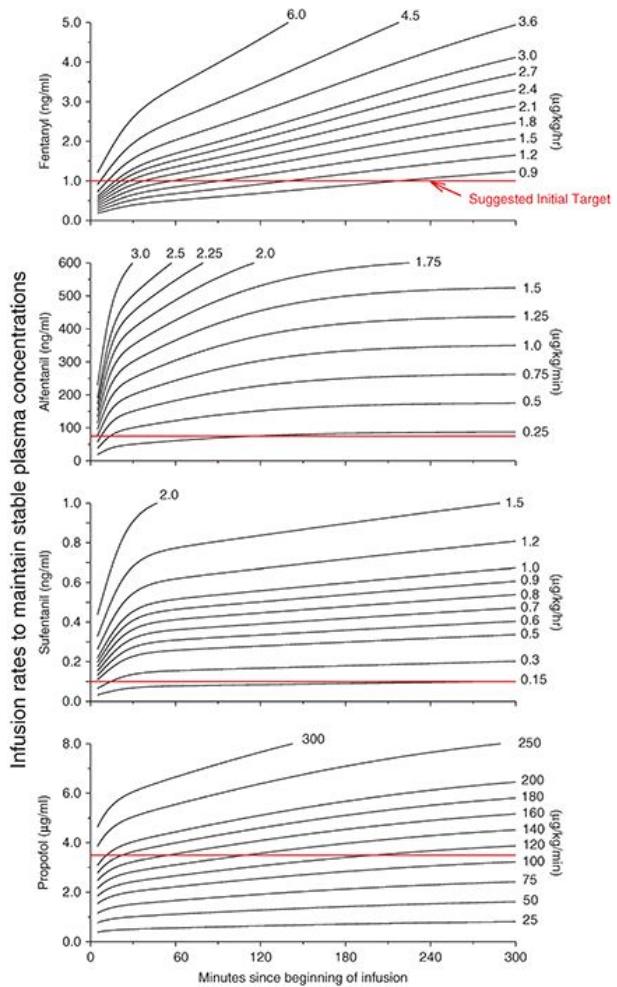

FIGURE 2.27 Dosing nomogram, showing the infusion rates (numbers on the perimeter) required to maintain stable concentrations of fentanyl (1.0 $\mu\text{g}/\text{mL}$), alfentanil (75 $\mu\text{g}/\text{mL}$), sufentanil (0.1 $\mu\text{g}/\text{mL}$), and propofol (3.5 ng/mL).

Another approach to determine infusion rates for maintenance of anesthesia to a desired target concentration is through the use of a specialized slide rule.²⁰ Figure 2.28 illustrates such a slide rule for propofol. As described by Bruhn et al,²⁰ “The bolus dose required to reach a given target plasma concentration is the product of the (weight-related) distribution volume and required concentration. Similarly, the infusion rate at a particular time point is the product of target concentration, body weight, and a correction factor that depends on the time elapsed from the start of the initial infusion. This factor can be determined for each time point using a PK simulation program.”

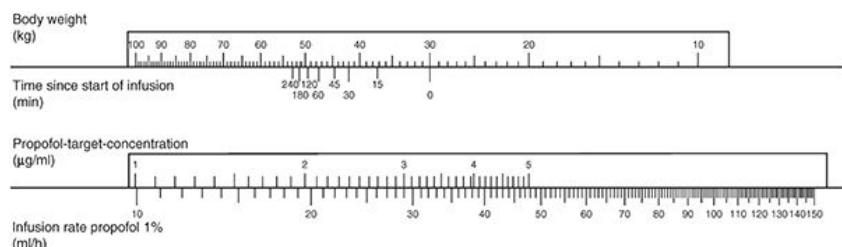

FIGURE 2.28 Propofol slide ruler to calculate maintenance infusion rate, based on the patient’s weight and the time since the start of the infusion, as proposed by Bruhn and colleagues. To make use of the calculator, make a photocopy and cut in to top (body weight), middle (time since start of infusion/propofol target

concentration), and bottom (infusion rate propofol 1%) sections—calculation requires sliding the middle piece in relationship to the top and bottom segments, which are fixed. *Adapted with permission from Bruhn J, Bouillon TW, Röpcke H, et al. A manual slide rule for target-controlled infusion of propofol: development and evaluation. Anesth Analg. 2003;96(1):142-147. Copyright © 2003 International Anesthesia Research Society.*

The best approach is through the use of target-controlled drug delivery. With target-controlled drug delivery, the user simply sets the desired plasma or effect site concentration. Based on the drug's pharmacokinetics and the mathematical relationship between patient covariates (eg, weight, age, gender) and individual pharmacokinetic parameters, the computer calculates the dose of drug necessary to rapidly achieve and then maintain any desired concentration. Most critically, it can raise and lower concentrations in a controlled fashion, a calculation that cannot be captured in any simple nomogram. Such computerized controlled drug delivery systems are now widely available.

An alternative approach is to use stanpumpR, which can be found online at <http://stanpumpR.io>. stanpumpR is an online, open-source (see <https://github.com/StevenLShaffer/stanpumpR>) pharmacokinetic simulator for intravenous anesthetic drugs and oral opioids. It was primarily developed by one of the authors (SLS) and remains in active development. **Figure 2.29** shows the screen of stanpumpR simulating an anesthetic with a propofol bolus and infusion, a fentanyl bolus, a remifentanil infusion, and two boluses of rocuronium. stanpumpR can be used to model specific anesthetic strategies before anesthesia or to model an ongoing anesthetic to see approximately what the drug levels are for the administered drugs.

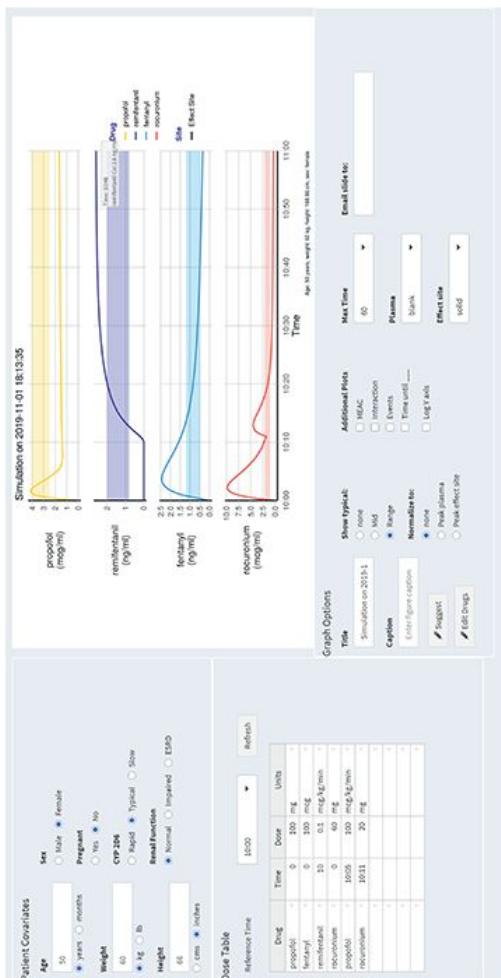

FIGURE 2.29 stanpumpR (<https://stanpumpR.io>) is a pharmacokinetic (PK)/pharmacodynamic (PD) simulation program for anesthesia. The program implements published PK/PD models for alfentanil, dexmedetomidine, etomidate, fentanyl, hydromorphone, ketamine, lidocaine, methadone, midazolam, morphine, naloxone, oxycodone, oxytocin, pethidine, propofol, remifentanil, rocuronium, and sufentanil.

Context-Sensitive Half-time

Special significance is often ascribed to the smallest exponent, which determines the slope of the final log-linear portion of the curve. When the medical literature refers to the half-life of a drug, unless otherwise stated, the half-life is based on the terminal half-life (ie, $0.693/\text{smallest exponent}$). However, the terminal half-life for drugs with more than one exponential term is nearly impossible to interpret. The terminal half-life sets an upper limit on the time required for the concentrations to decrease by 50% after drug administration. Usually, the time for a 50% decrease will be much faster than that upper limit. A more useful concept is the “context-sensitive half-time,” shown in [Figure 2.30](#),²¹ which is the time for the plasma concentration to decrease by 50% from an infusion that maintains a constant concentration. The “context” is the duration of the infusion. The context-sensitive half-time increases with longer infusion durations because it takes longer for the concentrations to fall if drug has accumulated in peripheral tissues.

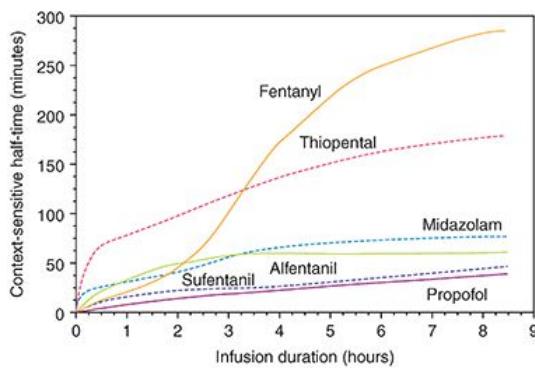

FIGURE 2.30 Context-sensitive half-times as a function of the duration of intravenous drug infusion for alfentanil, sufentanil, propofol, midazolam, and thiopental. Reprinted with permission from Hughes MA, Glass PSA, Jacobs JR. Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76(3):334-341. Copyright © 1992 American Society of Anesthesiologists, Inc.

The context-sensitive half-time is based on the time for a 50% decrease, which was chosen both to provide an analogy to half-life, and because, very roughly, a 50% reduction in drug concentration appears necessary for recovery after administration of most intravenous hypnotics at the termination of surgery. Of course, decreases other than 50% may be clinically relevant. Additionally, the context-sensitive half-time does not consider plasma-effect site disequilibrium and thus may be misleading for drugs with very slow plasma-effect site equilibration. A related but more clinically relevant representation is the context-sensitive effect site decrement time, as shown in [Figure 2.31](#).²² For example, the upper black line in [Figure 2.31](#) is the context-sensitive 20% effect site decrement time for fentanyl, that is, the time required for fentanyl effect site concentrations to fall by 20%, based on the duration of a fentanyl infusion. Context-sensitive half-time and effect site decrement times are more useful than elimination half-time in characterizing the clinical responses to drugs.²³

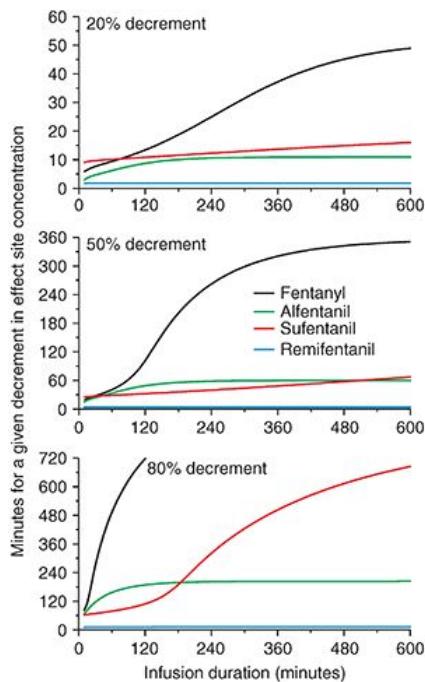

FIGURE 2.31 Effect site decrement times. The 20%, 50%, and 80% decrement times for fentanyl (black), alfentanil (green), sufentanil (red), and remifentanil (blue). When there is substantial plasma-effect site disequilibrium, the effect site decrement time will provide a better estimate of the time required for recovery than the context-sensitive half-time. *Adapted from Youngs EJ, Shafer SL. Pharmacokinetic parameters relevant to recovery from opioids. Anesthesiology. 1994;81:833-842.*

Pharmacodynamics

Pharmacodynamics is the study of the intrinsic sensitivity or responsiveness of the body to a drug and the mechanisms by which these effects occur. Thus, pharmacodynamics may be viewed as what the drug does to the body. Structure-activity relationships link the actions of drugs to their chemical structure and facilitate the design of drugs with more desirable pharmacologic properties. The intrinsic sensitivity is determined by measuring plasma concentrations of a drug required to evoke specific pharmacologic responses. The intrinsic sensitivity to drugs varies among patients and within patients over time with changes in physiology such as aging, disease, and injury. As a result, at similar plasma concentrations of a drug, some patients show a therapeutic response, others show no response, and others develop toxicity.

The basic principles of receptor theory were covered in the first section of this chapter. This section focuses on methods of evaluating clinical drug effects such as dose-response curves, efficacy, potency, the median effective dose (ED_{50}), the median lethal dose (LD_{50}), and the therapeutic index.

Concentration Versus Response Relationships

The most fundamental relationship in pharmacology is the concentration (or dose) versus response curve, shown in [Figure 2.32](#). This is the time-independent relationship between exposure to the drug (x-axis) and the measured effect (y-axis). The exposure can be the concentration, the dose, the area under the concentration versus time curve, or any other measure of drug exposure that is clinically meaningful. The measured effect can be an absolute response (eg, twitch height), a normalized response (eg, percentage of twitch depression), a population response (eg, fraction of subjects moving at incision), or any physiologic response (chloride current). The standard equation for this relationship is the “Hill” equation, sometimes called the **sigmoid-E_{max} relationship**:

$$\text{Effect} = E_0 + (E_{\max} - E_0) \frac{C^{\gamma}}{C_{50}^{\gamma} + C^{\gamma}}$$

Equation 2.32

In this equation, E_0 is the baseline effect in the absence of drug, and E_{\max} is the maximum possible drug effect. C is typically concentration or dose, although other measures of drug exposure (eg, dose, peak concentration, area under the concentration vs time curve) can be used. C_{50} is the concentration associated

with 50% of peak drug effect and is a measure of drug potency. The term $\frac{C^{\gamma}}{C_{50}^{\gamma} + C^{\gamma}}$ is a modification of the saturation equation $\frac{C}{C_{50} + C}$ presented in the prior section. Previously, it did not have an exponent. However, when used in pharmacodynamic models, the exponent γ , also called the **Hill coefficient**, appears. The exponent relates to the “sigmoidicity” and steepness of the curve. If γ is less than 1 and the curve is plotted on a standard x -axis, then the curve appears hyperbolic (see [Figure 2.8](#)). If γ is greater than 1, then the curve appears sigmoidal, as in [Figure 2.32](#). If the x -axis is plotted on a log scale, then the curve will always appear sigmoidal regardless of the value of γ .

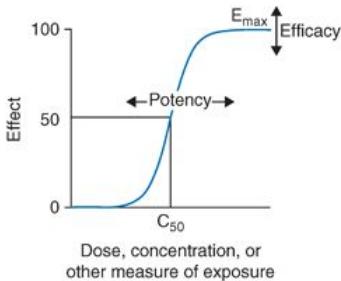

FIGURE 2.32 Drug exposure (dose, concentration, etc) versus drug effect relationship. Potency refers to the position of the curve along the x -axis. Efficacy refers to the position of the maximum effect on the y -axis.

Potency and Efficacy

There are two problems with the term **potency**. Clinicians often use potency to refer to the relative dose of two drugs, such as the relative potency of fentanyl and morphine. The problem with this definition is that when drugs have very different time courses, the relative potency varies depending on the time of the measurement. Fentanyl reaches peak effect 3.5 minutes after injection. Morphine reaches peak effect 90 minutes after injection. As a result, the “relative potency” 3.5 minutes after injection indicates that fentanyl is far more potent than morphine. However, when morphine has reached its peak effect 90 minutes after injection, the effect of the fentanyl has almost entirely dissipated. Measured 90 minutes after injection, morphine is more potent. From therapeutic perspective, potency is often defined in terms of relative doses without regard to time. This common practice, unfortunately, is scientifically flawed.

From a pharmacologic perspective, potency is described based on the concentration versus response relationship. As shown in [Figure 2.33](#), a drug with a left-shifted concentration versus response curve (ie, lower C_{50}) is considered more potent, whereas a drug with a right-shifted dose versus response curve is less potent. To be precise, potency should be defined in terms of a specific drug effect (eg, 50% of maximal effect of a full agonist). This is particularly important if the two drugs have differing Hill coefficients or efficacies (E_{\max}).

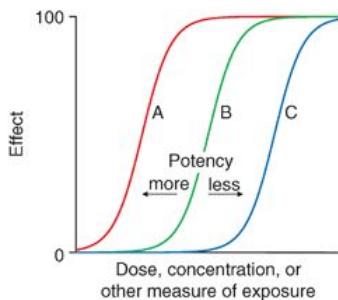

FIGURE 2.33 Dose versus response relationship for three drugs with potency. Drug A is the most potent, and drug C is the least potent.

Efficacy is a measure of the intrinsic ability of a drug to produce a given physiologic or clinical effect (see [Figure 2.32](#)). Consider the example of benzodiazepines given earlier (see [Figure 2.3](#)). Intrinsic efficacy ranged from full effect for midazolam to partial effect for bretazenil to no effect for flumazenil. The difference between a full agonist, a partial agonist, and an antagonist represents differences in efficacy. Efficacy refers to the position of the concentration versus response curve in the y-axis, whereas potency refers to relative drug concentration for a particular response on the y-axis.

Two drugs may have the same C_{50} but different efficacies. Because C_{50} is defined relative to the maximum drug effect, the drug with lower efficacy demonstrates less effect at C_{50} ([Figure 2.34](#)) and is therefore less potent. This introduces the second problem with the term potency. One can only compare potencies by comparing C_{50} values if the maximum effect and the Hill coefficient are identical for both drugs. If not, then potency must be described in terms of a specific drug effect (a specific point on the y-axis of the dose vs response curve).

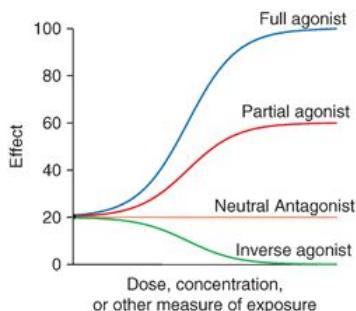

FIGURE 2.34 Concentration versus response curves for drugs with differing efficacies. Although the C_{50} of each curve is the same, the partial agonist is less potent than the full agonist because of the decreased efficacy.

Effective Dose and Lethal Dose

The ED_{50} is the dose of a drug required to produce a specific desired effect in 50% of individuals receiving the drug. The LD_{50} is the dose of a drug required to produce death in 50% of patients (or, more often, animals) receiving the drug. The therapeutic index is the ratio between the LD_{50} and the ED_{50} (LD_{50}/ED_{50}). The larger the therapeutic index of a drug, the safer the drug is for clinical administration. The relationship among ED_{50} , LD_{50} , and therapeutic index is shown in [Figure 2.33](#). The classic calculation of LD_{50} is not clinically very helpful in anesthesia where we expect 100% of patients to fall asleep and nobody to die. However, anesthetics have very narrow therapeutic windows. A more effective ratio is the LD_1/ED_{99} ratio. That ratio shows a far smaller margin of safety and actually is reversed in [Figure 2.35](#), meaning that there is appreciable risk of death, even at subtherapeutic doses in some individuals. Anesthetic drugs have uniquely

low therapeutic ratio. For example, the LD₅₀ for sevoflurane has been estimated to be 2.6.²⁴ This is why enormous vigilance is necessary for safe use of inhaled anesthetics.

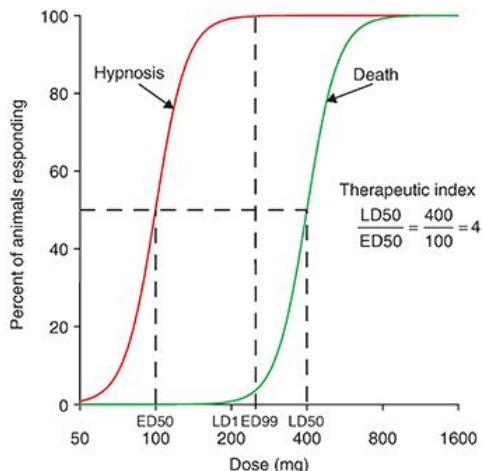

FIGURE 2.35 Analysis to determine the median lethal dose in 50% of the animals (LD₅₀), the median lethal dose in 99% of the animals (LD₉₉), and the therapeutic index of a drug.

Drug Interactions

Actions at Different Receptors

Opioids potently reduce the minimum alveolar concentration (MAC) of inhaled anesthetics required to suppress movement to noxious stimulation (Figure 2.36).^{25,26} Initially, the interaction is profound, with approximately 50% reduction in MAC at a plasma fentanyl concentration of 1.5 ng/mL. However, after the initial reduction in MAC, there is fairly limited benefit from additional fentanyl. The clinical pearl is that a modest amount of opioid dramatically reduces the concentrations of inhalational anesthetic required to prevent movement. The second pearl is that even with huge doses of opioids, some hypnotic component must be added to the anesthetic to prevent movement.

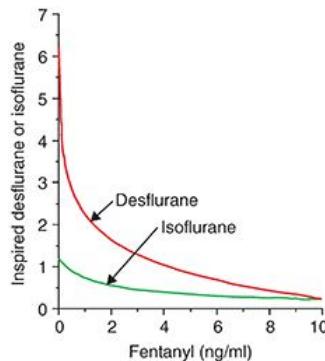

FIGURE 2.36 Interaction between fentanyl and isoflurane or desflurane on the minimum alveolar concentration required to suppress movement to noxious stimulation. Adapted from Sebel PS, Glass PS, Fletcher JE, Murphy MR, Gallagher C, Quill T. Reduction of the MAC of desflurane with fentanyl. Anesthesiology. 1992;76:52-59; McEwan AI, Smith C, Dyar O, Goodman D, Smith LR, Glass PS. Isoflurane minimum alveolar concentration reduction by fentanyl. Anesthesiology. 1993;78:864-869.

Similar work has been done for propofol. Vuyk and colleagues¹⁹ characterized the interaction of propofol with alfentanil. As shown in Figure 2.37, the interaction is markedly synergistic, with modest amounts of alfentanil greatly decreasing the amount of propofol associated with 50% chance of response to

intubation or surgical incision. Vuyk and colleagues¹⁹ also documented a similar interaction of propofol and alfentanil on return of consciousness.

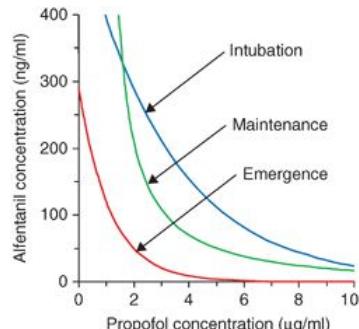

FIGURE 2.37 Interaction of propofol with alfentanil on the concentration required to suppress response to intubation, maintain nonresponsiveness during surgery and then awaken from anesthesia. Adapted with permission from Vuyk J, Lim T, Engbers FH, et al. The pharmacodynamics interaction of propofol and alfentanil during lower abdominal surgery in women. *Anesthesiology*. 1995;83(1):8-22. Copyright © 1995 American Society of Anesthesiologists, Inc.

Hendrickx and colleagues²⁷ surveyed the interaction of anesthetic drugs that affect nociception, analgesia, and hypnosis (Figure 2.38). They examined two endpoints: “hypnosis,” defined as loss of consciousness in humans and loss of righting reflex in animals, and “immobility,” defined as the loss of movement response to noxious stimulation in a nonparalyzed subject. As shown in Figure 2.38, the interaction between pairs of intravenous drugs and intravenous drugs and inhaled anesthetics is typically synergistic. An exception is the combination of the NMDA antagonists, ketamine and nitrous oxide, which demonstrate synergy, additivity, or infra-additivity in different models that have been studied. By contrast, the inhaled anesthetics are strictly additive in their interactions with other inhaled anesthetics, potentially suggesting a common mechanism of action.

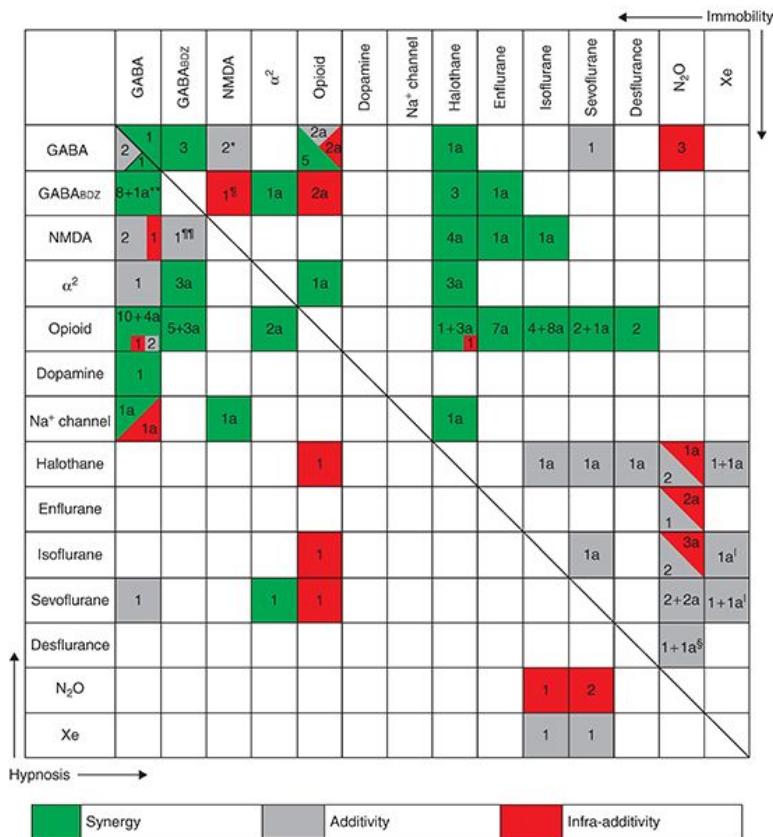

FIGURE 2.38 Survey of interactions between hypnotics and analgesics by Hendrickx et al. Reprinted with permission from Hendrickx JF, Eger EI II, Sonner JM, et al. Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility. Anesth Analg. 2008;107(2):494-550. Copyright © 2008 International Anesthesia Research Society.

Classic interaction studies, such as those described earlier, examine the concentrations associated with a particular response (such as a 50% chance of moving) for two drugs, evaluated separately and in combination. However, a more general view is that any combination of two drugs is associated with a response. This is best viewed as a “response surface” in which the x-axis and y-axis of the surface are concentrations (or doses) of drugs A and B, and the Z axis is the response to the particular combination. Minto et al²⁸ proposed a mathematical framework for response surfaces for a variety of interaction surfaces of interest to anesthesiologists. [Figure 2.39](#) shows six examples of possible response surfaces, depending on the nature of the interaction.

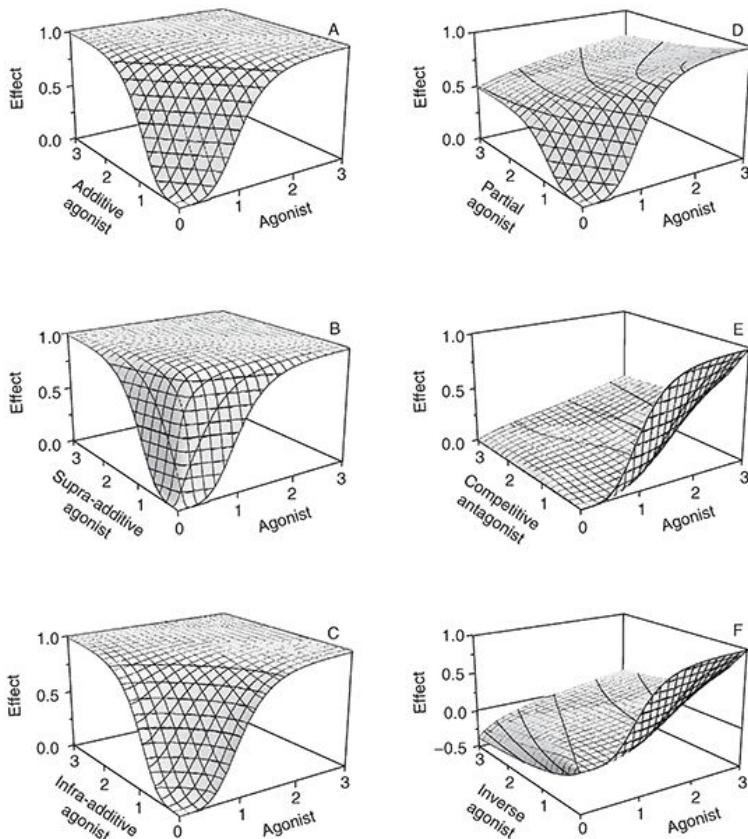

FIGURE 2.39 Interaction surfaces, showing simple additivity (A), synergy (B), and infra-additivity (C). More complex relationships exist between agonists and partial agonists (D), agonists and competitive antagonists (E), and agonists and inverse agonists (F). Reprinted with permission from Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. Anesthesiology. 2000;92(6):1603-1616. Stereochemistry

Stereochemistry is the study of how molecules are structured in three dimensions.^{29,30} **Chirality** is a unique subset of stereochemistry, and the term **chiral** is used to designate a molecule that has a center (or centers) of three-dimensional asymmetry. This kind of molecular configuration is almost always a function of the unique, tetrahedral bonding characteristics of the carbon atom.

Chirality is the structural basis of **enantiomerism**. Enantiomers are a pair of molecules existing in two forms that are mirror images of one another (right-handed and left-handed) but cannot be superimposed. In every other aspect, enantiomers are chemically identical. A pair of enantiomers is distinguished by the direction in which they rotate polarized light in solution. If the rotation is clockwise, then it is the D (dextrorotatory) or “+” enantiomer. If it is counterclockwise, then it is the L (levorotatory) or “-” enantiomer. The characteristic of rotation of polarized light is the origin of the term **optical isomers**. When the two enantiomers are present in equal proportions (50:50), they are referred to as a **racemic mixture**. A racemic mixture does not rotate polarized light (actually, because it rotates light equally both clockwise and counterclockwise, these effects cancel each other out so that the light is not rotated).

R and S designations have nothing to do with rotating light but are assigned based on numbering the atoms around the chiral center. D and L are the preferred nomenclature for referring to enantiomers.

When the two enantiomers are present in equal proportions (50:50), they are referred to as a **racemic mixture**.

The labels D and L are often confused with the designations R (rectus) and S (sinister) used in protein and carbohydrate chemistry. These classifications have nothing to do with rotating polarized light but are determined based on a formula for numbering each atom around the chiral center and then determining if the order is clockwise or counterclockwise.³⁰

Nearly every organic building block in biology is chiral, as are the resulting proteins, sugars, and lipids are chiral. As a result, the interaction of enantiomers with plasma proteins, membrane transporters, receptors, and metabolic enzymes will depend on the specific stereochemistry of the molecule because these interactions are invariably three-dimensionally exacting.^{29,30} Enantiomers can exhibit differences in absorption, distribution, clearance, potency, and toxicity (drug interactions). Enantiomers can even antagonize the effects of one another.

The administration of a racemic drug mixture represents two different drugs with distinct pharmacokinetic and pharmacodynamic properties. Only one enantiomer may be therapeutically active, whereas the other contributes to side effects. The therapeutically inactive isomer in a racemic mixture should be regarded as an impurity.³¹ An estimated one-third of drugs in clinical use are administered as racemic mixtures. Their use is likely to decrease in the future although the clinical advantages of single enantiomers must be balanced against the increased costs of drugs.³⁰ Regulatory agencies and pharmaceutical companies are aware of the importance of identification of the therapeutic enantiomer and strive to avoid approving new racemic mixtures.³²

Clinical Aspects of Chirality

More than one-third of all synthetic drugs are chiral, although most of them are utilized clinically as racemic mixtures.^{30,33} The majority of inhaled anesthetics are chiral with the notable exception of sevoflurane. Most evidence suggests that enantiomer-selective effects for volatile anesthetics are relatively weak in contrast to much stronger evidence for specific drug-receptor interactions for intravenous anesthetics.³³ Local anesthetics, including mepivacaine, prilocaine, and bupivacaine, have a center of molecular asymmetry. The S (+) enantiomer of ketamine is more potent than the R (-) form and is also less likely to produce emergence delirium. Similarly, in addition to pharmacokinetic differences, the cardiac toxicity of bupivacaine is thought to be predominantly due to the R-bupivacaine isomer. Ropivacaine is the S-enantiomer of a bupivacaine homolog, which has decreased cardiac toxicity. Likewise, the S-enantiomer of bupivacaine, levobupivacaine, is associated with less cardiac toxicity than bupivacaine. Cisatracurium is an isomer of atracurium that lacks histamine-releasing potential. Methadone is a racemic mixture of an opioid (L methadone) and a potent NMDA antagonist (D methadone). Based on demonstration of S-ketamine as an effective treatment for refractory depression, several companies are investigating d-methadone as a possible antidepressant without the psychotomimetic effects of ketamine.³⁴ Anesthetic drugs derived from natural precursors, such as curare (*d*-tubocurarine) and morphine (*l*-morphine), are not racemic because natural synthesis is invariably stereospecific.²⁹

Individual Variability

The response to drugs varies greatly among patients.³⁵ After administration of identical doses, some patients may have clinically significant adverse effects, whereas others may exhibit no therapeutic response. Some of this diversity of response can be ascribed to differences in the rate of drug metabolism, particularly by the CYP family of enzymes. The incorporation of pharmacogenetics into clinical medicine may become useful in predicting patient responses to drugs.

Variability of individual responses to a drug often reflects differences in pharmacokinetics and/or pharmacodynamics among patients (**Table 2.4**).⁴ This may even account for differences in pharmacologic effects of drugs in the same patient at different times. Accurate dosing is difficult to achieve in the presence of interindividual variability and it is not unusual to find a twofold or more variation in plasma concentrations achieved in different individuals using the same dosing scheme. This is true for inhaled as well as injected drugs. Furthermore, there may be a fivefold range in the plasma concentrations of a drug required to achieve

the same pharmacologic effect in different individuals, and this range may be even greater if tolerance has developed in some individuals.

TABLE 2.4

Events responsible for variations in drug responses between individuals

Pharmacokinetics
Bioavailability
Renal function
Hepatic function
Cardiac function
Patient age
Pharmacodynamics
Enzyme activity
Genetic differences
Drug interactions

The relative importance of the numerous factors that contribute to variations in individual responses to drugs depends, in part, on the drug itself and its usual route of excretion. Drugs excreted primarily unchanged by the kidneys tend to exhibit smaller differences in pharmacokinetics than drugs that are metabolized by the liver.

As discussed previously, changes in metabolic rate have little impact on drugs with a high extraction ratio as the efficiency of extraction is so great that hepatic blood flow is a more rate-limiting factor than metabolism. Conversely, the systemic clearance of low-extraction drugs is highly susceptible to small changes in the rate of metabolism. For example, the systemic clearance of alfentanil is exquisitely sensitive to CYP induction and inhibition, whereas clearance of high-extraction opioids such as fentanyl and sufentanil is minimally influenced.³⁶ Remifentanil is the extreme example: The only significant covariate of remifentanil metabolism is age.

Interindividual variability in the metabolism of codeine, a prodrug, to morphine, the active metabolite, is determined by activity of CYP2D6-mediated *O*-demethylation to morphine and morphine-6-glucuronide. CYP2D6-deficient individuals have diminished or absent morphine formation following administration of codeine, whereas individuals with CYP2D6 gene amplification experience exaggerated opioid effects following administration of codeine (“codeine intoxication”).³⁷ Quinidine inhibits CYP2D6 and markedly diminishes codeine metabolism the active metabolite, morphine.

The dynamic state of receptor concentrations, as influenced by diseases and other drugs, also influences the variation in drug responses observed among patients. Finally, inhaled anesthetics, by altering circulatory, hepatic, and renal function, may influence the pharmacokinetics of injected drugs.

In clinical practice, the impact of interpatient variability may be masked by the administration of high doses of a drug. For example, the administration of 2 to 3 × ED₉₅ of a nondepolarizing neuromuscular blocking drug is common practice for achieving a skeletal muscle paralysis in all patients. Interpatient variability, however, is manifest if the level of neuromuscular blockade and duration of action is monitored. Furthermore, it is common practice in anesthesia to administer drugs in proportion to body weight, although pharmacokinetic and pharmacodynamic principles may not support this practice. In attempts to minimize interindividual variability, computerized infusion systems (target-controlled infusion systems) have been developed to deliver intravenous drugs (alfentanil, remifentanil, etomidate, propofol) to achieve a desired (target) concentration (reviewed in Glass et al³). Programs such as stanpumpR (<https://stanpumpR.io>) incorporate variability into the pharmacokinetic simulations provided that influence of the variability has been quantified mathematically.

Elderly Patients

In elderly patients, variations in drug response most likely reflect (1) decreased cardiac output, (2) increased fat content, (3) decreased protein binding, and (4) decreased renal function. Decreased cardiac output

decreases hepatic blood flow and, thus, delivery of drug to the liver for metabolism. This decreased delivery, combined with the possibility of decreased hepatic enzyme activity, may prolong the duration of action of drugs such as lidocaine and fentanyl.³⁸ An enlarged fat compartment may increase the *Vd* and lead to the accumulation of lipid-soluble drugs such as diazepam and thiopental.³⁹ Increased total body fat content and decreased plasma protein binding of drugs accounts for the increased *Vd* that accompanies aging. A parallel decrease in total body water accompanies increased fat stores. The net effect of these changes is an increased vulnerability of elderly patients to cumulative drug effects. Effects of age on pharmacokinetics and pharmacodynamics are discussed in detail in [Chapter 46](#).

Enzyme Activity

Alterations in enzyme activity as reflected by enzyme induction may be responsible for variations in drug responses among individuals. For example, cigarette smoke contains polycyclic hydrocarbons that induce mixed-function hepatic oxidases, leading to increased dose requirements for drugs such as theophylline and tricyclic antidepressants. Acute alcohol ingestion can inhibit metabolism of drugs. Conversely, chronic alcohol use (>200 g per day) induces microsomal enzymes that metabolize drugs. Because of enzyme induction, this accelerated metabolism may manifest as tolerance to drugs such as barbiturates.

Genetic Disorders

Variations in drug responses among individuals are due, in part, to genetic differences that may also affect receptor sensitivity. Genetic variations in metabolic pathways (rapid vs slow acetylators) may have important clinical implications for drugs such as isoniazid and hydralazine. **Pharmacogenetics** describes genetically determined disease states that are initially revealed by altered responses to specific drugs. Examples of diseases that are unmasked by drugs include (1) atypical cholinesterase enzyme revealed by prolonged neuromuscular blockade after administration of succinylcholine or mivacurium; (2) malignant hyperthermia triggered by succinylcholine or volatile anesthetics; (3) glucose-6-phosphate dehydrogenase deficiency, in which certain drugs cause hemolysis; and (4) intermittent porphyria, in which barbiturates may evoke an acute attack.

Drug Interactions

A drug interaction occurs when a drug alters the intensity of pharmacologic effects of another drug given concurrently. Drug interactions may reflect alterations in pharmacokinetics (increased metabolism of neuromuscular blocking drugs in patients receiving anticonvulsants chronically) or pharmacodynamics (decrease in volatile anesthetic requirements produced by opioids). The net result of a drug interaction may be enhanced or diminished effects of one or both drugs, leading to desired or undesired effects. A physicochemical drug interaction occurs when two incompatible drugs are mixed in the same solution (precipitate of the conjugate salt of a weak acid and weak base when vecuronium and thiopental are mixed together in the same intravenous tubing). The potential for drug interactions in the perioperative period is great, considering the large number of drugs from different chemical classes that are likely to be part of anesthesia management. For example, a typical “balanced anesthetic” may include benzodiazepines, sedative-hypnotics, opioids, neuromuscular blocking drugs, anticholinergics, anticholinesterases, sympathomimetics, sympathetic nervous system blocking drugs, and antibiotics.

An example of a beneficial drug interaction is the concurrent administration of propranolol with hydralazine to prevent compensatory increases in heart rate that would offset the blood pressure-lowering effects of hydralazine. Interactions between drugs are frequently used to counter the effects of agonist drugs, as reflected by the use of naloxone to antagonize opioids. Adverse drug interactions typically manifest as impaired therapeutic efficacy and/or enhanced toxicity. In this regard, one drug may interact with another to (1) impair absorption, (2) compete with the same plasma protein-binding sites, (3) alter metabolism by enzyme induction or inhibition, or (4) change the rate of renal excretion.

PART II Neurologic System

Neurophysiology*

Updated by: Pamela Flood • Cassandra Bailey

The most amazing aspect of the daily miracle of anesthesia is turning off consciousness to permit surgery to proceed and then fully restoring consciousness in a controlled manner. We still do not know how this miracle occurs. A full understanding of consciousness, and the biology that underlies it, may be decades in the future, if it is tractable at all.¹ However, recent advances in neurophysiology are providing insight into how perioperative drugs interact with receptors throughout the nervous system to mediate anesthesia and analgesia. These concepts are likely familiar from previous training, but we review them to build our understanding of anesthetic and analgesic effects.

How Nerves Work

Neurons

Neurons are the basic element of all rapid signal processing within the body. A neuron consists of a cell body, also called the soma, dendrites, and the nerve fiber, also called the axon. Dendrites are highly specialized extensions of the cell body. The axon of one neuron commonly terminates (synapses) near the cell body or dendrites of another neuron. The axon connects to a neighboring cell with a *presynaptic terminal*. The *synaptic cleft* separates the presynaptic terminal and the cell body or dendrites of the next neuron in the signaling cascade. Transmission of impulses between neurons at a synapse is mediated by the release of a chemical mediator (neurotransmitter), such as *glutamate* or *γ-aminobutyric acid* (GABA) from the presynaptic terminal or in some cases direct activation through gap junctions. The membrane of the postsynaptic neurons contains receptors that bind neurotransmitters released from presynaptic nerve terminals, transducing the signal.

After signal transduction, the impulse travels along the nerve membrane as an *action potential*. This is entirely mediated by the channels within the membrane. Indeed, removal of the axoplasm from the nerve fiber does not alter conduction of impulses. Nerve fibers derive their nutrition from the cell body. Interruption of a nerve fiber causes the peripheral portion to degenerate (Wallerian degeneration). The axon of a peripheral neuron is able to regenerate, as does the myelin sheath. Regeneration has previously been thought to be the exception in most of the brain and spinal cord. Extensive research is underway to better understand the conditions that are required for central neuron regeneration to improve recovery from central neuronal injury.²

Classification of Afferent Nerve Fibers

Nerve fibers are called afferent if they transmit impulses from peripheral receptors to the central nervous system (CNS) and efferent if they transmit impulses from the CNS to the periphery. Afferent nerve fibers are classified as A, B, and C on the basis of fiber diameter and velocity of conduction of nerve impulses ([Table 3.1](#)). Conduction speed increases with nerve diameter because the larger diameter nerves have decreased longitudinal resistance to ion flux.³ The largest, and hence fastest, nerves are designated type A. Type A fibers are subdivided into alpha, beta, gamma, and delta. Type A- α_1 fibers innervate muscle spindles, and A- α_{1b} innervate the Golgi tendon organ. Both A- α afferents are important to muscle reflexes and control of muscle tone.

TABLE 3.1

Classification of peripheral nerve fibers

	Myelinated	Fiber diameter (μm)	Conduction velocity (m/s)	Function	Sensitivity to local anesthetic (subarachnoid, procaine, %)
A- α	Yes	12-20	70-120	Innervation of skeletal muscles Proprioception	1
A- β	Yes	5-12	30-70	Touch Pressure	1
A- γ	Yes	3-6	15-30	Skeletal muscle tone	1
A- δ	Yes	2-5	12-30	Fast pain Touch Temperature	0.5
B	Yes	3	3-15	Preganglionic autonomic fibers	0.25
C	No	0.4-1.2	0.5-2.0	Slow pain Touch Temperature Postganglionic sympathetic fibers	0.5

All cutaneous mechanoreceptors (Meissner corpuscles, hair receptors, Pacinian corpuscles) transmit signals in type A- β fibers. Touch and fast pain are transmitted by lightly myelinated type A- δ fibers with free nerve endings. Type C fibers transmit slow pain, pruritus, and temperature sensation.

Myelin that surrounds type A and B nerve fibers acts as an insulator that prevents flow of ions across nerve membranes. Type C fibers are unmyelinated. The myelin sheath is interrupted approximately every 1 to 2 μm by the nodes of Ranvier.⁴ Ions can flow freely between nerve fibers and extracellular fluid at the nodes of Ranvier. Action potentials are conducted from node to node by the myelinated nerve rather than continuously along the entire fiber as occurs in unmyelinated nerve fibers. This successive excitation of nodes of Ranvier by an action potential that jumps between successive nodes is termed *saltatory (or jumping) conduction* ([Figure 3.1](#)).⁴ Saltatory conduction allows for a 10-fold increase in the velocity of nerve transmission.³ It also conserves the membrane potential because only the membrane at the node of Ranvier depolarizes, resulting in less ion transfer than would otherwise occur. Furthermore, because depolarization is limited to the nodes of Ranvier, little energy is needed to reestablish the transmembrane sodium and potassium ion concentration gradients necessary for signal transmission. The energy savings is more than a hundredfold. As brilliantly understated by Hartline and Colman, “For a nervous system such as ours, which already accounts for 20% of the body’s resting metabolic energy budget, this is not an inconsequential advantage.”³

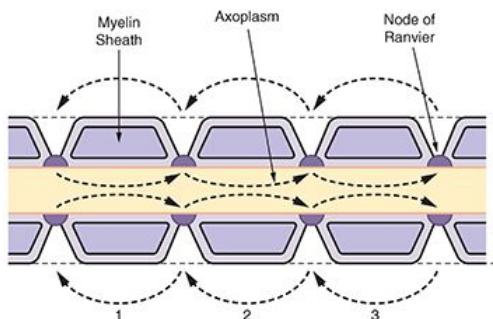

FIGURE 3.1 Saltatory conduction is transmission of nerve impulses that jump between successive nodes of Ranvier of myelinated nerves.

Evaluation of Peripheral Nerve Function

Peripheral nerves may be injured by ischemia of the intraneuronal vasa nervorum, as might be caused by excessive stretch of the nerve or external compression. Nerve conduction studies are useful in the localization and assessment of peripheral nerve dysfunction. Focal demyelination of nerve fibers causes slowing of conduction and decreased amplitudes of compound muscle and sensory action potentials. The presence of denervation potentials in skeletal muscle indicates axonal or anterior horn cell damage. Changes in motor unit potentials also arise from reinnervation of skeletal muscle fibers by surviving axons. Electromyographic testing is helpful in determining the etiology of neurologic dysfunction that may occur after surgery and provides assessment of whether reinnervation has taken place or not.⁵

The Action Potential

Electrical potentials exist across nearly all cell membranes, reflecting principally the difference in transmembrane concentrations of sodium and potassium ions. This unequal distribution of ions is created and maintained by the membrane-bound enzyme sodium-potassium adenosine triphosphatase, sometimes called the sodium-potassium pump. The sodium-potassium pump transfers three sodium ions out of the cell in exchange for two potassium ions brought into the cell. This causes a net transfer of positive charges out of the cell. The resulting voltage difference across the cell membrane is called the *resting membrane potential*. The cytoplasm is electrically negative (typically -60 to -80 mV) relative to the extracellular fluid (Figure 3.2).⁶

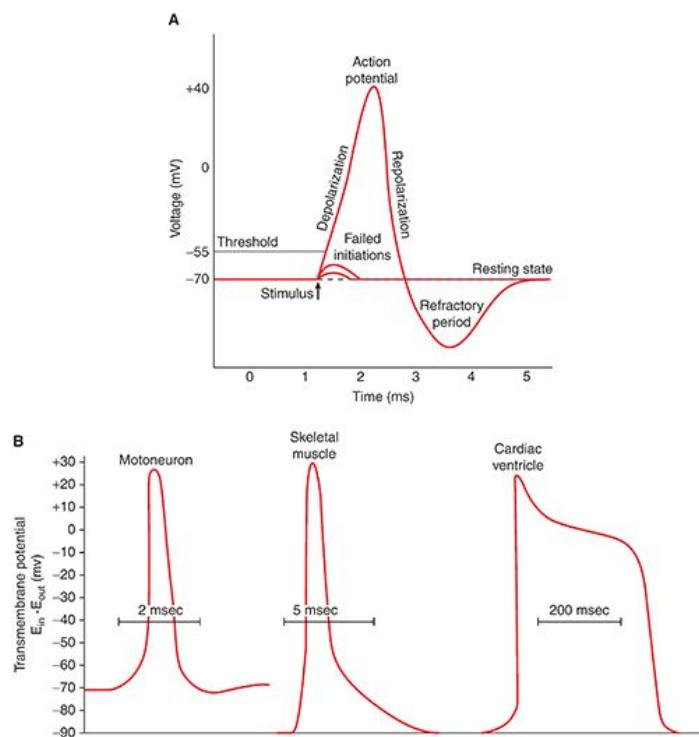

FIGURE 3.2 The elements of the action potential (A). The transmembrane potential and duration of the action potential varies with the tissue site (B). From Berne RM, Levy MN, Koeppen B, et al. Physiology. 5th ed. St Louis, MO: Mosby; 2004. Reprinted with permission from Bruce M. Koeppen, MD.

When channels open to specific ions, the ions generally flow in the direction of their concentration gradients. An action potential is the rapid change in transmembrane potential due to the opening of sodium channels (*depolarization*) and rapid influx of sodium ions down the concentration gradient, reversing the net

negative charge within the cell. The membrane resting potential is restored by the closing of the sodium channels and the opening of potassium channels (*repolarization*) after the action potential has passed. The outward flux of potassium ions down their concentration gradient restores the net negative charge within the cell. This is discussed in greater detail under “Ion Channels” section in the following text.

Propagation of Action Potentials

Propagation of action potentials along the entire length of a nerve axon is the basis of rapid signal transmission along nerve cells. The size and shape of the action potential varies among excitable tissues.⁶

Action potentials are conducted along nerve or muscle fibers by local current flow that produces depolarization of adjacent areas of the cell membrane. These propagated action potentials can travel in both directions along the entire extent of the fiber. The transmission of the depolarization process along nerve or muscle fibers is called a *nerve or muscle impulse*. The entire action potential usually occurs in less than 1 millisecond.

During much of the action potential, the cell membrane is completely refractory to further stimulation. This is termed the *absolute refractory period* and is due to the presence of a large fraction of inactivated sodium ion channels. During the last portion of the action potential, a stronger than normal stimulus can evoke a second action potential. This “relative refractory period” reflects the need to activate a critical number of sodium ion channels to trigger an action potential.

The action potential is dynamic, which is difficult to illustrate with a static textbook image. We encourage the motivated reader to search for the text “action potential animation” on the Internet. There are many high-quality animations of the action potential that dynamically display how it propagates.

Ion Channel Evaluation

Patch clamp electrophysiology can be used to study ion channel functions. In patch clamping, an electrode is placed on the cell surface and suction applied to create a tight seal. This electrode is able to control either the voltage or the current. Current flowing through individual ion channels are measured by clamping or maintaining the voltage of a cell membrane. The membrane potential can be measured by clamping the current.⁷ Currents carried through different types of channels can be isolated by the use of specific inhibitors. For example, tetraethylammonium blocks many types of potassium ion channels, whereas tetrodotoxin blocks many types of sodium ion channels. Patch clamping is a useful technique to characterize ion channels and to analyze the effects of pharmacologic interventions.⁸ Much that is known about the actions of anesthetics on individual ion channels has been learned using these methods.

Abnormal Action Potentials

A deficiency of calcium ions in the extracellular fluid (hypocalcemia) prevents the sodium channels from closing between action potentials. The resulting continuous leak of sodium contributes to sustained depolarization or repetitive firing of cell membranes (tetany). Conversely, high calcium ion concentrations decrease cell membrane permeability to sodium and thus decrease excitability of nerve membranes. Low potassium ion concentrations in extracellular fluid increase the negativity of the resting membrane potential, resulting in hyperpolarization and decreased cell membrane excitability. Skeletal muscle weakness that accompanies hypokalemia presumably reflects sustained hyperpolarization of skeletal muscle membranes. Local anesthetics block sodium channels and thus decrease permeability of nerve cell membranes to sodium ions, preventing achievement of a threshold potential that is necessary for generation of an action potential. Blockage of cardiac ion channels by local anesthetics or antiarrhythmic agents results in altered conduction of cardiac impulses and myocardial contractility.

Neurotransmitters and Receptors

Neurotransmitters are chemical mediators that are released into the synaptic cleft in response to the arrival of an action potential at the nerve ending. Neurotransmitter release is voltage dependent and requires the influx of calcium ions into the presynaptic terminals ([Figure 3.3](#)). Synaptic vesicles in the cell body and dendrites of neurons are the sites of continuous synthesis and storage of neurotransmitters. These vesicles may contain

and release more than one neurotransmitter. Neurotransmitters may be excitatory or inhibitory, depending on the ion selectivity of the protein receptor. A postsynaptic receptor may be excited or inhibited, reflecting the existence of both types of receptors in the same postsynaptic neuron. Furthermore, the same neurotransmitter may be inhibitory at one site and excitatory at another. This is particularly applicable to G protein–coupled receptors as the associated G protein determines the polarity of the response. Some neurotransmitters function as neuromodulators or coagonists in that they influence the sensitivity of receptors to other neurotransmitters. For example, glycine is an important coagonist at the *N*-methyl-D-aspartate (NMDA) receptor.

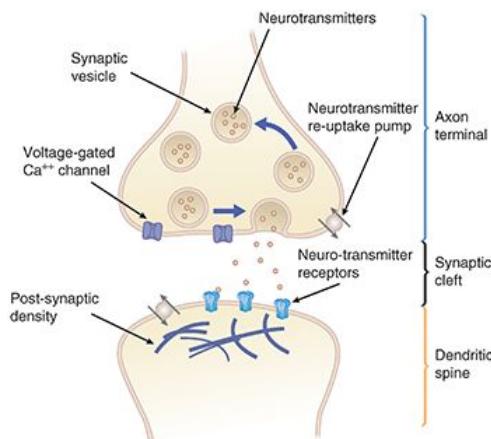

FIGURE 3.3 Basic structure of the synapse. The signal neurotransmitter arrives at the axon terminal, where it causes the release of neurotransmitters into the synapse. These cross the synaptic cleft, where they may or may not result in a propagation of the signal. Many synapses simply render the postsynaptic cell excited or inhibited without actually triggering an action potential.

Volatile anesthetics produce a broad spectrum of actions, as reflected by their ability to modify neurotransmission at presynaptic and postsynaptic loci within the CNS. Volatile anesthetics inhibit excitatory neurotransmission (via NMDA and nicotinic acetylcholine receptors) and enhance the inhibitory neurotransmission (via GABA and glycine receptors).⁹ Some intravenous anesthetics potentiate inhibitory receptors and have the majority of their anesthetic activity through the potentiation of GABAergic and glycinergic transmission, the precise details of which are known.^{10–12} In contrast, the mechanism of volatile effects on analgesia, amnesia, and motor function remain uncertain.¹³ To quote the famous investigator of general anesthetic mechanism, Ted Eger, “Volatile anesthetics inhibit excitatory receptors and activate inhibitory receptors. How do they know?”¹⁴

The list of chemical mediators functioning as excitatory or inhibitory neurotransmitters continues to increase ([Table 3.2](#)). Glutamate is the major excitatory neurotransmitter in the CNS, whereas GABA is the major inhibitory neurotransmitter. Acetylcholine, dopamine, histamine, and norepinephrine are widely distributed and play important roles in sleep pathways that are impacted upon by general anesthetics.¹⁵ Neuromodulators coexist in presynaptic terminals with neurotransmitters but do not themselves cause substantive voltage or conductance changes in postsynaptic cell membranes. They can, however, amplify, prolong, decrease, or shorten the postsynaptic response to selected neurotransmitters.

Receptors can be classified by their cellular localization. Receptors on the cell membrane transduce signals by binding the extracellular molecules and converting this information into an intracellular action that alters target cell function. Most signaling molecules are hydrophobic and interact with cell surface receptors that are directly or indirectly coupled to effector molecules. There are three classes of cell surface receptors as defined by their signal transduction mechanisms: **enzyme-linked transmembrane receptors**, **guanine nucleotide-binding protein (“G protein”) coupled receptors** and **ligand-gated ion channels**.

G protein-coupled receptors in the plasma membrane exert their effects by coupling to specific intracellular G proteins. The binding of the receptor to the ligand activates the G protein, which then activates or inhibits an enzyme, ion channel, or other target. G protein-coupled receptors consist of three separate components: a receptor protein, three guanine nucleotide binding proteins (G proteins α , β , and γ), and an effector mechanism.³ The G protein-coupled receptor consists of a single protein with seven transmembrane spanning domains. Binding of an extracellular ligand to the G protein-coupled receptor triggers a conformational change of the protein. That change causes activation of the G_α protein coupled to the interior portion of the receptor.

A number of different isoforms of G protein subunits (α , β , γ) are present and mediate stimulation, promoting a specific enzymatic reaction within the cell or inhibition, depressing a specific enzymatic reaction. For example, β -adrenergic receptors couple with stimulatory $G_{\alpha s}$ proteins and increase the activity of adenylyl cyclase (also called adenylate cyclase). Opioid receptors associate with inhibitory $G_{\alpha i}$ proteins that decrease the activity of adenylyl cyclase. By regulating the level of activity of adenylyl cyclase, the β -adrenergic and opioid receptors modulate the internal level of cyclic adenosine monophosphate (cAMP), which functions as an intercellular second messenger ([Figure 3.4](#)).

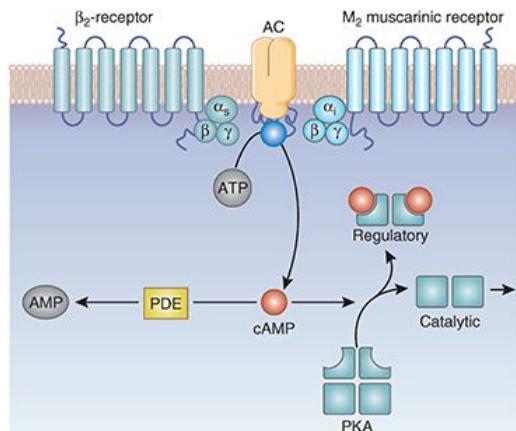

FIGURE 3.4 Schematic showing G protein–coupled receptors, the β_2 adrenergic receptor, which upregulates adenylyl cyclase, and the M_2 muscarinic receptor, which downregulates adenylyl cyclase (AC). The effects of these G protein–coupled receptors are then mediated through the intercellular concentration of cyclic adenosine monophosphate (cAMP). Abbreviations: AMP, adenosine monophosphate; ATP, adenosine triphosphate; PDE, phosphodiesterase; PKA, protein kinase A.

G protein–coupled receptors constitute the largest family of cell surface receptors. Most hormones and many neurotransmitters interact with G protein–coupled cell-surface receptors to produce the cellular response.¹⁶ The resulting response is often a change in transmembrane voltage thus neuronal excitability and the likelihood of response to a stimulus. There is great diversity in the number of G protein–coupled receptors for the same ligand. G protein receptors can couple to more than one G protein and many receptors can couple to the same G protein.¹⁷ Examples of hormones and drugs that act through G protein–coupled receptors, include catecholamines, opioids, anticholinergics, and antihistamines. In contrast to the immediate cellular responses associated with ion channels that manifest in milliseconds, signals mediated by G protein–coupled receptors are involved in functions that operate in seconds to minutes. Some ion channels are also gated by G proteins. These are discussed in the following text with the other ion channels.

Dopamine

Dopamine represents more than 50% of the CNS content of catecholamines, with high concentrations in the basal ganglia. Dopamine can be either inhibitory or excitatory depending on the specific dopaminergic receptor that it activates. Dopamine is important to the reward centers of the brain and plays a key role in addiction and tolerance to anesthetic and analgesic drugs. Dopamine also plays a key role in motor control and abnormalities in dopamine signaling can cause movement disorders as seen in Parkinson disease.

Norepinephrine

Norepinephrine is present in large amounts in the reticular activating system and the hypothalamus, where it plays a key role in natural sleep and analgesia. Neurons responding to norepinephrine send excitatory (through α_1) and inhibitory (through α_2) signals to widespread areas of the brain, including the cerebral cortex. The action of clonidine and dexmedetomidine is mediated by activation of α_2 -adrenergic receptors. The locus coeruleus in the brainstem is the site for the sedative action of dexmedetomidine and the spinal cord is the site for its analgesic effects.¹⁸ Descending noradrenergic fibers that project to the dorsal horn of the spinal cord play an important tonic inhibitory role in pain transmission. These pathways are augmented by epidural clonidine for postoperative and intrapartum analgesia. They are also augmented by serotonin norepinephrine reuptake inhibitors such as duloxetine and venlafaxine used in pain management as analgesic adjuvants.

Substance P

Substance P is an excitatory neurotransmitter coreleased by terminals of pain fibers that synapse in the substantia gelatinosa of the spinal cord. It is found with glutamate in primary afferents and activates the neurokinin 1 G protein–coupled receptor. Its release is not only important to acute pain mediation but also to sustained inflammatory pain. In the mediation of neurogenic inflammation, substance P induces expression of many cytokines that further augment release of substance P and upregulate expression of the neurokinin 1 receptor in a positive feedback response.¹⁹ The neurokinin 1 receptor is also involved in the manifestation of nausea and vomiting after anesthesia, and neurokinin 1 receptor antagonists such as aprepitant are used in its treatment.^{20,21}

Endorphins

Endorphins are endogenous opioid peptide agonists that are secreted by nerve terminals in the pituitary, thalamus, hypothalamus, brainstem, and spinal cord. Endorphins act through the μ -opioid receptor, the same receptor responsible for the effects of administered opioids. Endorphins are secreted after exercise and during

pain and anxiety. They facilitate dopamine release and activate inhibitory pain pathways.²² Endogenous opioids play important roles in many bodily functions including tolerance and dependence, stress, learning and memory, hunger, and the desire for alcohol, drugs, and sexual activity.

Metabotropic Serotonin Receptors

Serotonin (5-HT) is present in high concentrations in the brain, where it acts on both ligand-gated ion channels and G protein-coupled receptors. Many drugs for depression augment activation of serotonin receptors as do many other perioperative medications. Particularly in the setting of anesthesia, consideration of the potential for serotonin syndrome is important.

Histamine

Histamine is present in high concentrations in the hypothalamus and the reticular activating system. Histaminergic neurons present in the tuberomammillary nucleus of the hypothalamus are active during the wake cycle. The sleep promoting properties of antihistamine drugs that cross the blood-brain barrier are due to inhibition of H₁ G protein-coupled receptors.

Ion Channels

The normal resting membrane potential is -60 to -80 mV, with the interior of the cell negative relative to the extracellular fluid. The lipid bilayer is mostly impermeable to ions, which must pass in and out of the cell through ion channels. As discussed earlier, if the flux of ions makes the inside of the cell more negative ("hyperpolarized"), then it is harder for the cell to initiate an action potential. If the flux of ions makes the inside of the cell less negative ("depolarized"), then it is easier for the cell to initiate an action potential.

When ion channels open, ions usually flow in the direction favored by their concentration gradient. Extracellular concentrations of sodium, calcium, and chloride greatly exceed intracellular concentrations, and thus, these ions flow into cells when the appropriate ion channel opens. Some ion channels are restricted to the passage of certain ions. Intracellular concentrations of potassium greatly exceed extracellular concentrations, and thus, potassium follows out of cells whenever a potassium permeable channel is opened. The inwardly rectifying potassium channel is an exception in that potassium flows into the cell, opposite the concentration gradient, in response to the electrical gradient. These channels play an important role in cellular excitability and potassium homeostasis.

When sodium flows into a cell, it makes the interior less negative. Sodium channels are thus depolarizing. When potassium flows out of a cell, it makes the interior more negative. Therefore, potassium channels are hyperpolarizing. Sodium channels open to conduct action potentials, after which potassium channels open to restore the resting negative potential and terminate the action potential.

When chloride flows into a cell, the interior becomes more negative, or hyperpolarized. Because it is harder for a hyperpolarized cell to initiate an action potential, chloride channels are "inhibitory," at least after birth. When calcium flows into a cell, the interior becomes less negative, or "depolarized." Because it is easier for a depolarized cell to initiate an action potential, calcium channels are "excitatory." Calcium can also act as a second messenger within the cell.

When cell membranes are depolarized (the outside becomes less negative relative to the inside) or the appropriate ligand is present, these ion channels undergo conformational changes, the ion channel opens, and ions pass through. About 10⁴ to 10⁵ ions flow per millisecond per channel, and thousands of channels may open during a single action potential.

As mentioned previously, there are three basic types of ion channels: (1) ligand-gated ion channels (ionotropic receptors), (2) voltage-sensitive ion channels, and (3) ion channels that respond to other types of gating. Rapid synaptic transmission is entirely accomplished through the activation of ligand-gated ion channels, which transmit the signal across the synapse, and voltage-gated ion channels, which propagate action potentials.

Voltage-Gated Ion Channels

Voltage-gated ion channels are complexes of protein subunits that act as switchable portals sensitive to membrane potential through which ions can pass through the cell membrane. They are “voltage-sensitive” because they open and close in response to changes in voltage across cell membranes. Charged portions of the molecule physically move in response to voltage changes to energetically favor the open or closed state of the channel. For example, the sodium channel opens in response to a sudden depolarization, propagating the action potential in nerves. Voltage-gated ion channels are present in neurons, skeletal muscles, cardiac muscle, and endocrine cells. They are often named based on the ion that passes through the channel, for example, sodium, chloride, potassium, and calcium channels.

The voltage-gated sodium channel is of particular interest to anesthesiologists because it is the site of local anesthetic action. Local anesthetics block neural conduction by blocking passage of sodium through the voltage sodium channel.

The human *ether-a-go-go* related gene potassium channel is a voltage-gated inwardly rectifying potassium channel, mostly famous for its association with prolonged QT syndrome. The human *ether-a-go-go* related gene potassium channel is sensitive to many drugs and is responsible for sudden death from drugs that predispose the patient to *torsades de pointes*. It is difficult to provide anesthesia without combining drugs that alter the QTc causing great consternation to pharmacists and the U.S. Food and Drug Administration.²³ Despite this, *torsades de pointes* is extremely uncommon during anesthesia in the setting of normal electrolytes.

Ligand-gated ion channels are channels in the plasma membrane that respond directly to extracellular ligands, rather than require coupling through G proteins ([Figure 3.5](#)).

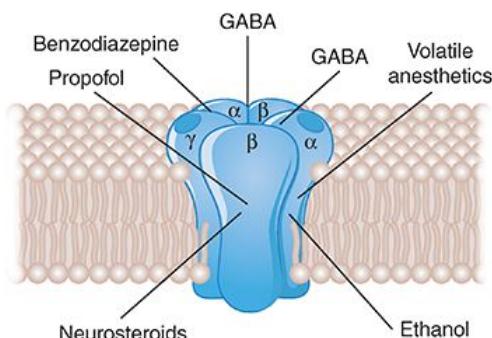

FIGURE 3.5 Schematic of the γ -aminobutyric acid (GABA) type A ligand-gated ion channel. The ligand binds to the external binding domain, modulating the conductance of ions through the central pore. The receptor is a pentamer of two α subunits, two β subunits, and one γ subunit. The binding sites show where several sedatives are known to act. These sedatives increase the flux of chloride through the channel, leading to hyperpolarization of the cell.

Ligand-gated ion channels are involved principally with fast synaptic transmission between excitable cells. Binding of signaling molecules to these receptors causes an immediate conformational change in the ion channels, opening or closing the channel to alter the ion permeability of the plasma membranes and therefore the membrane potential. Ligand-gated ion channels are typically activated by ligands for which they are named. Nicotinic acetylcholine receptors, serotonin receptors (5-HT₃), GABA receptors (GABA_A) (see [Figure 3.5](#)), and glycine receptors are opened in the presence of acetylcholine, serotonin, GABA, and glycine, respectively. Sometimes, the agonist for which the channel is named is not the native agonist. For example, NMDA and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors are named by NMDA and AMPA, the selective nonbiologic agonists that allowed for their specific identification in the laboratory, but the native agonist for both receptors is glutamate. Many general anesthetics act as ligands that may bind at multiple sites on gated ion channels causing inhibitory or excitatory effects.²⁴

Excitatory Ligand-Gated Ion Channels

Excitatory ligand-gated ion channels cause the inside of the cell to become less negative, typically by facilitating the influx of cations into the cell.

Acetylcholine. Acetylcholine is an excitatory neurotransmitter that activates muscarinic and nicotinic receptors in the CNS. Nicotinic acetylcholine receptors are nonspecific cation channels, permitting sodium and in some cases calcium to flow into cells, and potassium to flow out of cells. Because the flow of sodium and calcium is driven both by concentration and electrical gradients, the channel produces a net positive inward flux of cations and is therefore depolarizing (the interior becomes less negative). Nicotinic acetylcholine receptors in the brain are most commonly in a presynaptic location where they act as a “gain control mechanism” to enhance the release of other neurotransmitters. Acetylcholine releasing neurons play an important role in native sleep pathways where acetylcholine mediates arousal.²⁵ The excitatory effect on the CNS mediated through nicotinic ion channels contrasts with the inhibitory effects that are mediated by the G protein-coupled muscarinic acetylcholine receptors in the peripheral parasympathetic nervous system. Nicotinic acetylcholine receptors are also responsible for conducting action potentials to muscles.

While all volatile anesthetics are highly potent inhibitors of the nicotinic acetylcholine receptors,²⁶ direct nicotinic inhibition is not likely responsible for the hypnotic actions of volatile anesthetics because most nicotinic acetylcholine receptors that are expressed in the brain are fully inactivated at anesthetic concentrations that are present on emergence. The inhibition likely occurs through channel blockade, stabilization of close channels, and desensitization. Nicotinic acetylcholine receptors are largely antagonized at volatile anesthetic concentrations and induce immobility rather than mediate the behavioral effects of anesthesia.²⁴ Nicotinic acetylcholine muscle subtype ligand-gated ion channels have provided important tools for the early investigation of general anesthetics. Nondepolarizing muscle relaxants work by blocking the acetylcholine binding site. Because these channels cause depolarization, they are excitatory. Volatile anesthetics are inhibitory at muscle type acetylcholine receptors, but they likely play only a small role in muscle relaxation as there is only moderate inhibition at anesthetizing concentrations.

Glutamate. Glutamate is the major excitatory amino acid neurotransmitter in the CNS. Glutamate receptors are nonselective cation channels, permitting sodium and some calcium to flow into cells, and potassium to flow out of cells dependent on their gradient. Because nonspecific cation channels primarily favor net inward flux of cations down the electrical gradient, glutamate receptors are depolarizing and excitatory. Glutamate-responsive receptors are distributed widely in the CNS. Glutamate plays a key role in learning, and memory, central pain transduction, and pathologic processes such as excitotoxic neuronal injury following CNS trauma or ischemia.

Glutamate is released into the synaptic cleft in response to depolarization of the presynaptic nerve terminal. The release of glutamate from presynaptic terminals is a calcium ion-dependent process regulated by multiple types of calcium channels. In common with many other central neurotransmitter systems, the actions of glutamate within the synaptic cleft is tightly controlled and are terminated by high affinity sodium-dependent reuptake of glutamate and modified by activation of presynaptic receptors.

Ionotropic glutamate receptors (NMDA), AMPA, δ , and kainate receptors are ligand-gated ion channels. Glutamate receptors that respond to NMDA are associated with neuropathic pain and opioid tolerance and are blocked by ketamine. The NMDA receptors are highly calcium permeable. Glutamate receptors that respond to AMPA and kainite are involved with fast synaptic transmission and synaptic plasticity, including long-term potentiation. Ionotropic glutamate receptors are involved in many neurologic disease processes including stroke and Alzheimer disease.²⁷ Metabotropic glutamate receptors are transmembrane receptors that are linked to G proteins that modulate intracellular second messengers such as inositol phosphates and cyclic nucleotides.

Serotonin. The serotonin (5-HT₃) receptor is also excitatory, permitting passage of sodium, potassium, and calcium cations as described for the nicotinic acetylcholine receptor. Among other areas, serotonin receptors are located in the chemoreceptor trigger zone, where they are inhibited by ondansetron, granisetron, and other common antiemetic drugs.²⁰

Inhibitory Ligand-Gated Ion Channels

γ -Aminobutyric Acid. GABA is the major inhibitory neurotransmitter in the brain. The chloride channel is constructed from various combinations of five subunits. The channel is formed from the α and β subunits, with or without γ , δ , ϵ , π and θ subunits. When two molecules of GABA bind to the GABA receptor, the ligand-gated chloride channel in the center of the receptor opens allowing chloride ions to enter the cell following their concentration gradient (see [Figure 3.5](#)). This results in hyperpolarization of the cell membrane and inhibition of transduction.²⁷

As mentioned earlier, GABA receptors mediate many of the anesthetic effects of propofol, etomidate, and thiopental, which directly or at some concentrations indirectly open the channel, causing hyperpolarization of the cell. Benzodiazepines also work through GABA receptors but increase the sensitivity of the receptor to exogenous GABA rather than directly opening the ion channel. There is increasing evidence that extrasynaptic GABA receptors are important in volatile anesthetic-induced behavioral responses.²⁸

Glycine. Glycine is the principal inhibitory neurotransmitter in the spinal cord, acting through the glycine receptor to increase chloride ion conductance into the cell, causing hyperpolarization. Glycine receptors are also present in the brain. These channels are involved in many neurologic processes and are modulated by a variety of anesthetic drugs but are not known to be responsible for any specific anesthetic induced behavior.²⁹

Strychnine and tetanus toxin result in seizures because they antagonize the effects of glycine on postsynaptic inhibition. Visual disturbances after transurethral resection of the prostate in which glycine is the irrigating solution may reflect the role of this substance as an inhibitory neurotransmitter in the retina.³⁰ Amplitude and latency of visual evoked potentials are triggered by infusions of glycine.³¹

G Protein-Gated Ion Channels

Some ion channels are directly gated by G proteins ([Figure 3.6](#)). G protein-gated potassium channels are the most well studied of the G protein-regulated ion channels.³² The first identified G protein-regulated ion channel was the cardiac potassium channel, which is directly regulated by the M₂ muscarinic acetylcholine G protein-coupled receptor.³³ This is one of many inward rectifying potassium channels that share the unusual property of permitting influx of potassium ions into the cell following the electrical gradient, rather than the more typical outward flux of potassium following the ionic concentration gradient. G protein-regulated inwardly rectifying potassium channels, commonly referred to as GIRKs, are regulated by G_{B γ} rather than G_α. In addition to muscarinic acetylcholine, A₁ adenosine, α_2 -adrenergic, D₂ dopamine, opioid, serotonin, and GABA_B receptors are coupled directly to GIRKs.^{32,34}

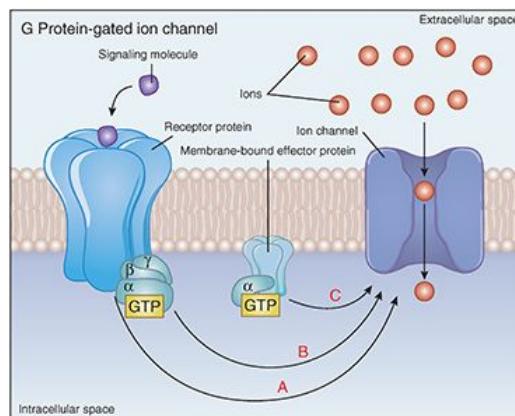

FIGURE 3.6 G protein-gated ion channel. When the signaling molecule binds to the G protein-coupled receptor, the G proteins either directly activate the ion channel (line B for activation by G_α, line C for

activation by $G_{\beta\gamma}$) or activate an intermediary membrane-bound effector protein, which in turn activates the ion channel (line A). Abbreviation: GTP, guanosine triphosphate.

Other-Gated Ion Channels

Other types of ion channel gating include gating by other ions (eg, hydrogen, calcium), second messengers (eg, cAMP, cyclic guanosine monophosphate), and tissue injury (acid, stretch, temperature, cytokines). These mechanisms are outside of the purview of this chapter.

Receptor Concentration

Receptors in cell membranes are not static components of cells. Excess circulating concentrations of ligand often modulate the density of the target receptors in cell membranes. For example, the excessive circulating norepinephrine in patients with pheochromocytoma leads to down regulation of β -adrenergic receptors. Desensitization of receptor responsiveness is the waning of a physiologic response over time despite the presence of a constant stimulus.¹⁶ Drug-induced antagonism of receptors results in an increased density of receptors in cell membranes (upregulation). Abrupt discontinuation of the antagonist can result in an exaggerated response to the endogenous agonist. This is one reason that most cardiovascular medicines should be continued throughout the perioperative period. In contrast, prolonged exposure to high-dose exogenous opioids results in receptor desensitization and internalization that can take significant time to recover. Tolerance to long-term opioid use results from related mechanisms and can take significant time to reverse.³⁵

Receptor Diseases

Numerous diseases are associated with receptor dysfunction.³⁶ For example, failure of parathyroid hormone and arginine vasopressin to produce increases in cAMP in target organs manifests as pseudohypoparathyroidism and nephrogenic diabetes insipidus, respectively. Graves disease and myasthenia gravis reflect development of antibodies against thyroid-stimulating hormone and nicotinic acetylcholine receptors, respectively.

The Synapse

Structure

The synapse functions as a diode that transmits the energy of an action potential from the presynaptic membrane to the postsynaptic membrane across the synaptic cleft ([Figure 3.7](#)). The presynaptic membrane contains the vesicles of neurotransmitter and the reuptake pump that returns the neurotransmitter to the presynaptic axoplasm following neurotransmitter release. It also contains the voltage-gated calcium channel and other channels and receptors that modulate neurotransmitter release. The reuptake pump is also important to modulate postsynaptic excitation and desensitization. Synaptic transmission starts when an afferent action potential arrives at the voltage-gated calcium channel.

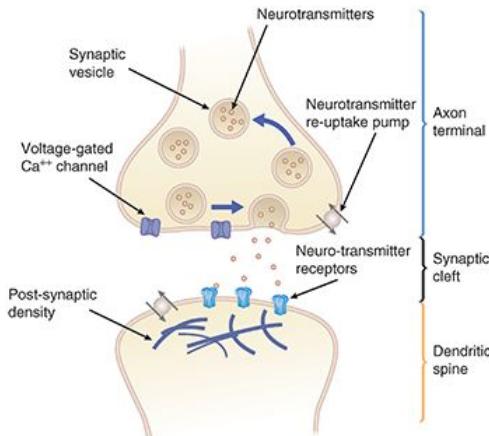

FIGURE 3.7 Structure of the synapse. Axons typically have many synapses, not just the single synapse, implied by the conventional typical rendition in the following text. The presynaptic membrane encloses the synaptic vesicles that contain the neurotransmitters, the reuptake pump that removes the neurotransmitter following synaptic transmission, and the voltage-gated calcium channel that responds to the incoming action potential. The ligand-gated receptors in the postsynaptic membrane trigger an efferent action potential. The postsynaptic density contains multiple proteins and receptors, and appears responsible for organizing the structure of the receptors on the synapse.

The depolarization of the presynaptic neuron permits the influx of calcium ions through the voltage-gated calcium channel. Calcium ions bind to specialized proteins called the release apparatus on axonal and vesicular membranes. Calcium triggers the fusion of the vesicle to the cell membrane and the release of the neurotransmitter into the synaptic cleft through exocytosis, resulting in the extrusion of the contents of the synaptic vesicles. Calcium in the extracellular fluid is essential to the release of neurotransmitters in response to an action potential. The effect of calcium is antagonized by magnesium. Maintenance of extracellular calcium and magnesium concentration is critical during anesthesia to protect both autonomic and CNS homeostasis.

The neurotransmitter in the cleft binds to receptors in the postsynaptic membrane. This binding initiates an efferent action potential in the dendrite or cell body of the efferent nerve, which is then propagated. Immediately distal to the postsynaptic membrane is the postsynaptic density. The postsynaptic density contains a variety of receptors, enzymes, and structural proteins responsible for maintaining synapse homeostasis. The earlier description of “typical synapse” is simplistic and does not consider the enormous variation that underlies the complexity of behavior or synaptic plasticity. More detail can be considered in reviews.^{37,38}

Synaptic Fatigue

Synaptic fatigue is a decrease in the number of discharges by the postsynaptic membrane when excitatory synapses are repetitively and rapidly stimulated. For example, synaptic fatigue decreases excessive excitability of the brain as may accompany a seizure, thus acting as a protective mechanism against excessive neuronal activity. The mechanism of synaptic fatigue is presumed to be exhaustion of the stores of neurotransmitter in the synaptic vesicles. Synaptic fatigue is unmasked at the neuromuscular junction in myasthenia gravis when the enormous reserve for neuromuscular transmission is limited by either pre- or postsynaptic autoimmune damage.

Posttetanic Facilitation

Posttetanic facilitation is increased responsiveness of the postsynaptic neuron to stimulation after a rest period that was preceded by repetitive stimulation of an excitatory synapse. This phenomenon reflects increased release of neurotransmitters due to a short-term increase in the concentration of calcium near the presynaptic apparatus.

Factors That Influence Neuron Responsiveness

Neurons are highly sensitive to changes in the pH of the surrounding interstitial fluids. For example, alkalosis enhances neuron excitability. Voluntary hyperventilation can evoke a seizure in a susceptible individual. Conversely, acidosis depresses neuron excitability, with a decrease in arterial pH to 7.0 potentially causing coma. Hypoxia can cause total refractoriness in neurons as reflected by the almost immediate onset of unconsciousness following cessation of cerebral blood flow. This response is in part protective because the metabolic activity of inactive neurons is an order of magnitude less than that of active neurons. The awake resting brain uses 20% to 25% of the body's total available energy, mostly in the form of glucose.³⁹

Central Nervous System

The brain, brainstem, and spinal cord constitute the CNS. The brain is a complex collection of neural networks that regulate their own and each other's activity. Activity within the CNS reflects a balance between excitatory and inhibitory influences, a homeostasis that is normally maintained within relatively narrow limits. Anatomic divisions of the brain reflect the distribution of brain functions (**Figure 3.8**).

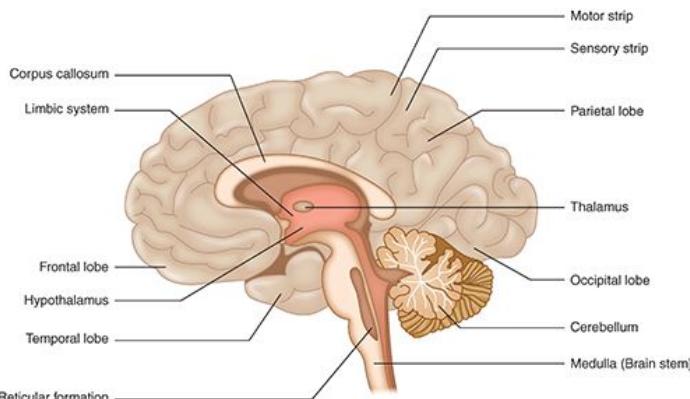

FIGURE 3.8 Brain anatomy.

The brainstem connects the cerebral cortex to the spinal cord and contains most of the nuclei of the cranial nerves and the reticular activating system. The reticular activating system is important for regulation of sleep and wakefulness. The cerebellum arises from the posterior pons and is responsible for coordination of movement, maintenance of body posture, and certain types of motor memory.

The spinal cord extends from the medulla oblongata to the lower lumbar vertebrae. Ascending and descending tracts are located within the white matter of the spinal cord, whereas intersegmental connections and synaptic contacts are concentrated in the gray matter. Sensory information flows into the dorsal portion (posterior) of the gray matter, and motor outflow exits from the ventral (anterior) portion. Preganglionic neurons of the autonomic nervous system are found in the intermediolateral portions of the gray matter.

Cerebral Hemispheres

The two cerebral hemispheres, known as the *cerebral cortex*, constitute the largest division of the human brain. Regions of the cerebral cortex are classically identified as *sensory*, *motor*, *visual*, *auditory*, and *olfactory*, depending on the type of information that is processed. *Frontal*, *temporal*, *parietal*, and *occipital* designate anatomic positions of the cerebral cortex (**Figure 3.9**). For each area of the cerebral cortex, there is a corresponding and connecting area to the thalamus such that stimulation of a small portion of the thalamus activates the corresponding and much larger portion of the cerebral cortex. Indeed, the cerebral cortex is actually an evolutionary outgrowth of the lower regions of the nervous system, especially the thalamus. In embryology and evolution, development the brain develops from the brainstem upward to the cortex.⁴⁰ The functional part of the cerebral cortex is comprised mainly of a 2- to 5-mm layer of neurons covering the surface of all the convolutions.

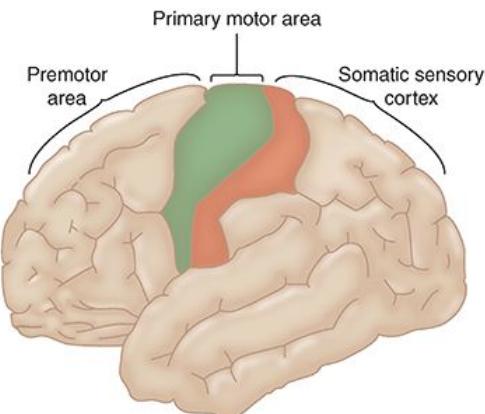

FIGURE 3.9 The sensorimotor cortex consists of the motor cortex, pyramidal (Betz) cells, and somatic sensory cortex.

Anatomy of the Cerebral Cortex

The sensorimotor cortex is the area of the cerebral cortex responsible for receiving sensation from sensory areas of the body and for controlling body movement (see [Figure 3.9](#)).⁴ The premotor cortex is important for controlling the functions of the motor cortex. The motor cortex lies anterior to the central sulcus. Its posterior portion is characterized by the presence of large, pyramid-shaped (pyramidal or Betz) cells.

Topographic Areas

The area of the cerebral cortex to which the peripheral sensory signals are projected from the thalamus is designated the *somesthetic cortex* (see [Figure 3.9](#)).⁴ Each side of the cerebral cortex receives sensory information from the opposite side of the body. The size of these areas is directly proportional to the number of specialized sensory receptors in each respective area of the body. For example, many specialized nerve endings are present in the lips and the thumbs, whereas only a few are present in the skin of the trunk. In the setting of amputation and other trauma, the sensory cortex can remap giving repurposing neurons to nearby healthy areas.⁴¹ While this process underlies rehabilitation after injury, it can be maladaptive and may underlie central pain states.⁴²

The motor cortex is organized into topographic areas corresponding to different regions of the skeletal muscles. The spatial organization is similar to that of the sensory cortex. In general, the size of the area in the motor cortex is proportional to the precision of the skeletal muscle movement required. As such, the digits, lips, tongue, and vocal cords have large representations in humans. The various topographic areas in the motor cortex were originally determined by electrical stimulation of the brain during local anesthesia and observation of the evoked skeletal muscle response. Such stimulation can be used intraoperatively to identify the location of the motor cortex and other areas to avoid damage and to determine function of implants for treatment of diseases such as Parkinson disease and epilepsy.^{43,44} The motor cortex is commonly damaged by loss of blood supply as occurs during a stroke.

Corpus Callosum

The two hemispheres of the cerebral cortex, with the exception of the anterior portions of the temporal lobes, are connected by fibers in the corpus callosum. The anterior portions of the temporal lobes, including the amygdala, are connected by fibers that pass through the anterior commissure. The corpus callosum and anterior commissure make information processed or stored in one hemisphere available to the other hemisphere. Resection of the corpus callosum can cause “split brain syndrome.” A feature is the inability to verbally describe or name an object placed in the left hand, left hemisphere dominance, and inability to understand written language if the writing is presented only to the left visual field. Although the information is transmitted from the left eye to the right cerebral hemisphere, it cannot be transferred to the left for interpretation and verbal output.⁴⁵

Dominant Versus Nondominant Hemisphere

Language function and interpretation is typically localized in the dominant cerebral hemisphere, whereas spatiotemporal relationships (ability to recognize faces) is localized in the nondominant hemisphere. The left hemisphere is dominant in 90% of right-handed individuals and 70% of left-handed individuals.

Memory

The cerebral cortex, especially the medial temporal lobes, serve as a storage and processing site for the formation of memories. The mechanisms for short- and long-term memory are not completely understood but are thought to be encoded through selective synaptic alteration in response to experience. There are several theories to explain the mechanisms of memory formation, many of which involve the modulation of synaptic connectivity. Long-term potentiation occurs when a tetanic stimulation leading to a high-frequency train of action potentials produces a prolonged strengthening of synaptic transmission. Long-term potentiation involves activation of NMDA receptors that produce an influx of postsynaptic calcium. The calcium activates protein kinases.⁴⁶

Short-term memory involves strengthening synaptic connections particularly in the hippocampus. Long-term potentiation of synapses is a major mechanism by which memories are stored in the short-term and for transmission to long-term memories.⁴⁷ Hippocampal function and dysfunction can be tested with neuropsychological tests of learning capacity, proactive interference, immediate recall, delayed recall, and delayed recognition.⁴⁸ Long-term memory is thought to rely on long-term synaptic potentiation mediated by structural changes that produce new proteins. Thus, protein transcription and synaptic remodeling are an essential component of long-term memory. The hippocampus and amygdala are critically involved in creating new long-term memories. However, long-term memories are not actually stored in the hippocampus and amygdala. The actual mechanism by which long-term memories are stored remains a fascinating unsolved puzzle.

Everyone knows from personal experience that repetition is essential to forming long-term memory. There is an old joke about a man asking a fellow pedestrian in New York, “How do you get to Carnegie Hall?” The pedestrian replies, “Practice, practice, practice.” It has been repeatedly demonstrated in animal studies as well that repetition is key to forming long-term memories. Long-term potentiation is the synaptic consequence of repeated stimulation, which is one reason that long-term potentiation is thought to be the fundamental building block of long-term memory.

We also know that memories are transferred from short-term memory to long-term memory. Because the creation of long-term memory requires anatomic changes in the synapse, this transfer requires time. This suggests, and studies confirm, that if the brain is not given adequate time to make this transfer, there will be no transfer from short-term memory to long-term memory. This has direct applicability to the practice of anesthesia. During the provision of general anesthesia, we are vigilant for signs of inadequate anesthesia and intraoperative awareness (discussed further at the end of this section). If a patient has conscious perception of the surgery, this will initially be part of the patient’s short-term memory. Rapid deepening of the anesthesia, for example, by administering a bolus of propofol in response to movement, may prevent transfer of the recall from short-term memory to the long-term memory, and the patient will be amnestic. Conversely, if the patient is paralyzed and is awake for many minutes without the anesthesiologist being aware of the situation, then there has been adequate time for transfer of the short-term memory to long-term memory. Movement inhibition requires higher concentrations of anesthetic than amnesia.⁴⁹ This may explain why targeting the *minimum anesthetic concentration* (MAC) that prevents immobility allows for an extremely low probability of memory under anesthesia.

Because the neural substrate of memory is not well understood, memory is often discussed from a psychological point of view. Memories typically involve multiple senses (sight, hearing, touch), emotions (fear, satisfaction, pleasure, anger), and cognitive assessment (“I remember thinking that . . . ”). These are thought to be held together in a facilitated circuit that has been called a memory engram or memory trace. The pieces of the engram are consolidated through hypothalamic circuitry. The memory engram is reinforced with every subsequent recall of the memory.⁵⁰ An important feature of the process of consolidation is that long-term memory is encoded into different categories. New memories are not stored randomly in the brain

but seem to be associated with previously encoded and similar information. This permits scanning of memory to retrieve desired information at a later date. We also know that memory scanning is often a subconscious process. This is confirmed by the daily experience of struggling to recall a fact or event, only to have the memory suddenly jump into our consciousness hours later.

Awareness and Recall During Anesthesia

Awareness or explicit memory during anesthesia is a dreaded complication. Memory may be considered to be conscious (explicit) or unconscious (implicit). Conscious memory includes spontaneous recall and recognition memory, both of which occur with the aid of a specific cue. Unconscious memory is manifest by altered performance or behavior due to experiences that are not consciously remembered. General anesthesia at an adequate concentration abolishes conscious memory, but the extent to which it also abolishes unconscious memory is controversial and dependent of the type of anesthesia used. The incidence of conscious recall of intraoperative events is rare and the development of posttraumatic stress disorder is even more uncommon. The incidence of awareness with recall (conscious memory) following general anesthesia in some settings where maintenance of anesthetic depth is not possible is surprisingly high, estimated at 5 per 1,000.⁵¹ A higher incidence of awareness has been described for major trauma where anesthetic depth is limited by autonomic function and cardiac surgery where opioids have classically been used as a major part of the anesthetic. While they are potent analgesics, opioids alone do not reliable provide amnesia.⁵²

Neuromuscular blocking drugs permit inadequate anesthesia to be administered without obvious patient withdrawal from the noxious stimulus. The use of neuromuscular blockade is a risk factor for awareness under general anesthesia, particularly awareness that is associated with memories of pain and complicated by posttraumatic stress disorder.⁵³ The use of benzodiazepines have been shown to reduce episodes of awareness. As expected, higher doses of volatile anesthetics reduce episodes of awareness when compare to lower doses.⁵¹

Recognizing Awareness

Monitoring patients during general anesthesia for the presence of awareness is challenging. Despite a variety of monitoring methods, awareness may be difficult to recognize in real time. Indicators of awareness (heart rate, blood pressure, and skeletal muscle movement) are often masked by anesthetic and adjuvant drugs (β -adrenergic blockers, opioids) and/or neuromuscular-blocking drugs. Several monitors, based on analysis of electroencephalogram (EEG) and SSEP patterns have been introduced in hopes of addressing this issue. However, the use of processed EEG anesthetic depth monitoring has not been consistently shown to reduce the risk of awareness.⁵¹

Postoperative Cognitive Dysfunction

Cognitive impairment including impaired memory and perception can occur after surgery and anesthesia. Postoperative cognitive dysfunction persisting after 3 months has been described in 10% of elderly patients receiving general anesthesia for noncardiac surgery without known arterial hypoxemia or systemic hypotension. Increased age and fewer years of education were associated with postoperative cognitive dysfunction (POCD).⁵⁴ Other studies have identified other possible risk factors including postoperative delirium and the used of sedative drugs.⁵⁵ Current recommended perioperative neurocognitive disorders as an inclusive nomenclature for cognitive impairment identified in the preoperative or postoperative period that may include worsening of cognitive decline diagnosed before operation, an acute event (postoperative **delirium**), and cognitive decline diagnosed up to 30 days after the procedure (delayed neurocognitive recovery) and up to 12 months (postoperative neurocognitive disorder).⁵⁶ Several studies have investigated the neurotoxicity related to anesthesia. Inhaled anesthetics have shown potentiation of the pathologic processes involving amyloid precursor protein that are associated with Alzheimer disease. Increased permeability of the blood–brain barrier, neuroinflammation, and microemboli all may play a role in the development of POCD. It is unclear whether the POCD is caused by anesthetic injury to the aged brain or is caused by the combined effects of surgical trauma, inflammation, social interruption, anesthesia, and other unidentified causes.

Brainstem

Homeostatic life sustaining processes are controlled subconsciously in the brainstem. Examples of subconscious activities of the body regulated by the brainstem include control of systemic blood pressure and breathing in the medulla. The thalamus serves as a relay station for most afferent impulses before they are transmitted to the cerebral cortex. The hypothalamus receives fibers from the thalamus and is also closely modulated by the cerebral cortex.

Limbic System and Hypothalamus

Behavior associated with emotions is primarily a function of structures known as the *limbic system* (hippocampus, basal ganglia) located in the basal regions of the brain. The hypothalamus functions in many of the same roles as the limbic system and is considered by some to be part of the limbic system rather than a separate structure. In addition, the hypothalamus controls many internal conditions of the body, such as core temperature, thirst, and appetite. The great Oxford neurophysiologist Sir Charles Sherrington called the *hypothalamus* the *head ganglion* of the autonomic nervous system. The suprachiasmatic nucleus of the hypothalamus helps to maintain the body clock by secreting melatonin and other mediators according to the circadian rhythm. This nucleus sits just above the optic chiasm and received inputs from the optic nerve that serve to entrain the circadian rhythm to environmental light. At high doses, melatonin and its analogs have properties similar to a general anesthetic.⁵⁷ Some general anesthetics activate a group of hypothalamic neurons near the supraoptic nucleus, consisting of neuroendocrine cells, that potentiate general anesthesia.⁵⁸

Basal Ganglia

The basal ganglia include the caudate nucleus, putamen, globus pallidus, substantia nigra, and subthalamic nucleus. Many of the impulses from basal ganglia are inhibitory mediated by dopamine and GABA. The balance between agonist and antagonist skeletal muscle contractions is an important role of the basal ganglia. A general effect of diffuse excitation of the basal ganglia is inhibition of skeletal muscles, reflecting transmission of inhibitory signals from the basal ganglia to both the motor cortex and the lower brainstem. Therefore, whenever destruction of the basal ganglia occurs, there is associated skeletal muscle rigidity. For example, damage to the caudate and putamen nuclei that normally secrete GABA results in both choreiform random and continuous uncontrolled movements. Destruction of the substantia nigra and loss of dopaminergic neurons results in a predominance of the excitatory neurotransmitter acetylcholine, manifesting as the skeletal muscle rigidity of Parkinson disease. Indeed, dopamine precursors or anticholinergic drugs are used in the treatment of Parkinson disease in an attempt to restore the balance between excitatory and inhibitory impulses traveling from the basal ganglia.

Reticular Activating System

The reticular activating system is a polysynaptic pathway that is intimately concerned with electrical activity of the cerebral cortex. Neurons of the reticular activating system are both excitatory and inhibitory. The reticular activating system determines the overall level of CNS activity, including nuclei important in determining wakefulness and sleep. Selective activation of certain areas of the cerebral cortex by the reticular activating system is crucial for direction of attention and certain aspects of mental activity. Injected and inhaled anesthetics exert some of their sedative effects through interaction with the brainstem and midbrain nuclei that mediate arousal and sleep.⁵⁹ This is not to say that general anesthesia is equivalent to sleep. While the EEG response to many anesthetics resembles deep slow-wave sleep, a key difference is that afferent stimulation does not cause arousal.

Slow-Wave Sleep

Most of the sleep that occurs each night is slow-wave sleep. The EEG is characterized by the presence of high-voltage delta waves occurring at a frequency of <4 cycles per second. Presumably, decreased activity of the reticular activating system that accompanies sleep permits an unmasking of this inherent rhythm in the cerebral cortex. Slow-wave sleep is restful and devoid of dreams. During slow-wave sleep, sympathetic nervous system activity decreases, parasympathetic nervous system activity increases, and skeletal muscle

tone is greatly decreased. As a result, there is a 10% to 30% decrease in systemic blood pressure, heart rate, breathing frequency, and basal metabolic rate.

Desynchronized Sleep

Periods of desynchronized sleep typically occur for 5 to 20 minutes during each 90 minutes of sleep. These periods tend to be shortest when the person is extremely tired. This form of sleep is characterized by active dreaming, irregular heart rate and breathing, and a desynchronized pattern of low-voltage beta waves on the EEG similar to those that occur during wakefulness. This brain wave pattern emphasizes that desynchronized sleep is associated with an active cerebral cortex, but this activity does not permit persons to be aware of their surroundings and thus be awake. Despite the inhibition of skeletal muscle activity, the eyes are an exception, exhibiting rapid movements. For this reason, desynchronized sleep is also referred to as *paradoxical sleep* or *rapid eye movement (REM) sleep*.

Cerebellum

The cerebellum operates subconsciously to monitor and elicit corrective responses in motor activity caused by stimulation of other parts of the brain and spinal cord. Rapid repetitive skeletal muscle activities, such as typing, playing musical instruments, and running, require intact function of the cerebellum. Loss of function of the cerebellum causes incoordination of fine skeletal muscle activities even though paralysis of the skeletal muscles does not occur. The cerebellum is also important in the maintenance of equilibrium and postural adjustments of the body.

Dysfunction of the Cerebellum

In the absence of cerebellar function, a person cannot predict prospectively how far movements will go. This results in overshoot of the intended mark (past pointing). This overshoot is known as *dysmetria*, and the resulting incoordinate movements are called *ataxia*. Dysarthria is present when rapid and orderly succession of skeletal muscle movements of the larynx, mouth, and chest do not occur. Failure of the cerebellum to dampen skeletal muscle movements results in intention tremor when a person performs a voluntary act. Cerebellar nystagmus is associated with loss of equilibrium, presumably because of dysfunction of the pathways that pass through the cerebellum from the semicircular canals. In the presence of cerebellar disease, a person is unable to activate antagonist skeletal muscles that prevent a certain portion of the body from moving unexpectedly in an unwanted direction. For example, a person's arm that was previously contracted but restrained by another person will move back rapidly when it is released rather than automatically remain in place.

Spinal Cord

The spinal cord extends from the medulla oblongata to the lower border of the first and, occasionally, the second lumbar vertebra. Below the spinal cord, the vertebral canal is filled by the roots of the lumbar and sacral nerves, which are collectively known as the *cauda equina* (the tail of a horse). The spinal cord is composed of gray and white matter, spinal nerves, and covering membranes.

Gray Matter

The gray matter of the spinal cord functions as the initial processor of incoming sensory signals from peripheral somatic receptors and as a relay station to send these signals to the brain.

In addition, this area of the spinal cord is the site for final processing of motor signals that are being transmitted downward from the brain to skeletal muscles. Anatomically, the gray matter of the spinal cord is divided into anterior, lateral, and dorsal horns consisting of nine separate laminae that are H shaped when viewed in cross-section ([Figure 3.10](#)). The anterior horn is the location of alpha and gamma motor neurons that give rise to nerve fibers that leave the spinal cord via the anterior (ventral) nerve roots and innervate skeletal muscles. Cells of Renshaw are intermediary neurons in the anterior horn, providing nerve fibers that synapse in the gray matter with anterior motor neurons. These cells inhibit the action of anterior motor neurons to limit excessive activity. Cells of the preganglionic neurons of the sympathetic nervous system are

located lateral to the thoracolumbar portions of the spinal cord. Cells of the intermediate neurons located in the portion of the dorsal horns of the spinal cord known as the *substancia gelatinosa* (laminae II-III) transmit afferent tactile, temperature, and pain impulses to the spinothalamic tract. The dorsal horn serves as a gate where impulses in sensory nerve fibers are translated into impulses in ascending tracts. There is evidence for a form of memory in the dorsal horn of the spinal cord that is evoked by intense stimulation. Resulting increases in intracellular calcium set into motion long lasting changes that are associated with central sensitization and result in increased sensitivity to subsequent inoffensive stimuli and may underly some types of chronic pain.⁶⁰

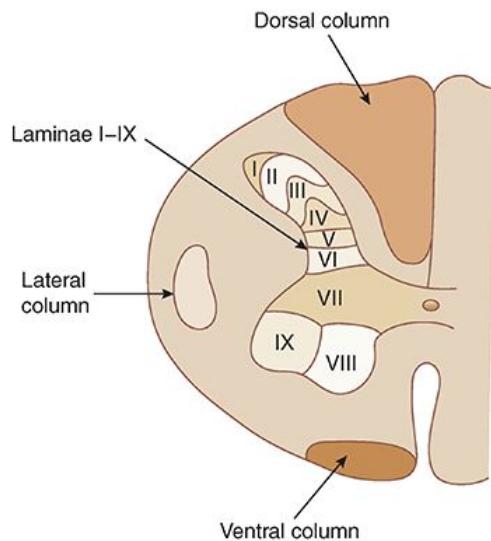

FIGURE 3.10 Schematic diagram of a cross-section of the spinal cord depicting anatomic laminae I to IX of the spinal cord gray matter and the ascending dorsal, lateral, and ventral sensory columns of the spinal cord white matter.

White Matter

The white matter of the spinal cord is formed by the axons that make up their respective ascending and descending tracts. This area of the spinal cord is divided into dorsal, lateral, and ventral columns (see [Figure 3.10](#)). The dorsal column of the spinal cord is composed of spinothalamic tracts that transmit touch and pain impulses to the brain.

Pyramidal and Extrapyramidal Tracts

A major pathway for transmission of motor signals from the cerebral cortex to the anterior motor neurons of the spinal cord is through the pyramidal (corticospinal) tracts ([Figure 3.11](#)).⁴ All pyramidal tract fibers pass downward through the brainstem and then cross to the opposite side to form the pyramids of the medulla. After crossing the midline at the level of the medulla, these fibers descend in the lateral corticospinal tracts of the spinal cord and terminate on motor neurons in the ventral horn of the spinal cord. A few fibers do not cross to the opposite side of the medulla but rather descend in the ventral corticospinal tracts. In addition to these pyramidal fibers, a large number of collateral fibers pass from the motor cortex into the basal ganglia, forming the extrapyramidal tracts. Extrapyramidal tracts are all those tracts beside the pyramidal tracts that transmit motor impulses from the cerebral cortex to the spinal cord.

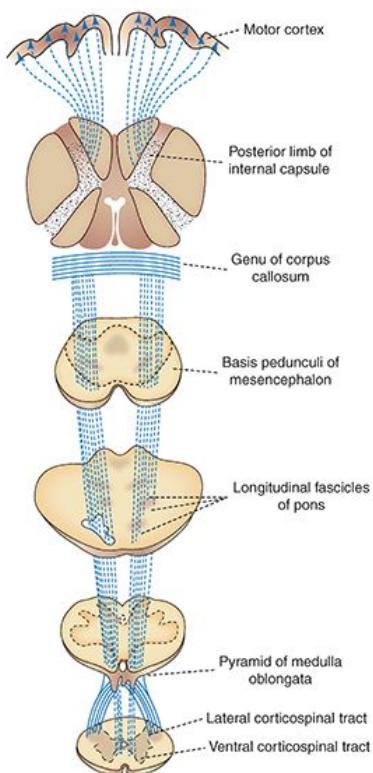

FIGURE 3.11 The pyramidal tracts are major pathways for transmission of motor signals from the cerebral cortex to the spinal cord.

The pyramidal and extrapyramidal tracts have opposing effects on the tone of skeletal muscles. For example, the pyramidal tracts cause continuous facilitation and therefore a tendency to produce increases in skeletal muscle tone. Conversely, the extrapyramidal tracts transmit inhibitory signals through the basal ganglia with resultant inhibition of skeletal muscle tone. Selective or predominant damage to one of these tracts manifests as spasticity or flaccidity.

Babinski Sign

A positive Babinski sign is characterized by upward extension of the first toe and outward fanning of the other toes in response to a firm tactile stimulus applied to the dorsum of the foot. A normal response to the same tactile stimulus is downward motion of all the toes. A positive Babinski sign reflects damage to the pyramidal tracts. Damage to the extrapyramidal tracts does not cause a positive Babinski sign.

Thalamocortical System

The thalamocortical system serves as the pathway for passage of nearly all afferent impulses from the cerebellum; basal ganglia; and visual, auditory, taste, and pain receptors as they pass through the thalamus on the way to the cerebral cortex. Signals from olfactory receptors are the only peripheral sensory signals that do not pass through the thalamus. Overall, thalamocortical integration controls the activity level of the cerebral cortex.

Spinal Nerve

A pair of spinal nerves arises from each of 31 segments of the spinal cord. Spinal nerves are made up of fibers of the anterior and dorsal (posterior) roots. Efferent motor fibers travel in the anterior roots that originate from axons in the anterior and lateral horns of the spinal cord gray matter. Sensory fibers travel in the dorsal nerve roots that originate from axons that arise from cell bodies in the spinal cord ganglia. These cell bodies send branches to the spinal cord and to the periphery. The anterior and dorsal nerve roots each

leave the spinal cord through an individual intervertebral foramen enclosed in a common dural sheath that extends just past the spinal cord ganglia where the spinal nerve originates.

Each spinal nerve innervates a segmental area of skin designated a *dermatome* and an area of skeletal muscle known as a *myotome*. A dermatome map is useful in determining the level of spinal cord injury or level of sensory anesthesia produced by a neuraxial anesthetic (Figure 3.12).⁴ Despite common depictions of dermatomes as having distinct borders, there is extensive overlap between segments. There is greater overlap in areas that are very sensitive. For example, three consecutive dorsal nerve roots need to be interrupted to produce complete denervation of some dermatomes. The scrotum has considerable sensory overlap, with innervation coming from T1 (variable) and L1 to L2 and S2 to S4 despite common depictions on dermatome charts as being limited to sacral innervation.⁶¹ Segmental innervation of myotomes is even less well defined than that of dermatomes, emphasizing that skeletal muscle groups receive innervation from several anterior nerve roots. In these settings, denervation of a dermatome for analgesia may require destruction or overdrive stimulation of several roots that may not be predicted by known dermatomal maps.⁶²

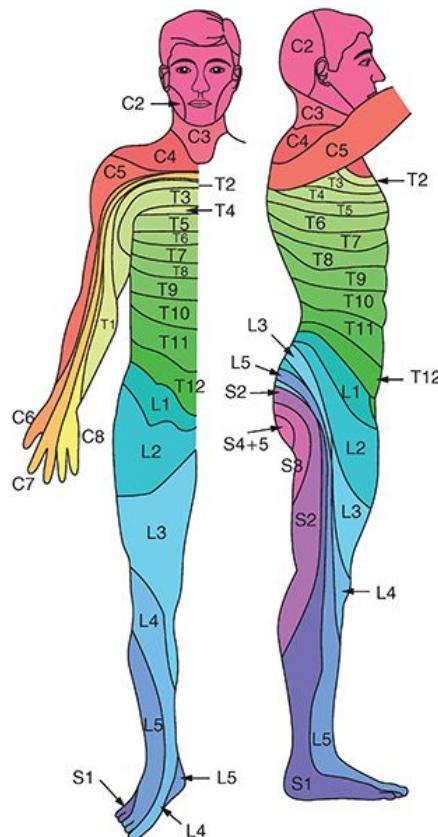

FIGURE 3.12 Dermatome map that may be used to evaluate the level of sensory anesthesia produced by regional anesthesia.

Sensory signals from the periphery are transmitted through spinal nerves into each segment of the spinal cord, resulting in automatic motor responses that occur instantly (muscle stretch reflex, withdrawal reflex) in response to sensory signals. Spinal cord reflexes are important in emptying the bladder and rectum. Segmental temperature reflexes allow localized cutaneous vasodilation or vasoconstriction in response to changes in skin temperature. The function of the spinal cord component of the CNS and spinal cord reflexes is particularly apparent in patients with transection of the spinal cord.

Central Nervous System Membranes

The spinal cord is enveloped by membranes (dura, arachnoid, pia) that are direct continuations of the corresponding membranes surrounding the brain. The dura consists of an inner and an outer layer. The outer periosteal layer in the cranial cavity is the periosteum of the skull, whereas this layer in the spine is the periosteal lining of the spinal cord. The epidural space is located between the inner and outer layers of the dura. The fact that the inner layer of the dura adheres to the margin of the foramen magnum and blends with the periosteal layer meaning that the epidural space does not extend beyond this point. As a result, drugs such as local anesthetics or opioids cannot travel cephalad in the epidural space beyond the foramen magnum. However, there is extensive equilibration between epidural and subarachnoid drug concentrations. Because of this equilibration hydrophilic opioids such as morphine given to the lumbar epidural space may cause delayed respiratory depression in patients at risk. The inner layer of the dura extends as a dural cuff that blends with the perineurium of spinal nerves. The cerebral arachnoid extends as the spinal arachnoid, ending at the second sacral vertebra. The pia is in close contact with the spinal cord.

The plica mediana dorsalis is a connective tissue band that divides the epidural space at the dorsal midline. This band binds the dura mater and the ligamentum flavum at the midline, making it difficult to feel loss of resistance during attempted midline identification of the epidural space. The plica mediana dorsalis may be implicated as a cause of unilateral epidural local anesthesia and has been managed with a bilateral double catheter technique in some settings.⁶³

Autonomic Reflexes

Segmental autonomic reflexes occur in the spinal cord and include changes in vascular tone, diaphoresis, and evacuation of the bladder and colon. Simultaneous excitation of all the segmental reflexes is the mass reflex (denervation hypersensitivity or autonomic hyperreflexia). The mass reflex typically occurs in the presence of spinal cord transection when a painful stimulus is applied to the skin below the level of the spinal cord transection, or following distension of a hollow viscus, such as the bladder or gastrointestinal tract. The principal manifestation of the mass reflex is systemic hypertension due to intense peripheral vasoconstriction, reflecting an inability of vasodilating inhibitory impulses from the CNS to pass beyond the site of spinal cord transection. This can be obviated in patients with high spinal cord lesions with neuraxial or deep general anesthesia that blocks the afferent input. Carotid sinus baroreceptor-mediated reflex bradycardia accompanies the systemic hypertension associated with the mass reflex.

Spinal Shock

Spinal shock is a manifestation of the abrupt loss of spinal cord reflexes that immediately follows transection of the spinal cord. It emphasizes the dependence of spinal cord reflexes on continual tonic discharges from higher centers. The immediate manifestations of spinal shock are hypotension due to loss of vasoconstrictor tone and absence of all skeletal muscle reflexes. Within a few days to weeks, spinal cord neurons gradually regain their intrinsic excitability. Sacral reflexes for control of bladder and colon evacuation are completely suppressed for the first few weeks after spinal cord transection, but these spinal cord reflexes also eventually return although their conscious control does not.

Imaging of the Nervous System

Neuroimaging continues to evolve. Not only can we visualize the anatomy of the brain, skull, and spinal cord but new imaging modalities allow us to visualize physiologic information regarding metabolism and perfusion. Computed tomography (CT) and magnetic resonance imaging (MRI) produce high-resolution cross-sectional images of the brain tissue and clear discrimination between gray and white matter. The CT scans are a fast and reliable way to visualize brain pathology, including detection of intracranial blood flow. The CT angiography uses injected contrast and reconstruction software to provide detailed imaging of the brain's vasculature. The CT perfusion is now widely used to assess acute stroke patients. The CT perfusion assesses cerebral blood flow and can indicate the area of the brain that is still at risk of ischemia. The CT perfusion has resulted in more patients being eligible for management with thrombectomy since we are able to see the areas of brain that are salvageable.

The MRIs have the advantage of imaging without ionizing radiation. A magnetic field and radio waves are used to create the images that are more detailed than CT images. Some patients are not able to undergo MRI because of the presence of artificial cardiac pacemakers, mechanical heart valves, or magnetizable intracranial metal clips.

Positron emission tomography (PET) and single-photon emission CT (SPECT) permit imaging of both structure and functional characteristics (blood flow, metabolism, and concentrations of neurochemicals and receptors) of the brain. The PET scans use radioactive isotopes that are taken up by highly metabolic cells. In combination with CT or MRI, PET scans are useful to assess for location and spread of malignancy.

Cerebral Blood Flow

Cerebral blood flow averages 50 mL/100 g/minute of brain tissue under normal conditions. For an adult, this is equivalent to 750 mL per minute, or about 15% of the resting cardiac output, delivered to an organ that represents only about 2% of the body's mass. The gray matter of the brain has a higher cerebral blood flow (80 mL/100 g/minute) than the white matter (20 mL/100 g/minute). As in most other tissues of the body, cerebral blood flow parallels cerebral metabolic requirements for oxygen (3-5 mL/100 g/minute). Ischemic injury occurs when blood flow decreases below 22 mL/100 g/minute. The cerebral vasculature responds to changes in PaCO_2 and PaO_2 known as vasomotor reactivity. Sympathetic and parasympathetic nerves play little or no role in the regulation of cerebral blood flow ([Figure 3.13](#)). Changes in the PaCO_2 between about 20 and 80 mm Hg produce corresponding linear changes in cerebral blood flow. For example, in this range, a 1-mm Hg increase in the PaCO_2 leads to a 1% to 6% increase in cerebral blood flow ([Table 3.3](#)). The change in blood flow with change in carbon dioxide is only temporary as the vasculature adapts to the chronic elevation of PaCO_2 and the cerebral blood flow will eventually return to normal.⁶³

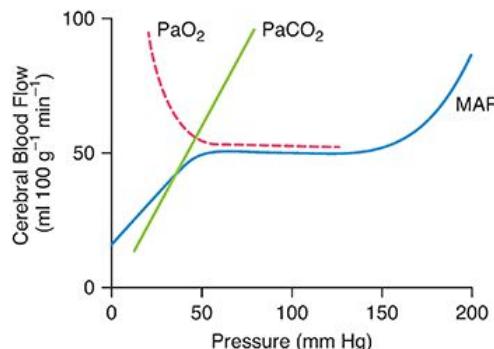

FIGURE 3.13 Cerebral blood flow is influenced by PaO_2 , PaCO_2 , and mean arterial pressure (MAP).

TABLE 3.3

Carbon dioxide and cerebral physiology

Cerebral blood flow (CBF)

Changes 1-2 mL/100 g/minute for each 1 mm Hg change in PaCO_2 between 20 and 80 mm Hg

Slope of the response depends on normocapnic CBF.

CBF returns to baseline over several hours during sustained alterations in PaCO_2 (reflects correction of brain extracellular fluid pH).

Response to hypocapnia not altered by aging if CBF is maintained

Response to changes in PaCO_2 not altered by untreated hypertension

Hypothermia decreases normocapnic CBF and the response of CBF to changes in PaCO_2 .

Cerebral blood volume (CBV)

Changes 0.05 mL/100 g for each 1 mm Hg change in PaCO_2

Returns to baseline during sustained alterations in Paco_2

Cerebral autoregulation

Modest hypercapnia impairs, and marked hypercapnia abolishes.

Hypotension below the lower limit of autoregulation abolishes hypocapnic cerebral vasoconstriction.

Carbon dioxide response and anesthetics

Maintained during inhaled and intravenous anesthetics

Relative response to hypcapnia depends on normocapnic CBF (anesthetics that increase CBF enhance the reduction of CBF by hypcapnia).

Carbon dioxide response in presence of disease or injury

Hypercapnic response intact with hypertension

Hypcapnia response present with brain injury (subarachnoid hemorrhage) but may be attenuated if vasospasm is present

Carbon dioxide increases cerebral blood flow by combining with water in body fluids to form carbonic acid that dissociates to form hydrogen ions. Hydrogen ions produce vasodilation of cerebral vessels that is proportional to the increase in hydrogen ion concentration.

Any other acid that increases hydrogen ion concentration, such as lactic acid, also increases cerebral blood flow. Increased cerebral blood flow in response to increases in Paco_2 serves to carry away excess hydrogen ions that would otherwise greatly depress neuronal activity.

Unlike the continuous response of cerebral blood flow to changes in Paco_2 , the response to PaO_2 is a threshold phenomenon (see [Figure 3.13](#)). If the Paco_2 is maintained, cerebral blood flow begins to increase when the PaO_2 decreases below 30 mm.⁶⁴

Autoregulation

Cerebral blood flow is closely autoregulated between a mean arterial pressure of about 50 and 160 mm Hg (see [Figure 3.13](#)). As a result, changes in systemic blood pressure within this range will not significantly alter cerebral blood flow. Chronic systemic hypertension shifts the autoregulation curve to the right such that decreases in cerebral blood flow may occur at a mean arterial pressure of >50 mm Hg. Autoregulation of cerebral blood flow is attenuated or abolished by hypercapnia, arterial hypoxemia, and volatile anesthetics. Furthermore, autoregulation is often abolished in the area surrounding an acute cerebral infarction. For example, reactivity of blood vessels in areas surrounding cerebral infarcts and tumors is abolished. These blood vessels are maximally vasodilated, presumably reflecting accumulation of acidic metabolic products. As a result, cerebral blood flow to this area is already maximal (luxury perfusion), and changes in Paco_2 have no effect on its local blood flow. If Paco_2 should increase, however, it is theoretically possible that resulting vasodilation in normal blood vessels would shunt blood flow away from the diseased area (intracerebral steal syndrome). Conversely, a decrease in Paco_2 that constricts normal cerebral vessels could divert blood flow to diseased areas (“Robin Hood” phenomenon). Increases in mean arterial pressure above the limits of autoregulation can cause leakage of intravascular fluid through capillary membranes, resulting in cerebral edema. Because the brain is enclosed in a solid vault, the accumulation of edema fluid increases intracranial pressure (ICP) and compresses blood vessels, decreasing cerebral blood flow and leading to destruction of brain tissue. Cerebral autoregulation can be altered by trauma and other diseases.

Electroencephalogram

The EEG is a recording of the brain waves that result from the summed electrical activity in the brain. The intensity of the electrical activity recorded from the surface of the scalp ranges from 0 to 300 μV , and the frequency may exceed 50 cycles per second. The character of the waves greatly depends on the level of activity of the cerebral cortex and the degree of wakefulness. There is a direct relationship between the degree of cerebral activity and the frequency of brain waves. Furthermore, during periods of increased mental

activity, brain waves become asynchronous rather than synchronous, so the voltage decreases despite greater cortical activity.

Classification of Brain Waves

Brain waves are classified as alpha, beta, theta, and delta waves depending on their frequency and amplitude ([Figure 3.14](#)). The classic EEG is a plot of voltage against time, usually recorded by 16 channels on paper moving at 30 mm per second. One page of recording is 10 seconds of data.

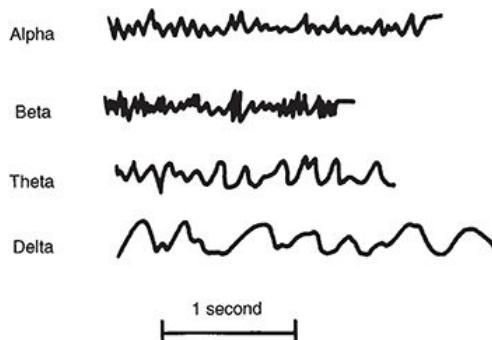

FIGURE 3.14 The electroencephalogram consists of alpha, beta, theta, and delta waves.

Alpha Waves

Alpha waves occur at a frequency of 8 to 12 Hz and a voltage of about 50 μ V. These waves are typical of an awake, resting state of cerebration with the eyes closed. During sleep, alpha waves disappear. Because alpha waves do not occur when the cerebral cortex is not connected to the thalamus, it is assumed these waves result from spontaneous activity in the thalamocortical system.

Beta Waves

Beta waves occur at a frequency of 13 to 30 Hz and a voltage usually of <50 μ V. These high-frequency and low-voltage asynchronous waves replace alpha waves in the presence of increased mental activity or visual stimulation.

Theta Waves

Theta waves occur at a frequency of 4 to 7 Hz. These waves occur in healthy people during sleep and also during general anesthesia.

Delta Waves

Delta waves include all the brain waves with a frequency of less than 4 Hz. These waves occur (1) in deep sleep, (2) during general anesthesia, and (3) in the presence of organic brain disease. Delta waves occur even when the connections of the cerebral cortex to the reticular activating system are severed, indicating these waves originate in the cerebral cortex independently of lower brain structures.

Clinical Uses

The EEG is useful in diagnosing different types of epilepsy and for determining the focus in the brain causing seizures. Brain tumors, which compress surrounding neurons and cause abnormal electrical activity, may be localized using the EEG. Monitoring of the EEG during carotid endarterectomy, cardiopulmonary bypass, or controlled hypotension may provide an early warning of inadequate cerebral blood flow. In this regard, the EEG may be influenced by anesthetic drugs, depth of anesthesia, and hyperventilation of the patient's lungs. Several different monitors of EEG activity use different algorithms designed to take time complex EEG and decompose it into a number that is predictive of anesthetic depth.

Brain Wave Monitors

Numerous quantitative EEG processing techniques have been developed to monitor brain depression during anesthesia including processed EEG and entropy monitors.

Many of these commercial monitors use proprietary algorithms to integrate EEG signals into a simple, intuitive output that can be used by clinicians who are not trained in the relatively complex interpretations of classical EEG. Spectral entropy represents an alternative concept to bispectral analysis for quantifying the EEG. Spectral entropy and response entropy are computed over specific frequency ranges of the EEG. Response entropy includes electromyographic activity. The question of whether processed EEG monitoring results in reduction of intraoperative awareness is controversial, and studies have been inconsistent.

Epilepsy

Epilepsy is characterized by excessive activity of either a part or all of the CNS. A grand mal seizure is characterized by intense neuronal discharges in multiple areas of the cerebral and reticular activating system. These impulses are transmitted to the spinal cord, resulting in alternating skeletal muscle contractions known as *tonic-clonic seizures*. Profound autonomic activity often results in defecation and urination. The grand mal seizure usually lasts from a few seconds to several minutes and is followed by generalized depression of the entire CNS (the postictal state). The EEG during a grand mal seizure reveals high-voltage, synchronous brain wave discharges over the entire cerebral cortex. Synaptic fatigue is a likely mechanism that contributes to spontaneous cessation of a grand mal seizure and postictal depression.

Status epilepticus is present, and electrographic seizures last longer than 5 minutes or when multiple seizures occur without return to baseline in between. Status epilepticus can be convulsive or nonconvulsive and is a neurologic emergency as ongoing epileptiform discharges may cause neuronal injury. Ongoing seizures can result in respiratory failure and metabolic acidosis. The development of status epilepticus from a single seizure involves a complex cascade of events occurring at the molecular level including excessive neurotransmitter release (glutamate), ion channel opening and closing and protein phosphorylation. The next stage involves receptor modulation resulting in a downregulation of GABA and an increase in NMDA and AMPA excitatory receptors. Proconvulsant neuropeptides then exhibit increased expression and inhibitory neuropeptides have reduced expression leading to sustained hyperexcitability and status epilepticus. There are antiepileptic drugs with many different mechanisms of action that are used for management of seizures. Drugs readily available to anesthesiologists include benzodiazepines and propofol, which work at the GABA receptors. Intravenous anesthetics are titrated to suppression of seizure on EEG.⁶⁵ Volatile anesthetics can also be used to control refractory status epilepticus but are not often available outside of the operating room.

Evoked Potentials

Evoked potentials are the electrophysiologic responses of the CNS to sensory, motor, auditory, or visual stimulation. The waveforms resulting from sensory stimulation reflect transmission of impulses through specific sensory pathways. Poststimulus latency is the time in milliseconds from application of the stimulus to a peak in the recorded waveform. The amplitude and latency of evoked potentials may be influenced by a number of events, especially volatile anesthetics. Physiologic parameters such as hypotension, hypothermia, and anemia can also affect the recording of evoked potentials. Evoked potentials are used to monitor spinal cord function during operations near or on the spinal cord and auditory nerve and brainstem function, as during operations on pituitary tumors or other lesions that impinge on the optic nerves or optic chiasm. The modes of sensory stimulation used to produce evoked potentials in the operating room are somatosensory, auditory, and visual.^{66,67} The intraoperative monitoring of evoked potentials is an alternative to wake-up testing during neurosurgery. The motor pathway, supplied by the anterior spinal artery is monitored with motor evoked potentials. The sensory pathway, supplied by the posterior spinal artery, is measured with somatosensory evoked potentials.

Somatosensory Evoked Potentials

Somatosensory evoked potentials are produced by application of a low-voltage electrical current that stimulates a peripheral nerve such as the median nerve at the wrist or the posterior tibial nerve at the ankle. The resulting evoked potentials reflect the integrity of sensory neural pathways from the peripheral nerve to

the somatosensory cortex. Somatosensory stimulation follows the dorsal column pathways of proprioception and vibration. Inhaled anesthetics, especially volatile anesthetics, produce dose-dependent depression of somatosensory evoked potentials (see [Chapter 4](#)). Although less so than volatile anesthetics, morphine and fentanyl also produce depressant effects on somatosensory evoked potentials, with a low-dose continuous infusion of the opioid producing less depression than intermittent injections.⁶⁸ Many anesthetic techniques have been described to optimize the recording of motor and sensory evoked potentials. Total intravenous anesthesia with continuous infusion is often used to maintain a constant level of anesthesia so that any observed changes to the evoked potentials will be less likely due to the anesthesia. Ketamine or etomidate may increase the amplitude of somatosensory evoked potentials (see [Chapter 5](#)).

Motor Evoked Potentials

The use of motor evoked potentials is limited by the fact that their recording requires direct (epidural) or indirect (transosseous) stimulation of the brain or spinal cord.⁶⁹ These evoked potentials reflect the integrity of motor neural pathways from the peripheral nerve to the motor cerebral cortex. Motor evoked potentials are extremely sensitive to depression by anesthetics. Furthermore, it is not possible to monitor motor evoked potentials in the presence of significant drug-induced neuromuscular blockade. During scoliosis surgery or other operations that place spinal cord motor function at risk, the use of motor evoked potentials obviates the need for an intraoperative wake-up test. In many instances, it is useful to monitor both motor and sensory evoked potentials to fully evaluate the functional integrity of both motor and sensory pathways. As an alternative to motor evoked potentials, transcranial motor stimulation may be used to monitor spinal cord function during spinal surgery.

Auditory Evoked Potentials

Auditory evoked potentials arise from brainstem auditory pathways. Volatile anesthetics produce dose-dependent depression of auditory evoked potentials. Auditory evoked potentials may provide an objective electrophysiologic alternative to the clinical assessment of sedation, particularly during brain surgery that may affect the cochlea or brain centers important for hearing.⁷⁰

Visual Evoked Potentials

Visual evoked potentials are produced by flashes from light-emitting diodes that are mounted on goggles placed over the patient's closed eyes. Visual evoked potentials may be useful to monitor the visual pathways during trans sphenoidal or anterior fossa neurosurgical procedures. Volatile anesthetics produce dose-dependent depression of visual evoked potentials, especially above concentrations equivalent to about 0.8 MAC.⁷¹

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) is present in the ventricles of the brain, cisterns around the brain, and subarachnoid space around the brain and spinal cord ([Figure 3.15](#)). The total volume of CSF is normally about 150 mL, and the specific gravity is 1.002 to 1.009. A major function of CSF is to cushion the brain in the cranial cavity. A blow to the head moves the entire brain simultaneously, causing no one portion of the brain to be selectively contorted by the blow. When a blow to the head is particularly severe, it usually does not damage the brain on the ipsilateral side but instead damage manifests on the opposite side. This phenomenon results in a *contrecoup* injury reflecting the vacuum between the brain and skull opposite the blow caused by sudden movement of the brain at this site away from the skull. When the skull is no longer being accelerated by the blow, the vacuum suddenly collapses and the brain strikes the interior of the skull.

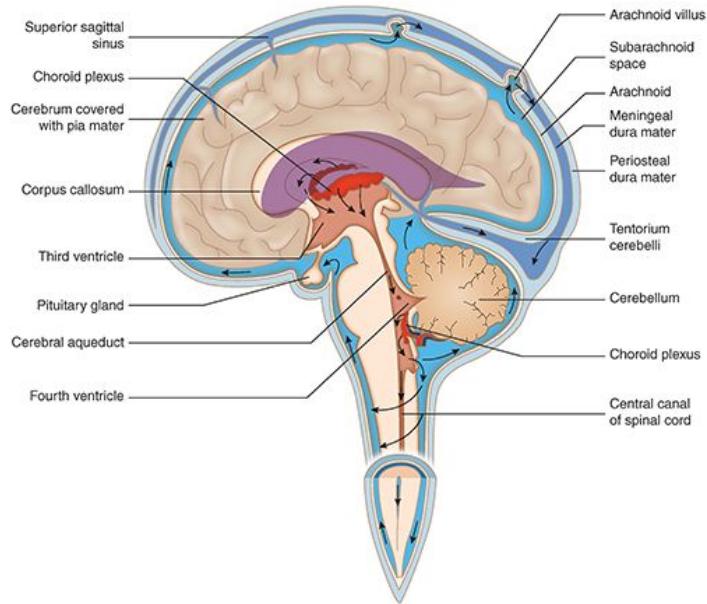

FIGURE 3.15 Cerebral spinal fluid fluxes in and out of the ventricles with the cardiac cycle.

Formation

The choroid plexuses (cauliflower-like growths of blood vessels covered by a thin layer of epithelial cells) in the four cerebral ventricles are the major site of formation of CSF that continually exudes from the surface of the choroid plexus at a rate of about 30 mL per hour. In comparison with other extracellular fluids, the concentration of sodium and chloride in CSF is 7% greater and the concentration of glucose and potassium is 30% and 40% less, respectively. This difference in composition from other extracellular fluids emphasizes that CSF is a choroid secretion and not a simple filtrate from the capillaries. The pH of CSF is closely regulated and maintained at 7.32. Changes in PaCO_2 , but not arterial pH, promptly alter CSF pH, reflecting the ability of carbon dioxide, but not hydrogen ions, to cross the blood–brain barrier easily. As a result, acute respiratory acidosis or alkalosis produce corresponding changes in CSF pH. Active transport of bicarbonate ions eventually returns CSF pH to 7.32, despite the persistence of alterations in arterial pH.

Reabsorption

Almost all the CSF formed each day is reabsorbed into the venous circulation through special structures known as *arachnoid villi* or *granulations*. These villi project the subarachnoid spaces into the venous sinuses of the brain and occasionally into veins of the spinal cord. Arachnoid villi are trabeculae that protrude through venous walls, resulting in highly permeable areas that permit relatively free flow of CSF into the circulation. The magnitude of reabsorption depends on the pressure gradient between the CSF and the venous circulation.

Intracerebral Circulation

The CSF formed in the lateral cerebral ventricles passes into the third ventricle through the foramen of Monro (see [Figure 3.15](#)). From there, CSF passes along the aqueduct of Sylvius into the fourth cerebral ventricle, where still more CSF is formed. It then passes into the cisterna magna through the lateral foramen of Luschka and via a middle foramen of Magendie. From this point, CSF flows through the subarachnoid spaces upward toward the cerebrum, where most of the arachnoid villi are located.

Hydrocephalus

Congenital or acquired obstruction to free circulation of CSF results in hydrocephalus. For example, blockage of the aqueduct of Sylvius results in expansion of the lateral and third cerebral ventricles and compression of

the brain. This type of obstruction producing a noncommunicating type of hydrocephalus is treated by surgical creation of an artificial pathway for flow of CSF between the cerebral ventricular system and the subarachnoid space. Other obstructive hydrocephalus is treated by placing a shunt between the lateral ventricle that drains to a position outside the CNS. The most common type of shunt is a ventricular peritoneal shunt that terminates in the peritoneum. Shunts can also terminate in the pleural space or internal jugular vein. Communicating or nonobstructive hydrocephalus occurs when there is an overproduction or underabsorption of CSF.

Intracranial Pressure

Normal ICP is <15 mm Hg. This pressure is regulated by the rate of CSF formation and resistance to CSF reabsorption through arachnoid villi as determined by venous pressure. In addition, increases in cerebral blood flow, as during inhalation of volatile anesthetics, can cause the ICP to increase because of the concomitant increase in cerebral blood flow and cerebral blood volume.⁷² Systemic blood pressure does not alter ICP within the range of normal autoregulation. Phasic variations in systemic blood pressure, however, are transmitted as variations in ICP. Regulation of global cerebral blood flow is thus particularly important when the brain is near the critical pressure that will result in compression of the brain parenchyma.⁷³

Papilledema

Anatomically, the dura of the brain extends as a sheath around the optic nerve and then connects with the sclera of the eye. Increases in ICP are transmitted to the optic nerve sheath. Increased pressure in the optic sheath impedes blood flow in the retinal veins, leading to increases in the retinal capillary pressure and retinal edema. The tissues of the optic disc are more distensible than the rest of the retina, so the disc becomes edematous and swells into the cavity of the eye. This swelling of the optic disc is termed *papilledema*. Papilledema can be observed with an ophthalmoscope or by using point of care ultrasound to measure the optic nerve sheath diameter.

Blood–Brain Barrier

The blood–brain barrier reflects the impermeability of capillaries in the CNS, including the choroid plexuses, to circulating substances such as electrolytes and exogenous drugs or toxins. The neural and glial cells in the CNS live in a relatively tightly controlled milieu in a healthy state; however, it becomes more porous in the setting of inflammation. The blood–brain barrier is maintained by the tight junction between endothelial cells of brain capillaries. Envelopment of brain capillaries by glial cells further decreases their permeability. The blood–brain barrier is less developed in the neonate and tends to break down in areas of the brain that are irradiated, infected, or compromised by neoplasm. The blood–brain barrier is also relatively permeable in the area around the posterior pituitary and the chemoreceptor trigger zone. It is characterized by active processes mediated by p-glycoprotein transporters. These proteins are of the adenosine triphosphate binding cassette family. Active transport of morphine out of the CNS by a p-glycoprotein transporter is responsible for the >90-minute delay between the plasma peak after a morphine bolus and peak morphine drug effect. Many techniques are being developed to selectively transport drugs across the blood–brain barrier, including targeting intrinsic blood–brain barrier transport proteins and the use of nanoparticles that are too small to be restricted.^{74,75}

Vision

The eye is optically similar to a photographic camera in that it contains a lens system, a variable aperture system (pupil), and light sensitive surface (retina) (**Figure 3.16**).⁷⁶ The lens system of the eye focuses an image on the retina. Relaxation and contraction of the ciliary muscles are responsible for altering the tension of ligaments attached to the lens, causing its refractive power to change. Stimulation of parasympathetic nervous system fibers to the ciliary muscle causes this muscle to relax, which in turn relaxes the ligaments of the lens and increases its refractive power. This increased refractive power allows the eye to focus on objects that are nearby. Interference with this process of accommodation may be noted by patients who have received an anticholinergic drug as part of the pharmacologic reversal of nondepolarizing neuromuscular blockade.

The principal function of the pupil is to increase or decrease the amount of light that enters the eye. For example, the pupil may vary from 1.5 to 8.0 mm in diameter, permitting a 30-fold variation in the amount of light that enters the eye.

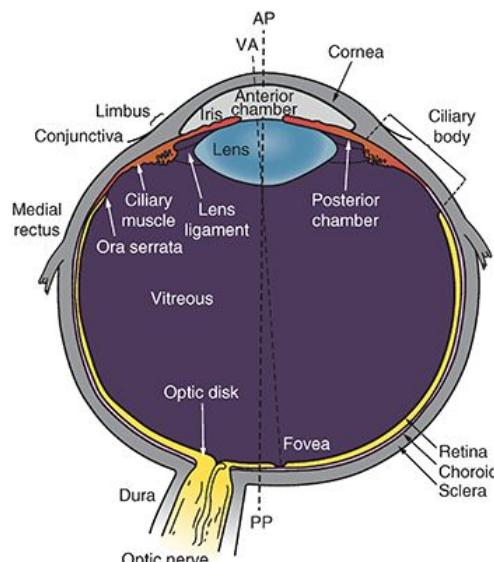

FIGURE 3.16 Schematic diagram of the eye. Abbreviations: AP, anterior pole; PP, posterior pole; VA, visual axis.

Intraocular Pressure

Intraocular pressure is normally 15 to 25 mm Hg. Glaucoma is associated with increased intraocular pressure sufficient to compress retinal artery inflow to the eye, leading to ischemic pain and eventually blindness. When medical control of glaucoma fails, it may be necessary to surgically create an artificial outflow tract for aqueous humor.

Retina

The retina is the light-sensitive portion of the eye containing the cones, which are responsible for color vision, and the rods, which are mainly responsible for vision in the dark. When the cones and rods are stimulated, impulses are transmitted and processed through successive neurons in the retina and optic nerve before reaching the cerebral cortex. The presence of melanin in the pigment layer of the retina prevents reflection of light throughout the globe. Without this pigment, light rays would be reflected in all directions within the globe, causing visual acuity to be impaired. Indeed, albinos, who lack melanin, have greatly decreased visual acuity.

The nutrient blood supply for the retina is largely derived from the central retinal artery, which accompanies the optic nerve. This independent retinal blood supply prevents rapid degeneration of the retina, should it become detached from the pigment epithelium, and allows time for surgical correction of a detached retina. The main arterial supply to the globe and orbital contents is from the ophthalmic artery, which is a branch of the internal carotid artery.⁷⁷

Ischemic Optic Neuropathy

Ischemic optic neuropathy (ION) results from infarction of the optic nerve and is the most frequently reported cause of vision loss following general anesthesia. An ION is classified as *anterior ION* (nonarteritic or arteritic) and *posterior ION*. Arteritic anterior ION is usually not associated with surgery but occurs secondary to temporal arteritis. Nonarteritic anterior ION occurs more often in patients with congenitally small optic discs. It is presumed that the small cross-sectional area of the optic disc results in little room for expansion of optic nerve fibers in response to ischemia-induced edema. Anterior ION associated with surgery

occurs more commonly with cardiac bypass, major vascular, and prone spine operations. Anterior ION results in sudden painless visual disturbances.

Posterior ION has been reported after diverse surgical procedures (prolonged spinal fusion surgery, cardiac operations requiring cardiopulmonary bypass, radical neck surgery), and its etiology appears to be multifactorial. The posterior optic nerve is vulnerable because it lacks overlapping blood supply. Prone positioning decreases venous return and increased intraocular pressure during anesthesia and could contribute to decreases in ocular perfusion pressure.⁷⁸ Head-down or prone position can cause decreased venous return and swelling with reduced perfusion to the optic nerve. Six independent risk factors have been identified for ION with spine surgery including male sex, obesity, the use of a Wilson frame, long operating time, lower colloid to crystalloid ratio for fluid administration, and greater blood loss.⁷⁹

Other Causes of Postoperative Blindness

Cortical blindness, retinal occlusion, and ophthalmic venous obstruction need to be excluded when postoperative blindness occurs. Cortical blindness is characterized by loss of visual sensation with retention of pupillary reaction to light and normal funduscopic examination results. Cortical blindness may be caused by an embolism or cerebral hypoperfusion. A CT or an MRI abnormality in the parietal or occipital lobe confirms the diagnosis. Central retinal artery occlusion presents as painless, monocular blindness caused by a decreased blood supply to the retina. Ophthalmoscopic examination of the eyes with retinal artery occlusion shows a pale edematous retina, a cherry-red spot at the fovea, and platelet-fibrin or cholesterol emboli in the narrowed retinal arteries. The pupillary light reflex will be absent. Obstruction of venous drainage from the eye may occur intraoperatively when patient positioning results in external pressure on the eyes.⁷⁹

Visual Pathway

Impulses from the retina pass backward through the optic nerve (Figure 3.17).⁷⁶ The macula is a small area in the center of the retina that is composed mainly of cones to permit detailed vision. The fovea is the central portion of the macula and is the site of the clearest vision. At the optic chiasm, all the fibers from the nasal halves of the retina cross to the opposite side to join fibers from the opposite temporal retina to form the optic tracts. Fibers of the optic tract synapse in the lateral geniculate body of the thalamus before passing into the visual (occipital) area of the cerebral cortex. Specific points of the retina connect with specific points of the visual cortex, which results in the detection of lines, borders, and colors.

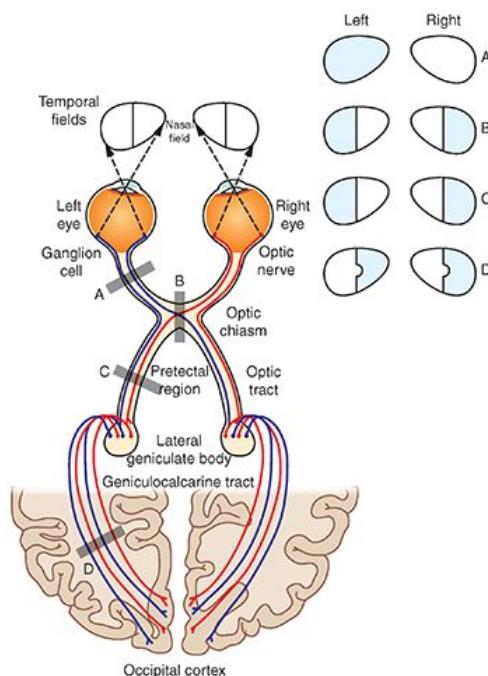

FIGURE 3.17 Visual impulses from the retina pass to the optic chiasm, where fibers from the nasal halves of the retina cross to the opposite side to join temporal fibers and form the optic tract. These fibers synapse in the lateral geniculate body before passing to the visual (occipital) area of the cerebral cortex. Visual field defects reflect lesions at various sites (A-D) in the nerve pathways.

Field of Vision

The field of vision is the area seen by the eye at a given instant. The area seen to the nasal side is called the *nasal field of vision*, and the area seen to the lateral side is called the *temporal field of vision* (see [Figure 3.17](#)).⁷⁶ An important use of visual fields is localization of lesions in the visual neural pathway. For example, anterior pituitary tumors may compress the optic chiasm, causing blindness in both temporal fields of vision (called *bitemporal hemianopia*). Thrombosis of the posterior cerebral artery is a cause of infarction of the visual cortex.

Muscular Control of Eye Movements

The cerebral control system for directing the eyes toward the object to be viewed is as important as the cerebral system for interpretation of the visual signals. Movements of the eyes are controlled by three pairs of skeletal muscles designated as the (1) medial and lateral recti, (2) superior and inferior recti, and (3) superior and inferior obliques. The medial and lateral recti contract reciprocally to move the eyes from side to side, the superior and inferior recti move the eyes upward or downward, and rotation of the globe is accomplished by the superior and inferior obliques. Each of the three sets of eye muscles is reciprocally innervated by cranial nerves III, IV, and VI so that one muscle of the pair contracts while the other relaxes.

Simultaneous movement of both eyes in the same directions is called *conjugate movement of the eyes*. Occasionally, abnormalities occur in the control system for eye movements that cause continuous nystagmus. Nystagmus is likely to occur when one of the vestibular apparatuses is damaged or when deep nuclei in the cerebellum are damaged or under the influence of ketamine anesthesia.

Innervation of the Eye

The eyes are innervated by the sympathetic and parasympathetic nervous system. The preganglionic fibers of the parasympathetic nervous system arise in the Edinger-Westphal nucleus of cranial nerve III and then pass to the ciliary ganglion, which gives rise to nerve fibers that innervate the ciliary muscle and sphincter of the iris. Sympathetic nervous system fibers innervate the radial fibers of the iris as well as several extraocular structures. Stimulation of the parasympathetic nervous system fibers to the eye excites the ciliary sphincter, causing miosis. Conversely, stimulation of sympathetic nervous system fibers to the eye excites the radial fibers of the iris and causes mydriasis. Pupillary response to autonomic tone is generally unreliable under anesthesia as many drugs used in anesthesia cause different effects on pupillary function. For example, volatile anesthetics cause midrange pupillary dilation while opioids cause pupillary constriction. Monitoring of pupillary diameter provides some indication of the residual opioid activity on anesthetic emergence.

Horner Syndrome

Interruption of the superior cervical chain of the sympathetic nervous system innervation to the eye results in miosis, ptosis, and vasodilation with absence of sweating on the ipsilateral side of the body, commonly referred to as *Horner syndrome*. Miosis occurs because of interruption of sympathetic nervous system innervation to the radial fibers of the iris. Ptosis reflects the normal innervation of the superior palpebral muscle by the sympathetic nervous system. Horner syndrome often occurs following stellate ganglion block and is occasionally a complication of interscalene block of the brachial plexus.

Hearing

Receptors for hearing and equilibrium are housed in the inner ear ([Figure 3.18](#)).⁷⁶ The external ear focuses sound waves on the ear drum, which oscillates in contact with the bones of the middle ear. The sound is amplified at the oval window, where the vibrations are transmitted to the hair cells of the cochlea in the inner

ear. The anatomic arrangement of the hair cells results in their responding to different frequencies, performing a mechanical Fourier transformation of the incoming sound waves. The electrical current generated from activation of a hair cell travels from the auditory nerve to the inferior colliculus and auditory cortex.

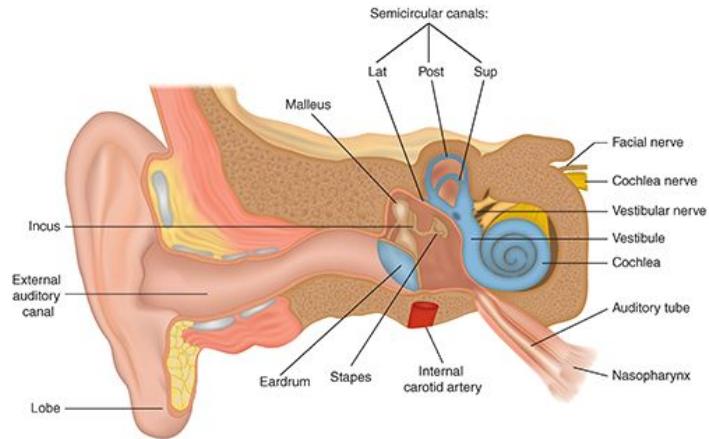

FIGURE 3.18 Schematic diagram of the outer and inner ear. Abbreviations: Lat, lateral; Post, posterior; Sup, superior.

The Eustachian tube connects the middle ear with the posterior tonsillar pillars and allows pressures on both sides of the tympanic membrane to be equalized during chewing or swallowing. Chronic obstruction of the Eustachian tube is often treated by placing small tubes through the eardrum, which is one of the most common procedures in children.⁸⁰ Nitrous oxide may increase middle ear pressure and has been associated with rupture of the tympanic membrane when the Eustachian tube is obstructed.⁸¹

Perioperative Hearing Impairment

Perioperative hearing impairment is often subclinical and may go unnoticed unless audiology is performed.⁸² Hearing loss (incidence may be as high as 50%) after dural puncture in the low-frequency range is most likely due to CSF leak and should resolve completely within days. Hearing loss following cardiopulmonary bypass, particularly in children, may be permanent and probably due to embolism and subsequent ischemic injury to areas of the organ of Corti.⁸³

Taste

Taste is mainly a function of taste buds located principally in the papillae of the tongue. Sweet, sour, salty, and bitter are the four primary sensations of taste. Sour taste is caused by acids. Sour taste intensity is approximately proportional to the logarithm of the hydrogen ion concentration (ie, pH). Sweet and salt are pleasurable tastes, of course. Bitter tastes are generally unpleasant. The bitter taste of alkaloids causes the individual to reject these substances. This may be protective as many plant toxins are alkaloids.

Smell

Olfactory receptors are located high in the nasal cavity. Each olfactory receptor is located on a single cilium. Olfactory receptors are coupled to G proteins, the activation of which increases activity of adenylyl cyclase, increasing the concentration of cAMP. A substance must be volatile and lipid soluble to stimulate olfactory cells. The importance of upward air movement in smell acuity is the reason sniffing improves the sense of smell, whereas holding one's breath prevents the sensation of unpleasant odors. Olfactory receptors adapt extremely rapidly, such that smell sensation may become extinct in about 60 seconds. Loss of the sense of taste and smell are unusual side effects of anesthesia. The effects 1 to 2 weeks likely related to the recovery of the peripheral receptors.⁸⁴

Nausea and Vomiting

Nausea is the conscious recognition of excitation of an area in the medulla that is associated with the vomiting (emetic) center ([Figure 3.19](#)).⁸⁵ Impulses are transmitted by afferent fibers of the parasympathetic and sympathetic nervous system to the vomiting center. Motor impulses transmitted via cranial nerves V, VII, IX, X, and XII to the gastrointestinal tract and through the spinal nerves to the diaphragm and abdominal muscles are required to cause the mechanical act of vomiting.

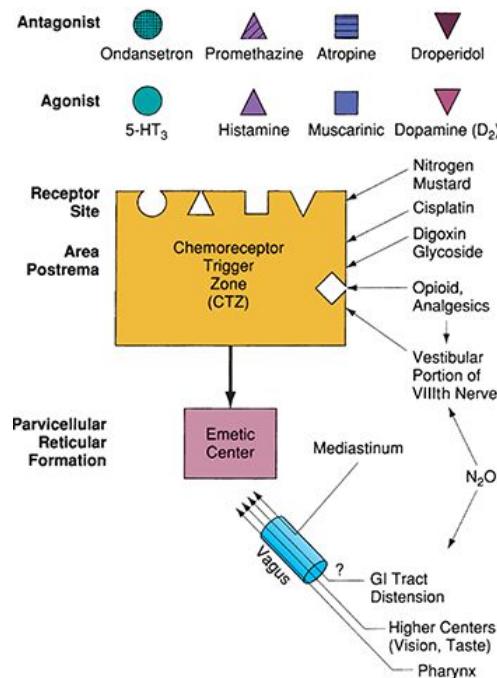

FIGURE 3.19 The chemoreceptor trigger zone and emetic center respond to a variety of stimuli resulting in nausea and vomiting. Abbreviations: 5-HT₃, 5-hydroxytryptamine; GI, gastrointestinal; N₂O, nitrous oxide.

The medullary vomiting center is located close to the fourth cerebral ventricle and receives afferents from the (1) chemoreceptor trigger zone, (2) cerebral cortex, (3) labyrinthovestibular center, and (4) neurovegetative system. Impulses from these afferents lead to nausea and vomiting. The chemoreceptor trigger zone includes receptors for serotonin, dopamine, histamine, and opioids. Stimulation of the chemoreceptor trigger zone located on the floor of the fourth cerebral ventricle initiates vomiting independent of the vomiting center. The chemoreceptor trigger zone is not protected by the blood-brain barrier, and thus, this zone can be activated by chemical stimuli received through the systemic circulation as well as the CSF. The cerebral cortex stimulates vomiting through a response to certain smells and physiologic stresses. Motion can stimulate equilibrium receptors in the inner ear, which may also stimulate the medullary vomiting center. Blocking of impulses from the chemoreceptor trigger zone does not prevent vomiting due to irritative stimuli (ipecac) arising in the gastrointestinal tract.²¹ Multiple drugs that take advantage of this physiology have been developed to treat nausea and vomiting in general and under anesthesia in particular. As a general rule, drugs that act via different mechanisms and pathways are at least additive if not synergistic. This is true for the common antiemetic drugs used in anesthesiology.^{86,87}

Peripheral Nervous System

The peripheral nervous system is composed of the sensory and motor nerves that connect the CNS to the tissues and organs ([Figure 3.20](#)). These nerves are familiar to anesthesiologists as the targets for regional

anesthetic techniques, and the anatomy is well reviewed in many atlases of regional anesthesia.

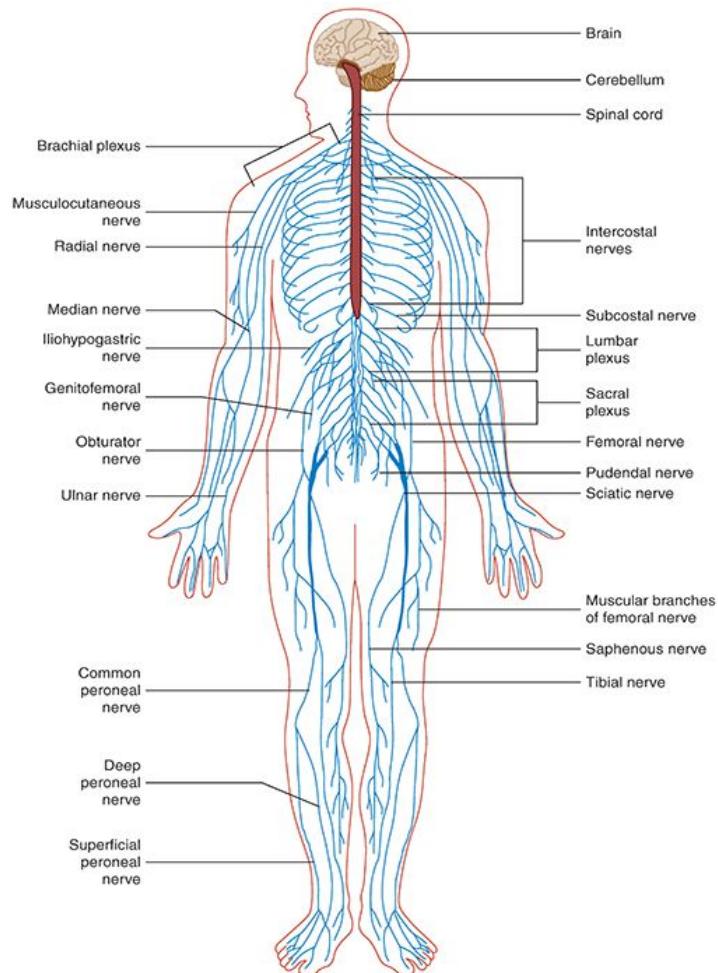

FIGURE 3.20 The peripheral nervous system connects the body tissues to the spinal cord and central nervous system.

Pathways for Peripheral Sensory Impulses

The peripheral nerves extend from the dendrite in the periphery to the dorsal root ganglion, where the cell body is located, and from there to the spinal cord by way of the dorsal root ([Figure 3.21](#)). By definition, dendrites conduct impulses toward the cell body, while axons conduct impulses away from the cell body. Thus, the portion of the nerve from the cell body to the peripheral receptor is a dendrite, while the relatively shorter connection from the dorsal root ganglion to the spinal cord is the axon. However, structurally the dendrite and the axon are indistinguishable, and the nerve behaves like one long axon, giving rise to the term *pseudounipolar neuron* that occasionally is used to describe peripheral nerves.

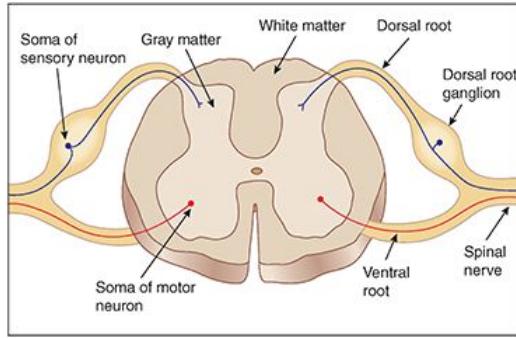

FIGURE 3.21 Cross-section of the spinal cord, showing the dorsal (posterior) and ventral (anterior) roots. The cell body of peripheral sensory nerves is in the dorsal root ganglion. The cell body of motor nerves is in the anterior horn.

After entering the spinal cord, peripheral sensory neurons synapse in the dorsal horn and give rise to long, ascending fiber tracts that transmit sensory information to the brain. These sensory signals are transmitted to the brain by the dorsal-lemniscal system, which includes dorsal column pathways and spinocervical tracts, and by anterolateral spinothalamic tracts (Figure 3.22).⁴ Impulses in the dorsal column pathways cross in the spinal cord to the opposite side before passing upward to the thalamus. Synapses in the thalamus are received by neurons that project into the somatic sensory area of the cerebral cortex. Nerve fibers of the anterolateral spinothalamic system cross in the anterior commissure to the opposite side of the spinal cord, where they turn upward toward the brain as the ventral (touch and pressure) and lateral (pain and temperature) spinothalamic tracts.

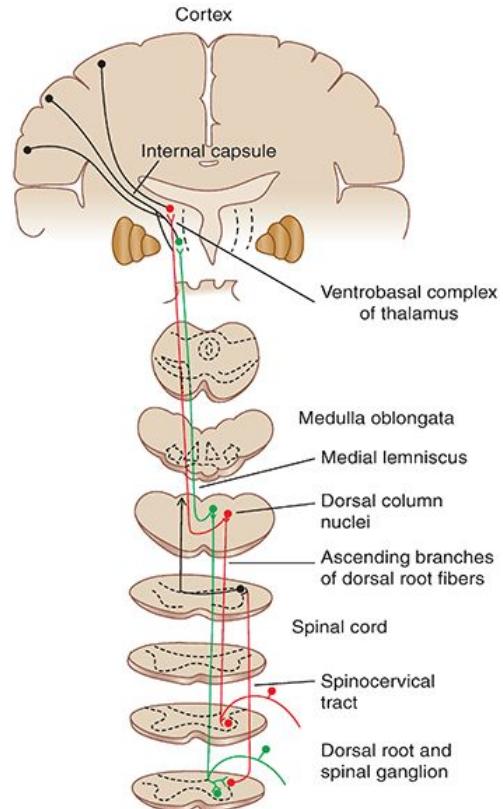

FIGURE 3.22 Sensory signals are transmitted to the brain by the dorsal column pathways and spinocervical tracts of the dorsal-lemniscal system.

Pathways for Peripheral Motor Responses

Sensory information is integrated at all levels of the nervous system and causes appropriate motor responses, beginning in the spinal cord with relatively simple reflex responses. Motor responses originating in the brainstem are more complex, whereas the most complicated and precise motor responses originate from the cerebral cortex.

Anterior motor neurons in the anterior horns of the spinal cord gray matter give rise to A- α fibers that leave the spinal cord by way of anterior nerve roots and innervate skeletal muscles. Skeletal muscles and tendons contain muscle spindles and Golgi tendon organs that operate at a subconscious level to relay information to the spinal cord and brain relative to changes in length and tension of skeletal muscle fibers. The stretch reflex is a reflex contraction of the skeletal muscle whenever stretch of the opposite balanced muscle results in stimulation of the muscle spindle. Tapping the patellar tendon elicits a knee jerk, which is a stretch reflex of the quadriceps femoris muscle. The ankle jerk is due to reflex contraction of the gastrocnemius muscle. Transmission of large numbers of facilitatory impulses from upper regions of the CNS to the spinal cord results in exaggerated stretch reflex responses. For example, lesions in the contralateral motor areas of the cerebral cortex, as caused by a cerebral vascular accident or brain tumor, cause greatly enhanced stretch reflexes. Clonus occurs when evoked muscle jerks oscillate. This phenomenon typically occurs when the stretch reflex is sensitized by facilitatory impulses from the brain, resulting in exaggerated facilitation of the spinal cord. When associated with recovery from general anesthesia, clonus as initiated by abrupt dorsiflexion of the foot can be eliminated by flexing the knees and keeping them in a flexed position.⁸⁸

Transection of the brainstem at the level of the pons (isolates the spinal cord from the rest of the brain) results in spasticity known as *decerebrate rigidity*. Decerebrate rigidity reflects diffuse facilitation of stretch reflexes.

The motor system is often divided into upper and lower motor neurons. Lower motor neurons originate in the spinal cord and directly innervate skeletal muscles. A lower motor neuron lesion is associated with flaccid paralysis, atrophy of skeletal muscles, and absence of stretch reflex responses. Upper motor neurons originate in the cerebral cortex or brainstem, and traverse down the anterior and lateral corticospinal paths until they connect with the lower motor neuron in the ventral horn of the spinal cord. Spastic paralysis with accentuated stretch reflexes is due to destruction of upper motor neurons in the brain.

Withdrawal flexor reflexes are a lower motor neuron reflex, typically elicited by a painful stimulus. Associated with withdrawal of the stimulated limb is extension of the opposite limb (cross-extensor reflex) that occurs 0.2 to 0.5 seconds later and serves to push the body away from the object causing the painful stimulus. The delayed onset of the cross-extensor reflex is due to the time necessary for the signal to pass through the additional neurons to reach the opposite side of the spinal cord.

Autonomic Nervous System

The autonomic nervous system controls the visceral functions of the body. In addition, the autonomic nervous system modulates systemic blood pressure, gastrointestinal motility and secretion, urinary bladder emptying, sweating, and body temperature maintenance. Activation of the autonomic nervous system occurs principally via centers located in the hypothalamus, brainstem, and spinal cord. The ANS is divided into the sympathetic, parasympathetic, and enteric nervous systems.

The sympathetic and the parasympathetic nervous systems usually function as physiologic antagonists such that the compiled action on any organ represents a balance of the influence of each component ([Table 3.4](#)). The sympathetic nervous system functions as an amplification response whereas the parasympathetic nervous system evokes discrete and narrowly targeted responses.

TABLE 3.4

Responses evoked by autonomic nervous system stimulation

	Sympathetic nervous system stimulation	Parasympathetic nervous system stimulation
Heart Sinoatrial node	Increase heart rate	Decrease heart rate

Atrioventricular node His-Purkinje system Ventricles	Increase conduction velocity Increase automaticity, conduction velocity Increase contractility, conduction velocity Automaticity	Decrease conduction velocity Minimal effect Minimal effects, slight decrease in contractility
Bronchial smooth muscle	Relaxation	Contraction
Gastrointestinal tract Motility Secretion Sphincters	Decrease Decrease Contraction	Increase Increase Relaxation
Gallbladder	Relaxation	Contraction
Urinary bladder Smooth muscle Sphincter	Relaxation Contraction	Contraction Relaxation
Uterus	Contraction	Variable
Ureter	Contraction	Relaxation
Eye Radial muscle Sphincter muscle Ciliary muscle	Mydriasis Relaxation for far vision	Miosis Contraction for near vision
Liver	Glycogenolysis Gluconeogenesis	Glycogen synthesis
Pancreatic beta cell secretion	Decrease	
Salivary gland secretion	Increase	Marked increase
Sweat glands	Increase ^a	Increase
Apocrine glands	Increase	
Arterioles Coronary Skin and mucosa Skeletal muscle Pulmonary	Constriction (α) Relaxation (β) Constriction Constriction (α) Relaxation (β) Constriction	Relaxation Relaxation Relaxation Relaxation

^aPostganglionic sympathetic fibers to sweat glands are cholinergic.

The enteric nervous system is arranged nontopographically, and its neurons and cells are located in the walls of the gastrointestinal tract. Although the gastrointestinal tract is influenced by sympathetic and parasympathetic nervous system activity, it is the enteric nervous system through the myenteric and submucous plexi that regulates digestive activity even in the presence of spinal cord transection.

An understanding of the anatomy and physiology of the autonomic nervous system is required for predicting the pharmacologic effects of drugs that act on either the sympathetic or parasympathetic nervous systems ([Table 3.5](#)). Relatively little is known about modulation of the enteric nervous system.

TABLE 3.5

Mechanism of action of drugs that act on the autonomic nervous system

Mechanism	Site	Drug
Inhibition of neurotransmitter synthesis	Central SNS	α -Methyldopa

False neurotransmitter	Central SNS	α -Methyldopa
Inhibition of uptake of neurotransmitter	Central noradrenergic synapses	Tricyclic antidepressants, cocaine
Displacement of neurotransmitter from storage sites	Central SNS PNS	Amphetamine Carbachol
Prevention of neurotransmitter release	SNS PNS	Bretylium Botulinum toxin
Mimic action of neurotransmitter at receptor	SNS α_1 α_2 β_1 β_2	Phenylephrine, methoxamine Clonidine dexmedetomidine Dobutamine Terbutaline, albuterol
Inhibition of action of neurotransmitter on postsynaptic receptor	SNS α_1 α_2 α_1 and α_2 β_1 β_1 and β_2 PNS M_1 M_1, M_2 N_1 N_2	Prazosin Yohimbine Phentolamine Metoprolol, esmolol Propranolol Pirenzepine Atropine Hexamethonium <i>d</i> -Tubocurarine
Inhibition of metabolism of neurotransmitter	SNS PNS	Monoamine oxidase inhibitors Neostigmine, pyridostigmine, edrophonium

Abbreviations: PNS, parasympathetic nervous system; SNS, sympathetic nervous system.

Anatomy of the Sympathetic Nervous System

Nerves of the sympathetic nervous system arise from the thoracolumbar (T1 to L2) segments of the spinal cord ([Figure 3.23](#)).⁴ These nerve fibers pass to the paravertebral sympathetic chains located lateral to the spinal cord. From the paravertebral chain, nerve fibers pass to tissues and organs innervated by the sympathetic nervous system.

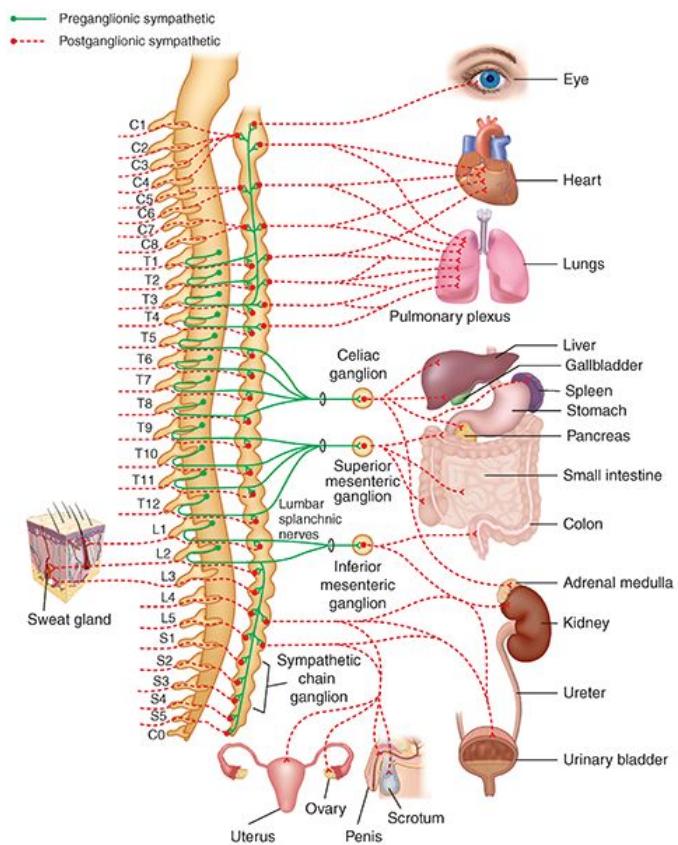

FIGURE 3.23 Anatomy of the sympathetic nervous system. Dashed lines represent postganglionic fibers in gray rami leading to spinal nerves for subsequent distribution to organs, blood vessels, and sweat glands.

Each nerve of the sympathetic nervous system consists of a preganglionic neuron and a postganglionic neuron ([Figure 3.24](#)). Cells bodies of preganglionic neurons are located in the intermediolateral horn of the spinal cord. Fibers from these preganglionic cell bodies leave the spinal cord with anterior (ventral) nerve roots and pass via white rami into 1 of 22 pairs of ganglia composing the paravertebral sympathetic chain. Axons of preganglionic neurons are mostly myelinated, slow-conducting type B fibers (see [Table 3.1](#)). In the ganglia of the paravertebral sympathetic chain, the preganglionic fibers can synapse with cell bodies of postganglionic neurons or pass cephalad or caudad to synapse with postganglionic neurons (mostly unmyelinated type C fibers) in other paravertebral ganglia. Postganglionic neurons then exit from paravertebral ganglia to travel to various peripheral organs. Other postganglionic neurons return to spinal nerves by way of gray rami and subsequently travel with these nerves to influence vascular smooth muscle tone and the activity of piloerector muscles and sweat glands.

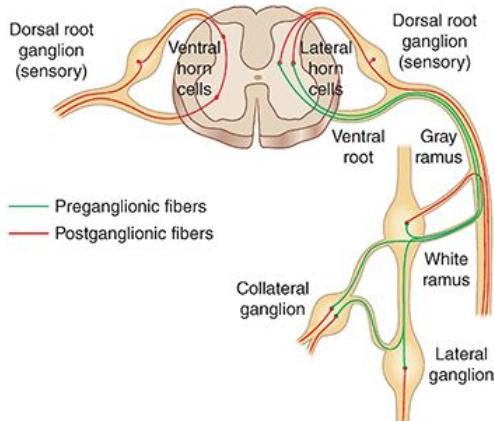

FIGURE 3.24 Anatomy of a sympathetic nervous system nerve. Preganglionic fibers pass through the white ramus to a paravertebral ganglion, where they may synapse, course up the sympathetic chain to synapse at another level, or exit the chain without synapsing to pass to an outlying collateral ganglion.

Fibers of the sympathetic nervous system are not necessarily distributed to the same part of the body as the spinal nerve fibers from the same segments. For example, fibers from T1 usually ascend in the paravertebral sympathetic chain into the head, T2 into the neck, T3 to T6 into the chest, T7 to T11 into the abdomen, and T12 and L1 to L2 into the legs. The distribution of these sympathetic nervous system fibers to each organ is determined in part by the position in the embryo from which the organ originates. In this regard, the heart receives many sympathetic nervous system fibers from the neck portion of the paravertebral sympathetic chain because the heart originates in the neck of the embryo. Abdominal organs receive their sympathetic nervous system innervation from the lower thoracic segments, reflecting the origin of the gastrointestinal tract from this area.

Anatomy of the Parasympathetic Nervous System

Nerves of the parasympathetic nervous system leave the CNS through cranial nerves III, V, VII, IX, and X (vagus) and from the sacral portions of the spinal cord ([Figure 3.25](#)).⁴ About 75% of all parasympathetic nervous system fibers are in the vagus nerves passing to the thoracic and abdominal regions of the body. As such, the vagus nerves supply parasympathetic innervation to the heart, lungs, esophagus, stomach, small intestine, liver, gallbladder, pancreas, and upper portions of the uterus. Fibers of the parasympathetic nervous system in cranial nerve III pass to the eye. The lacrimal, nasal, and submaxillary glands receive parasympathetic nervous system fibers via cranial nerve VII, whereas the parotid gland receives parasympathetic nervous system innervation via cranial nerve IX.

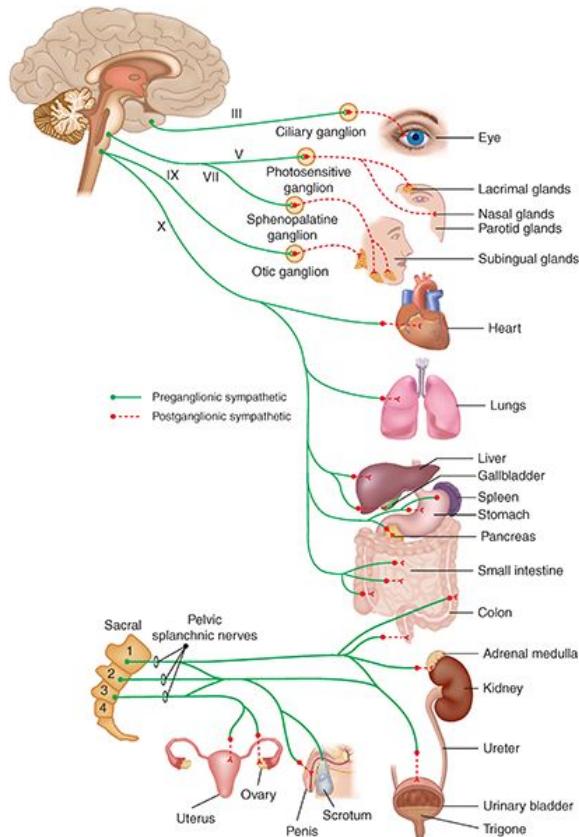

FIGURE 3.25 Anatomy of the parasympathetic nervous system.

The sacral part of the parasympathetic nervous system consists of the second and third sacral nerves, and, occasionally, the first and fourth sacral nerves. Sacral nerves form the sacral plexus on each side of the spinal cord. These nerves distribute fibers to the distal colon, rectum, bladder, and lower portions of the uterus. In addition, parasympathetic nervous system fibers to the external genitalia transmit impulses that elicit sexual responses.

In contrast to the sympathetic nervous system, preganglionic fibers of the parasympathetic nervous system pass uninterrupted to ganglia near or in the innervated organ (see [Figure 3.25](#)).⁴ Postganglionic neurons of the parasympathetic nervous system are short because of the location of the corresponding ganglia. This situation contrasts with the sympathetic nervous system, in which postganglionic neurons are relatively long, reflecting their origin in the ganglia of the paravertebral sympathetic chain, which is often distant from the innervated organ. Furthermore, unlike the amplified and diffuse discharges characteristic of sympathetic nervous system responses, activation of the parasympathetic nervous system is tonic and discrete. The vasodilatory effects of acetylcholine depend on the integrity of the vascular endothelium because activation of muscarinic receptors on the endothelium results in the release of nitric oxide.⁸⁹

Physiology of the Autonomic Nervous System

Preganglionic fibers of both the sympathetic and parasympathetic ganglia use acetylcholine as a transmitter activating nicotinic acetylcholine receptors with different subunit composition than those that mediate CNS function and muscle activation.⁹⁰ Postganglionic fibers of the sympathetic nervous system secrete norepinephrine as the neurotransmitter. These norepinephrine-secreting neurons are classified as *adrenergic fibers*. Postganglionic fibers of the parasympathetic nervous system secrete acetylcholine as the. These acetylcholine-secreting neurons are classified as *cholinergic fibers*. In addition, innervation of sweat glands and some blood vessels is by postganglionic sympathetic nervous system fibers that release acetylcholine as the neurotransmitter.

Norepinephrine as a Neurotransmitter

Synthesis

Norepinephrine acts as a neurotransmitter in the central and peripheral nervous systems. Synthesis of norepinephrine involves a series of enzyme-controlled steps that begin in the cytoplasm of postganglionic sympathetic nerve endings (varicosities) and are completed in the synaptic vesicles ([Figure 3.26](#)). For example, the initial enzyme-mediated steps leading to the formation of dopamine take place in the cytoplasm. Dopamine then enters the synaptic vesicle, where it is converted to norepinephrine by dopamine β -hydroxylase. The enzyme is present in noradrenergic cells of the locus coeruleus and postganglionic sympathetic fibers. Altered activity of the enzyme dopamine β -hydroxylase and therefore lower levels of norepinephrine has been reported in neurologic and psychiatric disorders including Alzheimer disease, posttraumatic stress disorder, and major depressive disorder.⁹¹ These enzymes are not highly specific, and other endogenous substances, as well as certain drugs, may be acted on by the same enzyme. For example, dopa-decarboxylase can convert the antihypertensive drug α -methyldopa to α -methyldopamine, which is subsequently converted by dopamine β -hydroxylase to the weakly active (false) neurotransmitter α -methylnorepinephrine that decreases the activation of central α_1 -adrenergic synapses and results in the reduction of blood pressure.

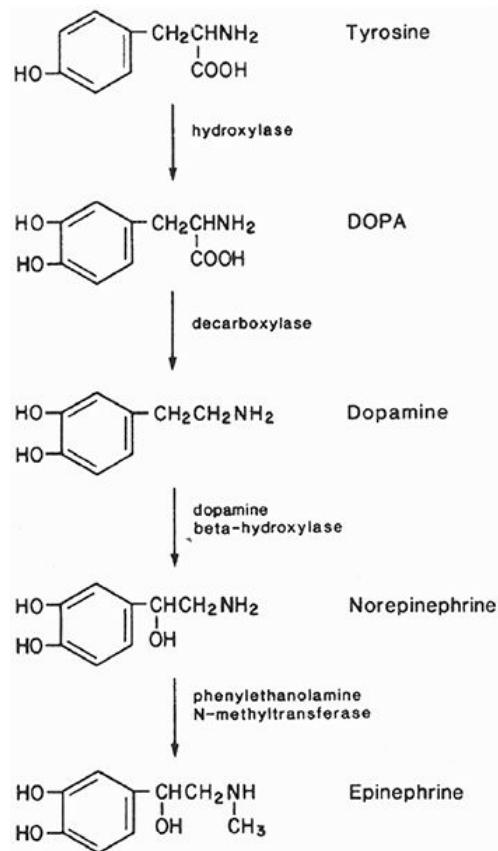

FIGURE 3.26 Steps in the enzymatic synthesis of endogenous catecholamines and neurotransmitters.

Storage and Release

Like most neurotransmitters, norepinephrine is stored in synaptic vesicles. In response to an action potential, it is released into the synaptic cleft where it interacts with pre- and postsynaptic receptors. Adrenergic fibers can sustain output of norepinephrine during prolonged periods of stimulation. Tachyphylaxis in response to

repeated administration of ephedrine and other indirect-acting sympathomimetics may reflect depletion of the norepinephrine stored in sympathetic nerve endings rather than an effect at the postsynaptic receptor.

Termination of Action

Termination of the action of norepinephrine is by (1) uptake (reuptake) back into postganglionic sympathetic nerve endings, (2) dilution by diffusion from receptors, and (3) metabolism by the enzymes monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). Norepinephrine released in response to an action potential exerts its effects at receptors for only a brief period, reflecting the efficiency of these termination mechanisms.

Reuptake

Uptake of previously released norepinephrine back into postganglionic sympathetic nerve endings is probably the most important mechanism for terminating the action of this neurotransmitter on receptors. As much as 80% of released norepinephrine undergoes reuptake. Reuptake provides a source for reuse of norepinephrine in addition to synthesis.

It is likely that two active transport systems are involved in reuptake of norepinephrine, with one system responsible for uptake into the cytoplasm of the varicosity and a second system for passage of norepinephrine into the synaptic vesicle for storage and reuse. The active transport system for norepinephrine uptake can concentrate the neurotransmitter 10,000-fold in postganglionic sympathetic nerve endings. Magnesium and adenosine triphosphate are essential for function of the transport system necessary for the transfer of norepinephrine from the cytoplasm into the synaptic vesicle. The transport system for uptake of norepinephrine into cytoplasm is blocked by numerous drugs, including cocaine and tricyclic antidepressants.

Metabolism

Metabolism of norepinephrine is of relatively minor significance in terminating the actions of endogenously released norepinephrine. The exception may be at some blood vessels, where enzymatic breakdown and diffusion account for the termination of action of norepinephrine. Norepinephrine that undergoes uptake is vulnerable to metabolism in the cytoplasm of the varicosity by MAO. Any neurotransmitter that escapes reuptake is vulnerable to metabolism by COMT, principally in the liver. Inhibitors of MAO including some antidepressants cause an increase in tissue levels of norepinephrine and may be accompanied by a variety of pharmacologic effects. Conversely, no striking pharmacologic change accompanies inhibition of COMT.

The primary urinary metabolite resulting from metabolism of norepinephrine by MAO or COMT is 3-methoxy-4-hydroxymandelic acid. This metabolite is also referred to as *vanillylmandelic acid (VMA)*. Normally, the 24-hour urinary excretion of 3-methoxy-4-hydroxymandelic acid is 2 to 4 mg, representing primarily norepinephrine that is deaminated by MAO in the cytoplasm of the varicosity of the postganglionic sympathetic nerve endings. Elevated levels of urinary vanillylmandelic acid suggests excessive circulating norepinephrine as in pheochromocytoma or a drug induced reduction in metabolism.

Acetylcholine as a Neurotransmitter

Synthesis

Acetylcholine is synthesized in the cytoplasm of varicosities of the preganglionic and postganglionic parasympathetic nerve endings. The enzyme choline acetyltransferase is responsible for catalyzing the combination of choline with acetyl coenzyme A to form acetylcholine. Choline enters parasympathetic nerve endings from the extracellular fluid through an active transport system. Acetyl coenzyme A is synthesized in mitochondria present in high concentrations in parasympathetic nerve endings.

Storage and Release

Acetylcholine is stored in synaptic vesicles for release in response to an action potential. Arrival of an action potential at a parasympathetic nerve ending results in the release of 100 or more vesicles of acetylcholine. It is estimated that a single nerve ending contains >300,000 presynaptic vesicles of acetylcholine.

Metabolism

Acetylcholine has a brief effect at receptors (<1 millisecond) because of its rapid hydrolysis by acetylcholinesterase to choline and acetate. Choline is transported back into parasympathetic nerve endings, where it is used for synthesis of new acetylcholine. Plasma cholinesterase is an enzyme found in low concentrations around acetylcholine receptors, being present in the highest amounts in plasma. The physiologic significance of plasma cholinesterase is unknown, as it is too slow to be physiologically important in the metabolism of acetylcholine. Absence of plasma cholinesterase produces no detectable clinical signs or symptoms until a drug such as succinylcholine or mivacurium is administered that require it for metabolism.

Residual Autonomic Nervous System Tone

The sympathetic and parasympathetic nervous systems are continually active, and this basal rate of activity is referred to as *sympathetic* or *parasympathetic tone*. The value of this tone is that it permits alterations in sympathetic or parasympathetic nervous system activity to mediate a fine increase or decrease in responses at innervated organs. For example, sympathetic nervous system tone normally keeps blood vessels about 50% constricted. As a result, increased or decreased sympathetic nervous system activity produces corresponding changes in systemic vascular resistance. If sympathetic tone did not exist, the sympathetic nervous system could only cause vasoconstriction.

In addition to continual direct activity of the sympathetic nervous system, a portion of overall sympathetic tone reflects basal secretion of norepinephrine and epinephrine by the adrenal medulla. The normal resting rate of secretion of norepinephrine is about 0.05 µg/kg/minute, and epinephrine is about 0.2 µg/kg/minute. These secretion rates are nearly sufficient to maintain systemic blood pressure in a normal range even if all direct sympathetic nervous system innervation to the cardiovascular system is removed.

Determination of Autonomic Nervous System Function

Autonomic dysfunction is associated with aging and diabetes mellitus. As anesthesia alters autonomic function, the combination of anesthesia and existing autonomic neuropathy can result in hemodynamic instability and cardiac complications. This may increase operative risk and can be associated with increased morbidity and mortality.⁹² Diagnosis of autonomic neuropathy in patients with diabetes mellitus is facilitated by tests of cardiovascular function (**Table 3.6**). Autonomic neuropathy is best assessed using heart rate variability or the difference between R wave intervals in an electrocardiogram. These tests measure activity of the sympathetic and parasympathetic nervous systems and precede changes in the measures of blood pressure. Simply stated, increased variability indicates a balance where parasympathetic tone is predominant and decreased variability is found in sympathetic excess and in autonomic neuropathy such as in diabetes. In addition to clinical tests of autonomic function, sensitive techniques for measuring plasma catecholamines are available. Interpretation of these data is confounded by other influences. Plasma epinephrine concentrations (normally 100-400 pg/mL) reflect adrenal release but vary greatly with psychological and physical stress. Plasma norepinephrine concentrations (normally 100-400 pg/mL) reflect both sympathetic nervous system and adrenal activity. Unlike plasma epinephrine levels, plasma norepinephrine concentrations reflect spillover from neuroeffector junctions, which may represent 10% to 20% of total release and vary among various organ systems. Because of these limitations, plasma catecholamine levels are not routinely measured for clinical diagnosis. On the other hand, as previously mentioned, 24-hour measurement urine catecholamines and metabolites avoids error due to moment to moment variability, providing an “area under the curve” that is useful in the diagnosis of hypersympathetic states such as pheochromocytoma.

TABLE 3.6

Clinical assessment of autonomic nervous system function

Clinical observation	Method of measurement	Normal value
Parasympathetic nervous system		
Heart rate	Patient blows into a mouthpiece maintaining a pressure of 40 mm Hg for	Ratio >1.21

response to Valsalva	15 seconds. The Valsalva ratio is the ratio of the longest R-R interval on the electrocardiogram immediately after release to the shortest R-R interval during the maneuver.	
Heart rate response to standing	Heart rate is measured as the patient changes from the supine to standing position (increase maximal around 15th beat after standing and slowing maximal around 30th beat). The response to standing is expressed as the “30:15” ratio and is the ratio of the longest R-R interval (around 30th beat) to the shortest R-R interval (around 15th beat).	Ratio >1.04
Heart response to deep breathing	Patient takes six deep breaths in 1 minute. The maximum and minimum heart rates during each cycle are measured, and the mean of the differences (maximum heart rate–minimum heart rate) during three successive breathing cycles is taken as the maximum–minimum heart rate.	Mean difference >15 beats per minute
Sympathetic nervous system		
Blood pressure response to standing	The patient changes from the supine to standing position, and the standing systolic blood pressure is subtracted from the supine systolic blood pressure.	Difference <10 mm Hg
Blood pressure response to sustained handgrip	The patient maintains a handgrip of 30% of maximum squeeze for up to 5 minutes. The blood pressure is measured every minute, and the initial diastolic blood pressure is subtracted from the diastolic blood pressure just prior to release.	Difference >16 mm Hg

Aging and Autonomic Nervous System Dysfunction

Common clinical manifestations of autonomic nervous system dysfunction in elderly patients are orthostatic hypotension, postprandial hypotension, hypothermia, and heat stroke. These responses reflect limited ability of elderly patients to adapt to stresses with vasoconstriction and vasodilation as mediated by the autonomic nervous system. Decreased autonomic nervous system function in elderly patients is due to fewer preganglionic terminals and therefore decreased response to catecholamines. Plasma epinephrine concentrations and the numbers of β -adrenergic receptors are unchanged with aging. Plasma norepinephrine concentrations increase with age, suggesting a primary physiologic deficit in reuptake mechanisms.⁹³

Clinically, there is attenuation of physiologic responses to β -adrenergic stimulation in the elderly. Exogenous β -adrenergic agonists have less profound effects on heart rate.⁹⁴ This decreased response to adrenergic stimulation seems to reflect decreased affinity (number of receptors unchanged) of β receptors for the neurotransmitter and decreases in coupling of stimulatory G proteins and adenylate cyclase units.

Diabetic Autonomic Neuropathy

Diabetic autonomic neuropathy is present in 20% to 40% of insulin-dependent diabetic patients. Common manifestations of diabetic autonomic neuropathy include impotence, diarrhea, postural hypotension, sweating abnormalities, and gastroparesis. When impotence or diarrhea is the sole manifestations of autonomic neuropathy, there is little impact on survival. Conversely, 5-year mortality rates may exceed 50% when postural hypotension or gastroparesis is present. Anesthetic risk is increased in diabetic patients with autonomic neuropathy associated with gastroparesis (aspiration hazard) and postural hypotension (hemodynamic instability) and is a marker for vasculopathy in other organs including the heart.⁹⁵

Chronic Sympathetic Nervous System Stimulation

Chronic sympathetic nervous system stimulation may increase morbidity and mortality. Pheochromocytoma is characterized by explosive release of catecholamines. Patients with pheochromocytoma often present with

severe episodic hypertension and tachycardia. Even physiologic responses and surgical stress that lead to sustained autonomic nervous system hyperactivity can result in metabolic and endocrine responses including increased glucose levels from gluconeogenesis. Preoperative alpha and beta blockade has been used in the past aimed at decreasing morbidity and mortality from pheochromocytoma resection. Historically, alpha blockade was established prior to initiating beta blockade. Beta blockade alone can result in unopposed alpha stimulation from circulating catecholamines. The unopposed alpha stimulation can cause vasoconstriction and worsening of blood pressure. Conflicting studies looking at alpha and beta blockade have not brought into question the necessity of this preoperative medical treatment. The use of alpha blockade has not shown to significantly reduce hemodynamic lability and yet mortality remains low.^{96,97}

Acute Denervation

Acute removal of sympathetic nervous system tone, as produced by a regional anesthetic or spinal cord transection, results in immediate maximal vasodilation of blood vessels (spinal shock). In the anesthetic setting this is transient and can be treated with fluid or alpha vasoconstrictors. In the chronic setting, over several days, intrinsic tone of vascular smooth muscle increases, usually restoring almost normal vasoconstriction.

Denervation Hypersensitivity

Denervation hypersensitivity is the increased responsiveness (decreased threshold) of the innervated organ to norepinephrine or epinephrine that develops during the first week or so after acute interruption of autonomic nervous system innervation. The presumed mechanism for denervation hypersensitivity is the proliferation of receptors (upregulation) on postsynaptic membranes that occurs when norepinephrine or acetylcholine is no longer released at synapses. As a result, more receptor sites become available to produce an exaggerated response when circulating neurotransmitter does become available.

Adrenal Medulla

The adrenal medulla is innervated by preganglionic fibers that bypass the sympathetic chain. As a result, these fibers pass directly from the spinal cord to the adrenal medulla. Cells of the adrenal medulla are derived embryologically from neural tissue and are analogous to postganglionic sympathetic neurons. Stimulation of the sympathetic nervous system causes release of epinephrine (80%) and norepinephrine from the adrenal medulla. As such, epinephrine and norepinephrine released by the adrenal medulla into the blood function as hormones and not as neurotransmitters.

Synthesis

In the adrenal medulla, most of the synthesized norepinephrine is converted to epinephrine by the action of phenylethanolamine-N-methyltransferase (see [Figure 3.26](#)). Activity of this enzyme is enhanced by cortisol, which is carried by the intra-adrenal portal vascular system directly to the adrenal medulla. For this reason, any stress that releases glucocorticoids also results in increased synthesis and release of epinephrine.

Release

The triggering event in the release of epinephrine and norepinephrine from the adrenal medulla is the liberation of acetylcholine by preganglionic cholinergic fibers. Acetylcholine acts on α_3 and β_4 subunit containing nicotinic receptors in the adrenal medulla, resulting in a change in permeability (localized depolarization) that permits entry of calcium ions through extracellular calcium channels. Calcium ions result in extrusion, by exocytosis, of synaptic vesicles containing epinephrine.

Norepinephrine and epinephrine released from the adrenal medulla evoke responses similar to direct stimulation of the sympathetic nervous system. The difference, however, is that effects are greatly prolonged (10-30 seconds) compared with the brief duration of action on receptors that is produced by norepinephrine released as a neurotransmitter from postganglionic sympathetic nerve endings. The prolonged effect of circulating epinephrine and norepinephrine released by the adrenal medulla reflects the time necessary for metabolism of these substances by COMT and MAO.

Circulating norepinephrine from the adrenal medulla causes vasoconstriction of blood vessels, inhibition of the gastrointestinal tract, increased cardiac activity, and dilatation of the pupils (see [Table 3.4](#)). The effects of circulating epinephrine differ from those of norepinephrine in that the cardiac and metabolic effects of epinephrine are greater, whereas relaxation of blood vessels in skeletal muscles reflects a predominance of beta- over alpha-effects at low concentrations of epinephrine. Circulating norepinephrine and epinephrine released by the adrenal medulla and acting as hormones can substitute for sympathetic nervous system innervation of an organ. Another important role of the adrenal medulla is the ability of circulating norepinephrine and epinephrine to stimulate areas of the body that are not directly innervated by the sympathetic nervous system. For example, the metabolic rate of all cells can be influenced by hormones released from the adrenal medulla, even though these cells are not directly innervated by the sympathetic nervous system.

Thermoregulation

Body temperature is determined by the relationship between heat production and heat dissipation. Heat is continually being produced in the body as a product of metabolism. As heat is produced, it is also continuously being lost to the environment. Both heat generation and heat loss are adjusted in order to regulate body temperature within narrow limits. Normal core body temperatures range from about 36°C to 37.5°C and undergo circadian fluctuations, being lowest in the morning and highest in the evening.

Heat Loss

The important mechanisms of heat loss from the body include radiation, conduction, convection, and evaporation. Their relative contributions vary and depend upon the environmental circumstances.⁹⁸ The skin is the most important route for heat dissipation, while the lungs account for only about 10% of heat loss. Under typical circumstances, most heat (about 60%) is lost by radiation. A warm object emits energy in the form of radiation, predominantly in the infrared range, independent of ambient air temperature. Significant radiant losses can occur from the unclothed patient in the operating room. In infant incubators, radiant heat losses occur from the exposed infant. Radiant heat loss is countered by heating the surrounding surfaces so that radiant heat loss is offset by the absorption of radiant heat from nearby surfaces. Radiant heat loss is also countered by blankets, which absorb and then return radiant heat.

Conduction of heat from the body occurs by direct contact with a cooler object, for example, between the patient and cold air or an adjacent mattress. The area of the conducting surfaces, the temperature difference, and the heat capacity affects conductive heat transfer. Conductive loss to still air is limited because a stationary layer of air next to the skin acts as a good insulator. Air has a very low heat capacity and warms quickly, thus promptly eliminating the temperature gradient. In humans, piloerection reduces heat loss by trapping a layer of air next to the skin.

Although pure conduction accounts for <5% of heat loss, conductive heat loss to air is greatly facilitated by air movement and is termed *convection* or *facilitated conduction*. Thus, a fan is comfortable on a hot summer day because it facilitates heat loss. The rate of convective loss depends on both the air temperature and its velocity (the “wind-chill” phenomenon). Convection accounts for approximately 15% to 30% of heat loss in the operating room but increases significantly in high “wind-chill” environments such as a laminar flow unit. However, significant convective heat loss occurs even in a draft-free environment because warmed air rises to be replaced by denser cold air, thus maintaining cutaneous airflow.

Evaporative heat losses are important because significant energy is required to vaporize water. Evaporation from the skin accounts for about 20% of total heat loss. The magnitude of evaporative loss depends upon environmental humidity, exposed skin surface area, presence of diaphoresis, wound and bowel exposure, and application of fluid to the skin (prep solutions). Evaporation is the only mechanism by which the body can eliminate excess heat when the temperature of the surroundings is higher than that of the skin. Diaphoresis occurs in response to stimulation of the preoptic area of the hypothalamus. A normal individual has a maximal sweat production of about 700 mL per hour. With continued exposure to a warm environment, sweat production may increase to 1,500 mL per hour. Evaporation of this amount of sweat can remove heat from the body at a rate of >10 times the normal basal rate of heat production. Evaporation accounts for two-

thirds of the heat loss from the respiratory tract. Evaporative heat and fluid loss are important considerations during surgery in which large segments of moist bowel are exposed for evaporation. Reductions in core temperature also follow infusions of cold intravenous fluids and blood products.

Regulation of Body Temperature

Body temperature is regulated by feedback mechanisms predominantly mediated by the preoptic nucleus of the anterior hypothalamus,⁹⁹ which integrates afferent input from thermoreceptors in the skin, deep tissues, and spinal cord. Afferent thermoregulatory input is modulated in the brainstem and spinal cord before arrival in the hypothalamus. Heat-sensitive neurons in the preoptic nucleus receive additional thermal input from extrahypothalamic areas of the brain. Reflex responses to cold (vasoconstriction, piloerection, shivering, and nonshivering thermogenesis) originate in the posterior hypothalamus. Reflex responses to heat (vasodilatation, sweating) originate in the anterior hypothalamus.

The hypothalamic thermostat detects body temperature changes and initiates autonomic, somatic, and endocrine responses when the various set points are reached. However, in the awake individual, behavioral responses (putting on a jacket) usually occur before the core temperature reaches the set points. If the behavioral response to hypothermia fails or is abolished by anesthesia, the hypothalamic thermostat stimulates vasoconstriction at 36.5°C and shivering at 36.2°C. As a result, the rate of heat transfer to the skin is decreased, heat production rises from shivering, and body temperature increases.

There is a narrow range of normal core temperature, 36.7°C to 37.1°C, within which thermoregulatory responses are not triggered. General anesthesia abolishes much of the ability to regulate temperature through drug induced vasodilation and muscle relaxation. Maintenance of body temperature at a value close to the optimum for enzyme activity assures a constant rate of metabolism, optimal enzyme function, nervous system conduction, and skeletal muscle contraction. Even modest hypothermia (<36°C) reduces the drug metabolism, delaying emergence from anesthesia. Hyperthermia is even less well tolerated, as protein denaturation begins at about 42°C.

Nonshivering Thermogenesis

Nonshivering thermogenesis (alternatively called chemical thermogenesis) is an increase in the rate of cellular metabolism in brown adipose tissue evoked by sympathetic nervous system stimulation or by circulating catecholamines. In infants, chemical thermogenesis in brown fat located in the interscapular space and around the great vessels in the thorax and abdomen can increase the rate of heat production by as much as 200%. Historically, it was thought that adults had almost no brown fat; however, recent studies have shown functional brown adipose tissue in adults that becomes activated during exposure to cold.¹⁰⁰ In contrast to other fat depots, brown fat contains large numbers of mitochondria, and has extensive sympathetic innervation. Within these mitochondria, the generation of adenosine triphosphate is uncoupled as oxidative phosphorylation is short-circuited to generate heat. This process is dependent upon an uncoupling protein (UCP 1). Lipolysis and heat generation in brown fat is mediated via β-adrenergic receptors.

Shivering

Skeletal muscle activity is a major source of heat. Shivering increases body heat production in response to decreased core temperature. The posterior hypothalamic area responsible for the response to hypothermia controls reflex shivering. Shivering occurs due to both increased motor traffic via anterior motor neurons and to upregulation of the muscle stretch reflex. However, shivering is inefficient and induces significant metabolic demand. Awake patients find shivering intensely unpleasant.

Causes of Increased Body Temperature

A variety of disorders can increase body temperature. Those disorders resulting from thermoregulatory failure (excessive metabolic production of heat, excessive environmental heat, and impaired heat dissipation) are properly characterized as *hyperthermia*, whereas those resulting from intact homeostatic responses are categorized as *fever* (**Table 3.7**).⁹⁹

TABLE 3.7**Causes of hyperthermia**

Disorders associated with excessive heat production
Malignant hyperthermia
Neuroleptic malignant syndrome
Thyrotoxicosis
Delirium tremens
Pheochromocytoma
Salicylate intoxication
Drug abuse (cocaine, amphetamine, 3,4-methylenedioxymethamphetamine)
Status epilepticus
Exertional hyperthermia
Disorders associated with decreased heat loss
Autonomic nervous system dysfunction
Anticholinergics
Drug abuse (cocaine)
Dehydration
Occlusive dressings
Heat stroke
Disorders associated with dysfunction of the hypothalamus
Trauma
Tumors
Idiopathic hypothalamic dysfunction
Cerebrovascular accidents
Encephalitis
Neuroleptic malignant syndrome

In hyperthermic states, the hypothalamic set-point is normal, but peripheral mechanisms are unable to maintain body temperature that matches the set-point. In contrast, fever occurs when the hypothalamic set-point is increased by the action of circulating pyrogenic cytokines, causing intact peripheral mechanisms to conserve and generate heat until the body temperature increases to the elevated set-point. Despite their physiologic differences, hyperthermia and fever cannot be differentiated clinically based on the height of the temperature or its pattern. However, the clinical management of hyperthermia and fever are very different. The treatment of hyperthermia should be directed at promoting heat dissipation and terminating excessive heat production (eg, administration of dantrolene for malignant hyperthermia), whereas the treatment of fever should be directed at identification and eradication of pyrogens and lowering the thermoregulatory set-point with antipyretic drugs such as aspirin, acetaminophen, and cyclooxygenase inhibitors.

Fever

Pyrogens are bacterial and viral toxins that indirectly cause the set-point of the hypothalamic thermostat to increase. Bacterial pyrogens stimulate host inflammatory cells (mononuclear phagocytes) to generate endogenous pyrogens, including interleukins, prostaglandins, and tumor necrosis factor. Viruses do not release pyrogens directly but stimulate infected cells to release interferons α and β that act as endogenous pyrogens. All known endogenous pyrogens are polypeptides and are therefore unlikely to cross the blood–brain barrier. However, endogenous pyrogens have actions in the organum vasculosum of the lamina terminalis, which is a structure adjacent to the lateral ventricles that lies outside the blood–brain barrier. It is likely that endogenous pyrogens acting in the organum vasculosum of the lamina terminalis evoke the release of prostaglandins in the CNS, leading to stimulation of the preoptic nucleus and generation of the febrile response.⁷⁶

Chills

Sudden resetting of the hypothalamic thermostat to a higher level because of tissue destruction, pyrogens, or dehydration, results in a lag between blood temperature and the new hypothalamic set point. During this period, the person experiences chills and feels cold even though body temperature may be increased. The skin is cold because of cutaneous vasoconstriction. Chills continue until the body temperature increases to the new set point of the hypothalamic thermostat. As long as the process causing the hypothalamic thermostat to be set at a higher level is present, the body's core temperature will remain increased above normal. Sudden removal of the factor that is causing the body temperature to remain increased is accompanied by intense diaphoresis and feeling of warmth because of generalized cutaneous vasodilation.

Cutaneous Blood Flow

Cutaneous blood flow is a major determinant of heat loss. The cutaneous circulation is among the most variable in the body, reflecting its primary role in regulation of body temperature in response to alterations in the rate of metabolism and the temperature of the external surroundings. The skin's metabolic needs are so low that the typical cutaneous blood flow is about 10 times higher than needed to supply nutritive needs of the skin.

Cutaneous blood flow is largely regulated by the sympathetic nervous system. Vascular structures concerned with heat loss from skin consist of subcutaneous venous plexuses that can hold large quantities of blood. The cutaneous circulation of the fingers, palms, toes, and earlobes has richly innervated arteriovenous anastomoses that facilitate significant heat loss. In an adult, typical total cutaneous blood flow is about 400 mL per minute. This flow can decrease to as little as 50 mL per minute in severe cold and may increase to as much as 2,800 mL per minute in extreme heat. Patients with borderline cardiac function may become symptomatic in hot environments as the heart attempts to supply increased blood flow to the skin. During acute hemorrhage, the sympathetic nervous system can produce enough cutaneous vasoconstriction to transfer large amounts of blood into the central circulation. As such, the cutaneous veins act as an important blood reservoir that can supply 5% to 10% of the blood volume in times of need. Acute hemorrhage may be less well tolerated in a warm environment because the hypothalamic vasodilator response may override the vasoconstrictor response to hypovolemia. Inhaled anesthetics increase cutaneous blood flow, perhaps by inhibiting the temperature-regulating center of the hypothalamus.¹⁰¹

Perioperative Temperature Changes

The thermoregulatory system contains three key elements: afferent input, central processing, and the efferent response. General anesthesia affects all three elements and regional anesthesia affects both the afferent and efferent components. Thus, anesthesia and surgery in a cool environment makes perioperative hypothermia a likely occurrence (**Table 3.8**).^{102,103} General and regional anesthesia increase the homeostatic range to 4.0°C, approximately 20 times the normal range. The threshold for sweating and vasodilation is increased about 1°C, and the threshold for vasoconstriction and shivering is decreased about 3°C. As a result, anesthetized patients are relatively poikilothermic, with body temperatures determined by the environment. Anesthetics inhibit thermoregulation in a dose-dependent manner and inhibit vasoconstriction and shivering about 3 times as much as they restrict sweating.¹⁰⁴

TABLE 3.8
Events that contribute to decreases in body temperature during surgery
Resetting of the hypothalamic thermostat
Ambient temperature <21°C
Administration of unwarmed intravenous fluids
Drug-induced vasodilation
Basal metabolic rate decreased
Attenuated shivering response
Core compartment exposed to ambient temperature
Heat required to humidify inhaled dry gases

Alfentanil and propofol similarly lower the threshold for vasoconstriction and sweating. Volatile anesthetics such as isoflurane and desflurane decrease the threshold temperatures for cold responses in a nonlinear fashion. Nonshivering thermogenesis does not occur during general anesthesia in adults or infants.

Sequence of Temperature Changes During Anesthesia

In the awake individual, body heat is unevenly distributed. Tonic thermoregulatory vasoconstriction maintains a temperature gradient between the core and periphery of 2°C to 4°C. The core compartment that is insulated from the environment by the peripheral compartment, consists of the major viscera, and includes the head, chest, abdomen, and pelvis. Under general anesthesia, tonic vasoconstriction is attenuated and heat contained in the core compartment will move to the periphery, thus allowing the core temperature to decrease toward the anesthetic-induced lowered threshold for vasoconstriction. This core to peripheral heat redistribution is responsible for the 0.5°C to 1.55°C decrease in core temperature that occurs during the first hour of general anesthesia ([Figure 3.27](#)).¹⁰⁵ For this reason, protection from heat loss early in a surgical procedure is important to reduce the temperature gradient from the environment to the peripheral compartment as significant heat energy has been shunted to the periphery.

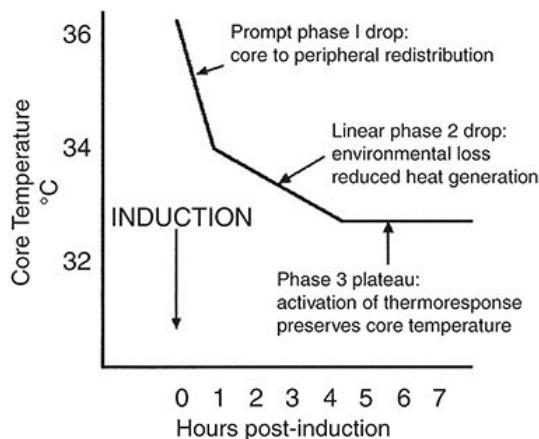

FIGURE 3.27 Graphic representation of the typical triphasic core temperature pattern that occurs after induction of anesthesia. Note that the phase 3 plateau may not occur, particularly during regional anesthesia or during combined regional and general anesthesia. Although core temperature is preserved during the phase 3 plateau, heat will continue to be lost to the environment from the peripheral compartment.

After the first hour of general anesthesia, the core temperature usually decreases at a slower rate. This decrease is nearly linear and occurs because continuing heat loss to the environment exceeds the metabolic production of heat. After 3 to 5 hours of anesthesia, the core temperature often stops decreasing (see [Figure 3.27](#)). This thermal plateau may reflect a steady state in which heat loss equals heat production. This type of thermal steady state is especially likely in patients who are well insulated or effectively warmed. However, if a patient becomes sufficiently hypothermic, activation of thermoregulatory vasoconstriction will occur, decreasing cutaneous heat loss and retaining heat in the core compartment. Intraoperative vasoconstriction thus reestablishes the normal core-to-periphery temperature gradient by preventing the loss of centrally generated metabolic heat to peripheral tissues. Although vasoconstriction may effectively maintain the core temperature plateau, mean body temperature and the total heat content of the body continue to decrease as continued loss of heat occurs from the peripheral compartment to the environment. Because reflex vasoconstriction is usually effective in maintaining core temperature, the intraoperative core temperature rarely decreases the additional 1°C necessary to trigger shivering during general anesthesia.¹⁰³

Although regional anesthesia is thought to have minimal effect upon the central processing and integration of the thermoregulatory response, afferent cold input from the lower body may be overridden by a sense of warmth from cutaneous vasodilatation. Decreases in core temperature of a similar or greater

magnitude to those experienced during general anesthesia may occur during spinal or epidural techniques despite the sensation of warmth. The initial redistributive temperature drop may be less precipitous during regional anesthesia because vasodilatation is restricted to the blocked area. However, because reflex vasoconstriction is abolished below the level of the block, the plateau phase seen during general anesthesia may not occur during regional anesthesia (see [Figure 3.27](#)). Indeed, core temperature may decrease sufficiently during regional anesthesia to trigger the shivering response. However, the ability of reflex shivering to generate heat is markedly attenuated because it is restricted to the unblocked upper body.

Beneficial Effects of Perioperative Hypothermia

Oxygen consumption is decreased by approximately 5% to 7% per °C of cooling. Even moderate decreases in core temperature of 1°C to 3°C below normal provide substantial protection against cerebral ischemia and arterial hypoxemia. Indeed, induced hypothermia to 28°C, as used during cardiopulmonary bypass, will reduce cerebral metabolic rate by 50%. Hypothetically, mild hypothermia (33°C-36°C) during operations likely to be associated with cerebral ischemia such as carotid endarterectomy and aneurysm clipping should be neuroprotective but there has not been conclusive evidence showing the benefit.[106,107](#) Operations involving aortic cross-clamping can jeopardize spinal cord perfusion and may also benefit from the increased margin of safety afforded by mild hypothermia. Mild hypothermia also slows the triggering of malignant hyperthermia.[108](#)

Outside the operating room, induced hypothermia after cardiac arrest from ventricular fibrillation has shown to improve survival and neurologic function.[109](#) More recent trials have shown that targeting a temperature of 36°C is as beneficial as 33°C.[110](#) It may be that actively controlling a temperature to avoid fever is what confers the neurologic benefit rather than the process of cooling. The main benefit of mild hypothermia accrues from a reduction in metabolic demand. Typical approaches to achieve mild hypothermia often include surface cooling. However, surface cooling may induce shivering, which will delay core cooling. For targeted temperature management after cardiac arrest, medications are often given to control shivering, including neuromuscular blockade.

Adverse Consequences of Perioperative Hypothermia

Perioperative hypothermia may predispose to several significant complications ([Table 3.9](#)). These include postoperative shivering (significantly increasing metabolic rate and cardiac work) and impaired coagulation (impaired platelet function, decreased activation of the coagulation cascade). Indeed, hypothermia-induced coagulopathy is associated with increased transfusion requirements. A 1°C decrease in temperature is associated with a 5% reduction in anesthetic requirements (MAC) and an increase in volatile anesthetic blood/gas solubility. Drug metabolism is decreased by hypothermia, particularly that of nondepolarizing neuromuscular-blocking drugs. These factors all conspire to delay emergence from anesthesia and delay recovery room discharge. Hypothermia also impairs wound healing and is associated with decreased resistance to surgical wound infection.[104](#) The underlying mechanism is thought to be hypothermia-induced vasoconstriction, which decreases wound perfusion and local tissue oxygen partial pressure. Perioperative hypothermia is also associated with delayed hospital discharge and an increased catabolic state. Shivering occurs in approximately 40% of unwarmed patients who are recovering from general anesthesia and is associated with substantial sympathetic nervous system activation and discomfort from the sensation of cold. Core hypothermia equal to a 1.5°C decrease triples the incidence of ventricular tachycardia and morbid cardiac events.[111](#)

TABLE 3.9

Immediate adverse consequences of perioperative hypothermia

Adverse outcome	Mechanism
Increased operative blood loss	Coagulopathy and platelet dysfunction Increased myocardial work load Increased sympathetic activity

Increased morbid cardiac events Dysrhythmias and myocardial ischemia Wound infection Delayed wound healing Delayed anesthetic emergence Delayed recovery room discharge	Sympathetic mediated cutaneous vasoconstriction Decreased drug metabolism and increased volatile agent solubility; decreased minimum anesthetic concentration Postanesthetic shivering; delayed recovery

Perioperative Temperature Measurement

The significant adverse physiologic effects of changes in body temperature are a compelling reason to monitor body temperature during anesthesia. Unless hypothermia is specifically indicated, as for protection against tissue ischemia, it is recommended that intraoperative core temperature be maintained at $\geq 36^{\circ}\text{C}$. Measuring the temperature of the lower 25% of the esophagus (about 24 cm beyond the corniculate cartilages or site of the loudest heart sounds heard through an esophageal stethoscope) gives a reliable approximation of blood and cerebral temperature. Readings elsewhere in the esophagus are more likely to be influenced by the temperature of inhaled gases. A nasopharyngeal temperature probe positioned behind the soft palate gives a less reliable measure of cerebral temperature than a correctly positioned esophageal probe. Leakage of gases around the tracheal tube may also influence nasopharyngeal temperature measurements. Heat-producing bacteria in the gastrointestinal tract, cold blood returning from the lower limbs, and insulation of the probe by feces can all influence rectal temperature. Bladder temperature is also subject to a prolonged response time, particularly if urine flow is $<270 \text{ mL per hour}$.¹¹² Tympanic membrane and aural canal temperatures provide a rapidly responsive and accurate estimate of hypothalamic temperature and correlate well with esophageal temperature. Thermistors in pulmonary artery catheters provide the best continuous estimate of body temperature but are invasive. Skin temperature gives no information other than the temperature of that area of the skin.

Prevention of Perioperative Hypothermia

Passive or active airway heating and humidification contribute little to perioperative thermal management in adults because <10% of metabolic heat is lost via ventilation.¹⁰⁴ Each liter of intravenous fluid at ambient temperature that is infused into adult patients, or each unit of blood at 4°C decreases the mean core body temperature about 0.25°C . In this regard, the administration of unwarmed fluids can markedly decrease body temperature. Warming fluids to near 37°C is useful for preventing hypothermia, especially if large volumes of fluids are being infused.

The skin is the predominant source of heat loss during anesthesia and surgery, although evaporation from large surgical incisions may also be important. A high ambient temperature maintains normothermia in anesthetized patients, but temperatures of $>25^{\circ}\text{C}$ are uncomfortable for operating room personnel.

Covering the skin with surgical drapes or blankets can decrease cutaneous heat loss. A single layer of insulator decreases heat loss by approximately 30%, but additional layers do not proportionately increase the benefit.¹¹³ For this reason, active warming is needed to prevent intraoperative hypothermia. Forced-air warming is probably the most effective method available, although any method or combination of methods that maintains core body temperature near 36°C is acceptable.¹⁰⁴ Circulating warm water mattresses are generally ineffective because cutaneous blood flow to the back is limited in the supine position.

Inhaled Anesthetics

Pamela Flood • Steven L. Shafer • Ardin S. Berger

History

The discovery of the anesthetic properties of nitrous oxide, diethyl ether, and chloroform in the 1840s was followed by a hiatus of about 80 years before other inhaled anesthetics were introduced (Figure 4.1).¹ In 1950, all inhaled anesthetics, with the exception of nitrous oxide, were flammable or potentially toxic to the liver. Recognition that replacing a hydrogen atom with a fluorine atom decreased flammability led to the introduction, in 1951, of the first halogenated hydrocarbon anesthetic, fluroxene. Fluroxene was used clinically for several years before its voluntary withdrawal from the market due to its potential flammability and increasing evidence that this drug could cause organ toxicity.²

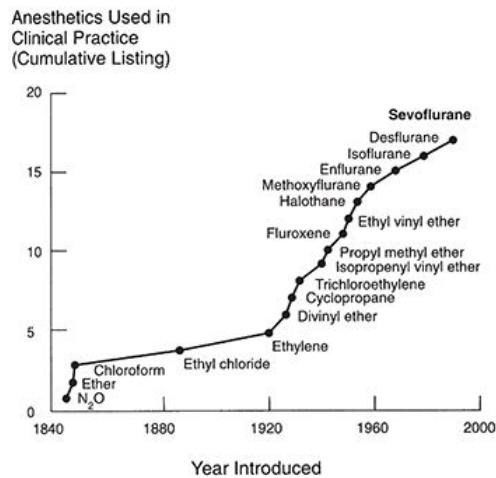

FIGURE 4.1 Inhaled anesthetics introduced into clinical practice beginning with the successful use of nitrous oxide in 1844 for dental anesthesia followed by recognition of the anesthetic properties of ether in 1846 and of chloroform in 1847. Modern anesthetics, beginning with halothane, differ from prior anesthetics in being fluorinated and nonflammable. *Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.*

Halothane was synthesized in 1951 and introduced for clinical use in 1956. However, the tendency for alkane derivatives such as halothane to enhance the arrhythmogenic effects of epinephrine led to the search for new inhaled anesthetics derived from ethers. Methoxyflurane, a methyl ethyl ether, was the first such derivative. Methoxyflurane was introduced into clinical practice in 1960. Although methoxyflurane did not enhance the arrhythmogenic effects of epinephrine, its high solubility in blood and lipids resulted in a prolonged induction and slow recovery from anesthesia. More importantly, methoxyflurane caused hepatic toxicity. Extensive hepatic metabolism increased plasma concentrations of fluoride, which caused nephrotoxicity, especially with prolonged exposures to the anesthetic. Methoxyflurane has analgesic properties at concentrations far below those that induce anesthesia. Although its use was abandoned in the United States and Canada in the 1970s, it continues to be used in Australia for brief painful procedures and emergency transport.³ Enflurane, the next methyl ethyl ether derivative, was introduced for clinical use in 1973. This anesthetic, in contrast to halothane, does not enhance the arrhythmogenic effects of epinephrine or cause hepatotoxicity. Nevertheless, side effects were present, including metabolism to inorganic fluoride and stimulation of the central nervous system (CNS), lowering the seizure threshold. In search of a drug with fewer side effects, isoflurane, a structural isomer of enflurane, was introduced in 1981. This drug was resistant to metabolism, making organ toxicity unlikely after its administration.

Inhaled Anesthetics for the Present and Future

The search for even more pharmacologically “perfect” inhaled anesthetics did not end with the introduction and widespread use of isoflurane. The exclusion of all halogens except fluorine results in nonflammable liquids that are poorly lipid soluble and extremely resistant to metabolism. Desflurane, a totally fluorinated methyl ethyl ether, was introduced in 1992 and was followed in 1994 by the totally fluorinated methyl isopropyl ether, sevoflurane.^{4,5} The low solubility of these volatile anesthetics in blood facilitated rapid induction of anesthesia, precise control of end-tidal anesthetic concentrations during maintenance of anesthesia, and prompt recovery at the end of anesthesia independent of the duration of administration. The development, introduction, and rapid clinical acceptance of desflurane and sevoflurane reflects market forces (ambulatory surgery and the desire for rapid awakening possible with poorly soluble but potent anesthetics) more than an improved pharmacologic profile on various organ systems as compared with isoflurane. The challenge to the anesthesiologist is to exploit the pharmacokinetic advantages of these drugs while minimizing the risks (airway irritation, sympathetic nervous system stimulation, carbon monoxide production from interaction with carbon dioxide absorbent and complex vaporizer technology with desflurane, and compound A production from sevoflurane) and the increased expense associated with the manufacture and increased cost of administration of desflurane and sevoflurane.

Cost Considerations

Cost is an important consideration in the adoption of new drugs, including inhaled anesthetics. Factors that may influence the cost of a new inhaled anesthetics include (1) price (cost per milliliter of liquid); (2) inherent characteristics of the anesthetic, such as its vapor pressure (milliliter of vapor available per milliliter of liquid), potency, and solubility; and (3) fresh gas flow rate selected for delivery of the anesthetic.⁶ The costs of new inhaled anesthetics can be decreased by using low fresh gas flow rates. Less soluble anesthetics are more suitable for use with low gas flow rates because their poor solubility permits better control of the delivered concentration. Furthermore, there is less depletion of these anesthetics from the inspired gases so that fewer molecules need to be added to the returning rebreathed gases. This conservation offsets the decreased potency of a drug such as desflurane compared with isoflurane. For example, desflurane is one-fifth as potent as isoflurane; yet, the amount of desflurane that must be delivered to sustain minimal alveolar concentration (MAC) is only slightly more than threefold the amount of isoflurane. Similarly, although MAC of sevoflurane is 74% greater than isoflurane, the amount of sevoflurane that must be delivered to sustain MAC is only 30% greater.

Current Clinically Useful Inhaled Anesthetics

Commonly administered inhaled anesthetics include the inorganic gas nitrous oxide and the volatile liquids isoflurane, desflurane, and sevoflurane (**Table 4.1**) (**Figure 4.2**).^{4,5} Halothane and enflurane are administered infrequently but are included in the discussion of the comparative pharmacology of volatile anesthetics because halothane in particular has been studied extensively.^{4,5}

TABLE 4.1

Physical and chemical properties of inhaled anesthetics

	Nitrous oxide	Halothane	Enflurane	Isoflurane	Desflurane	Sevoflurane
Molecular weight	44	197	184	184	168	200
Boiling point (°C)		50.2	56.5	48.5	22.8	58.5
Vapor pressure (mm Hg; 20°C)	Gas	244	172	240	669	170
Odor	Sweet	Organic	Ethereal	Ethereal	Ethereal	Ethereal
Preservative necessary	No	Yes	No	No	No	No
Stability in soda lime (40°C)	Yes	No	Yes	Yes	Yes	No
Blood:gas partition coefficient	0.46	2.54	1.90	1.46	0.42	0.69
	104	0.75	1.63	1.17	6.6	1.80

MAC (37°C, 30-55 years old, P_B 760 mm Hg) (%)

Abbreviations: MAC, minimal alveolar concentration; P_B, brain partial pressure.

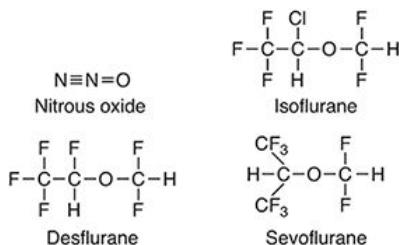

FIGURE 4.2 Inhaled anesthetics.

Volatile liquids are administered as vapors after their vaporization in devices known as **vaporizers**. Diethyl ether and chloroform are still available but mostly used only in veterinary medicine. Xenon is an inert gas with anesthetic properties, but its clinical use is hindered by its high cost.⁷

Nitrous Oxide

Nitrous oxide is a low-molecular-weight, odorless to sweet-smelling nonflammable gas of low potency and poor blood solubility (blood:gas partition coefficient 0.46) that is most commonly administered in combination with opioids or volatile anesthetics to produce general anesthesia. Although nitrous oxide is nonflammable, it will support combustion.⁸ Its poor blood solubility permits rapid achievement of an alveolar and brain partial pressure of the drug (Figure 4.3).^{9,10} The analgesic effects of nitrous oxide are prominent but short lived, dissipating after about 20 minutes of use while sedative effects persist.¹¹ Nitrous oxide causes minimal skeletal muscle relaxation. Nitrous oxide has no effect on tissue PO₂ measurements but does cause a small increase in the P₅₀ (about 1.6 mm Hg).¹² Nitrous oxide has not only acute analgesic activity but may also attenuate hyperacute hyperalgesia by remifentanil¹⁰ and have efficacy to reduce chronic pain.¹³

The benefits of nitrous oxide must be balanced against its possible adverse effects related to the high-volume absorption of nitrous oxide in gas-containing spaces, ability to inactivate vitamin B₁₂ that may be relevant in patients with depleted reserves or related genetic defects in the vitamin B₁₂ pathway. The impact of nitrous oxide on postoperative nausea and vomiting is a topic that evokes passionate fixed beliefs in many anesthesia practitioners for unclear reasons¹⁴ as it has been well studied. When used as part of some anesthetic techniques, nitrous oxide increases the incidence of nausea and vomiting. A 2010 meta-analysis that included 30 published studies of many anesthetic regimens suggests that avoidance of nitrous oxide is associated with a lower risk of postoperative nausea and vomiting (relative risk = 0.80 [0.71-0.90], p = 0.0003).¹⁵ However, the capacity of nitrous oxide to increase the likelihood of postoperative nausea and vomiting needs to be considered in light of the alternatives. Many practitioners eschew nitrous oxide in light of the postoperative nausea and vomiting risk but have no concerns about using volatile anesthetics. An elegant factorial trial published in *The New England Journal of Medicine* in 2004 (the IMPACT trial) put this issue into clinical context.¹⁶ This was a study of young women having gynecologic surgery at high risk for nausea and vomiting. Without any antiemetic, approximately 60% had nausea and vomiting when anesthetized with volatile anesthetic alone, volatile anesthetic with nitrous oxide, or propofol with nitrous oxide. The only anesthetic with significantly reduced incidence of nausea and vomiting was propofol alone. The addition of a single antiemetic reduced the incidence of postoperative nausea and vomiting to approximately 35% with the exception of a volatile anesthetic with nitrous oxide that was 45%. Environmental considerations are addressed later in the chapter.

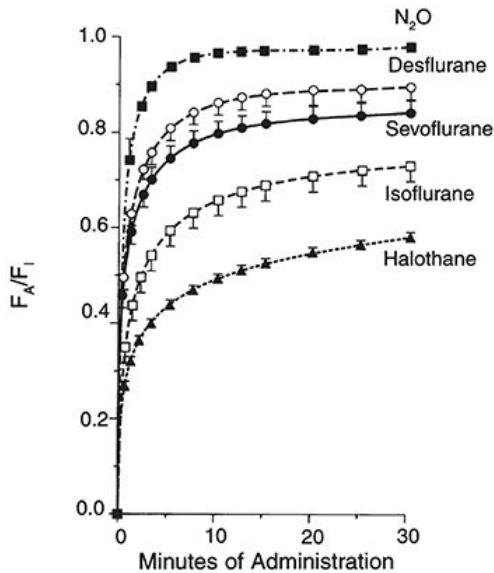

FIGURE 4.3 The pharmacokinetics of inhaled anesthetics during the induction of anesthesia is defined as the ratio of the end-tidal anesthetic concentration (F_A) to the inspired anesthetic concentration (F_I). Consistent with their relative blood:gas partition coefficients, the F_A/F_I of poorly soluble anesthetics (nitrous oxide, desflurane, sevoflurane) increases more rapidly than that of anesthetics with greater solubility in blood. A decrease in the rate of change in the F_A/F_I after 5 to 15 minutes (three time constants) reflects decreased tissue uptake of the anesthetic as the vessel-rich group tissues become saturated. (Data are mean \pm standard deviation.) Reprinted with permission from Yasuda N, Lockhart SH, Eger EI, et al. Comparison of kinetics of sevoflurane and isoflurane in humans. Halothane

Halothane is a halogenated alkane derivative that exists as a clear, nonflammable liquid at room temperature. The vapor of this liquid has a sweet, bland odor. An intermediate solubility in blood, combined with a high potency, permits intermediate onset and recovery from anesthesia using halothane alone or in combination with nitrous oxide or injected drugs such as opioids.

Halothane was developed on the basis of predictions that its halogenated structure would provide intermediate blood solubility, anesthetic potency, and molecular stability and avoid flammability. Specifically, carbon-fluorine bond decreases flammability, and the trifluorocarbon contributes to molecular stability. The presence of a carbon-chlorine and carbon-bromine bond plus the retention of a hydrogen atom ensures anesthetic potency. Despite its chemical stability, halothane is susceptible to decomposition to hydrochloric acid, hydrobromic acid, chloride, bromide, and phosgene. For this reason, halothane is stored in amber-colored bottles, and thymol is added as a preservative to prevent spontaneous oxidative decomposition. Thymol that remains in vaporizers after vaporization of halothane can cause vaporizer turnstiles or temperature-compensating devices to malfunction.

Enflurane

Enflurane is no longer in common use in the United States. It is a halogenated methyl ethyl ether that exists as a clear, nonflammable volatile liquid at room temperature and has a pungent, ethereal odor. Its intermediate solubility in blood combined with a high potency permits intermediate onset and recovery from anesthesia, using enflurane alone or in combination with nitrous oxide or injected drugs such as opioids. Enflurane decreases the threshold for seizures. Enflurane is oxidized in the liver to produce inorganic fluoride ions that can be nephrotoxic. It was primarily used for procedures in which a low threshold for seizure generation is desirable, such as electroconvulsive therapy.

Isoflurane

Isoflurane is a halogenated methyl ethyl ether that exists as a clear, nonflammable liquid at room temperature and has a pungent, ethereal odor. Its intermediate solubility in blood combined with a high potency permits intermediate onset and recovery from anesthesia using isoflurane alone or in combination with nitrous oxide or injected drugs such as opioids.

Isoflurane is characterized by extreme physical stability, undergoing no detectable deterioration during 5 years of storage or on exposure to carbon dioxide absorbents or sunlight. The stability of isoflurane obviates the need to add preservatives such as thymol to the commercial preparation.

Desflurane

Desflurane is a fluorinated methyl ethyl ether that differs from isoflurane only by substitution of a fluorine atom for the chlorine atom found on the alpha-ethyl component of isoflurane. Fluorination rather than chlorination increases vapor pressure (decreases intermolecular attraction), enhances molecular stability, and decreases potency. Indeed, the vapor pressure of desflurane exceeds that of isoflurane by a factor of three such that desflurane would boil at normal operating room temperatures. A new vaporizer technology addressed this property, producing a regulated concentration by converting desflurane to a gas (heated and pressurized vaporizer that requires electrical power), which is then blended with diluent fresh gas flow. The only evidence of metabolism of desflurane is the presence of measurable concentrations of serum and urinary trifluoroacetate that are one-fifth to one-tenth those produced by the metabolism of isoflurane. The potency of desflurane as reflected by MAC is about fivefold less than isoflurane.

Unlike halothane and sevoflurane, desflurane is pungent, making it unlikely that inhalation induction of anesthesia would be feasible or pleasant for the patient. Indeed, the pungency of desflurane produces airway irritation and an appreciable incidence of salivation, breath holding, coughing, or laryngospasm when >6% inspired desflurane is administered to an awake patient.⁴ Carbon monoxide results from degradation of desflurane by the strong base present in desiccated carbon dioxide absorbents. Desflurane produces the highest carbon monoxide concentrations, followed by enflurane and isoflurane, whereas amounts produced from halothane and sevoflurane are trivial.

Intraoperative Diagnosis of Carbon Monoxide Poisoning

Intraoperative detection of carbon monoxide is difficult because pulse oximetry cannot differentiate between carboxyhemoglobin and oxyhemoglobin. Moderately decreased pulse oximetry readings despite adequate arterial partial pressures of oxygen (especially during the first case of the day, “Monday morning phenomena”) should suggest the possibility of carbon monoxide exposure and the need to measure carboxyhemoglobin.¹⁷ Furthermore, there is no routinely available means to reliably identify the presence of carbon monoxide in the breathing circuit or to detect when carbon dioxide absorbent has become desiccated (absorbent color change does not occur in response to desiccation or carbon monoxide formation). In addition to decreased pulse oximeter readings, an erroneous gas analyzer reading (indicates mixed gas readings or enflurane when desflurane is being administered) has been described as an early indirect warning of carbon monoxide formation.^{18,19} This erroneous gas analyzer reading was attributed to trifluoromethane, which is produced along with carbon monoxide by degradation of isoflurane, enflurane, and desflurane but not sevoflurane. Trifluoromethane has an infrared absorption profile similar to enflurane resulting in the gas analyzer indicating administration of this volatile anesthetic when the vaporizer is known to contain desflurane or isoflurane. An erroneous gas analyzer reading as an early warning of carbon monoxide exposure does not occur during administration of sevoflurane.¹⁸ Carboxyhemoglobin can be measured acutely with CO-oximetry; this technology is routinely available.²⁰ Delayed neurophysiologic sequelae due to carbon monoxide poisoning (cognitive defects, personality changes, gait disturbances) may occur as late as 3 to 21 days after anesthesia. Intraoperative hemolysis has the potential to result in carbon monoxide exposure, which can mimic carbon monoxide production from degradation of volatile anesthetics.²¹

Solubility characteristics (blood:gas partition coefficient 0.45) and potency (MAC 6.6%) permit rapid achievement of an alveolar partial pressure necessary for anesthesia followed by prompt awakening when desflurane is discontinued. It is this lower blood-gas solubility and more precise control over the delivery of

anesthesia and more rapid recovery from anesthesia that distinguish desflurane (and sevoflurane) from earlier volatile anesthetics.

Sevoflurane

Sevoflurane is a fluorinated methyl isopropyl ether. The vapor pressure of sevoflurane resembles that of halothane and isoflurane, permitting delivery of this anesthetic via a conventional unheated vaporizer. The solubility of sevoflurane (blood:gas partition coefficient 0.69) resembles that of desflurane, ensuring prompt induction of anesthesia and recovery after discontinuation of the anesthetic. Compared with isoflurane, recovery from sevoflurane anesthesia is 3 to 4 minutes faster and the difference is magnified in longer duration surgical procedures (>3 hours) (**Figure 4.4**).²² Sevoflurane is nonpungent, has minimal odor, produces bronchodilation similar in degree to isoflurane, and causes the least degree of airway irritation among the currently available volatile anesthetics. For these reasons, sevoflurane, like halothane, is acceptable for inhalation induction of anesthesia.

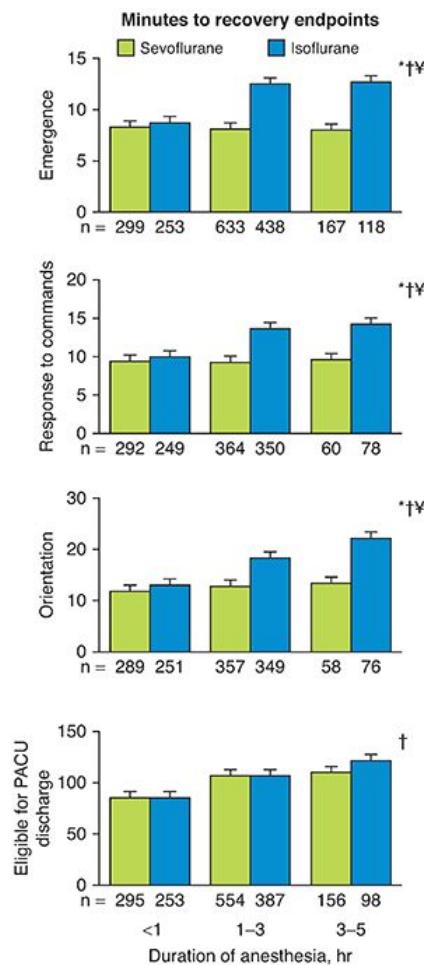

FIGURE 4.4 Times to emergence, responses to commands, orientation, and discharge from the postanesthesia care unit (PACU) are presented with minutes to end point on the y-axis and number of patients studied and duration of anesthesia on the x. (Data are mean \pm standard error of the mean.) Abbreviations: n, number of patients studied; *, significant difference between sevoflurane and isoflurane; †, significant difference with increasing duration of anesthesia; ‡, significant interaction between anesthetic and duration of anesthesia. Reprinted with permission from Ebert TJ, Robinson BJ, Uhrich TD, et al. Recovery from sevoflurane anesthesia: a comparison to isoflurane and propofol anesthesia. *Anesthesiology*. 1998;89(6):1524-1531. Copyright © 1998 American Society of Anesthesiologists, Inc.

Sevoflurane may be 100-fold more vulnerable to metabolism than desflurane, with an estimated 3% to 5% of the dose undergoing biodegradation. The resulting metabolites include inorganic fluoride (plasma concentrations exceed those that occur after enflurane) and hexafluoroisopropanol. Sevoflurane metabolism does not result in the formation of trifluoroacetylated liver proteins and therefore cannot stimulate the formation of antitrifluoroacetylated protein antibodies. In this regard, sevoflurane differs from halothane, enflurane, isoflurane, and desflurane, all of which are metabolized to reactive acyl halide intermediates with the potential to produce hepatotoxicity as well as cross-sensitivity between drugs.²³ Sevoflurane is the least likely volatile anesthetic to form carbon monoxide on exposure to carbon dioxide absorbents. In contrast to other volatile anesthetics, sevoflurane breaks down in the presence of the strong bases present in carbon dioxide absorbents to form compounds that are toxic in animals (**Figure 4.5**).⁵ The principal degradation product is fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl-ether (compound A). Although nephrotoxic in animal studies, the levels of these compounds (principally compound A) that occur during administration of sevoflurane to patients are far below speculated toxic levels, even when total gas flows are 1 L per minute.^{23,24}

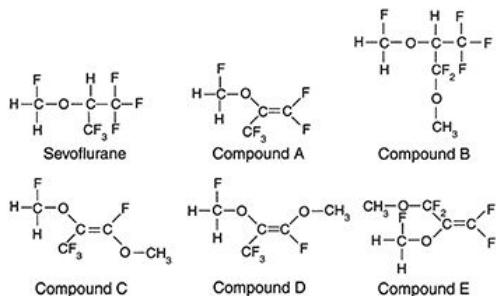

FIGURE 4.5 Degradation products of sevoflurane on exposure to soda lime. The formation of these degradation products is increased under experimental conditions in which the soda lime is heated to $\geq 65^{\circ}\text{C}$.

Xenon

Xenon is an inert gas with many of the characteristics considered important for an ideal inhaled anesthetic.⁷ The MAC is 63% to 71% in humans, suggesting that this gas is more potent than nitrous oxide (MAC 104%).²⁵ The MAC-awake for xenon is 33%.²⁶ Unlike MAC for other volatile anesthetics, there is evidence that xenon MAC is gender dependent, being less in females.²⁷ Xenon is nonexplosive, odorless, and chemically inert as reflected by absence of metabolism and low toxicity. Unlike other inhaled anesthetics, it is not harmful to the environment because it is prepared by fractional distillation of the atmospheric air. To date, its high cost has hindered its acceptance in anesthesia practice. This disadvantage may be offset to some degree by using low fresh gas flow rates and development of a xenon-recycling system. Nevertheless, even if cost considerations can be negated, acceptance of xenon as a replacement for current inhaled anesthetics (that also share many of the same advantages of xenon) would be based more on evidence of special properties or that morbidity and mortality is considerably less when this drug is administered during anesthesia.⁷

Xenon has a blood:gas partition coefficient of 0.115, which is lower than that of other clinically useful anesthetics and even lower than that of nitrous oxide (0.46), sevoflurane (0.69), and desflurane (0.42). Like nitrous oxide, xenon anesthesia results in gas exchange conditions that favor air bubble expansion, which could worsen neurologic injury from venous air embolism.²⁸ Diffusion of xenon into highly compliant bowel occurs but is less compared with nitrous oxide (**Figure 4.6**).²⁹ It is possible this minimal effect on bowel may be different when xenon diffuses into less compliant cavities as represented by pneumothorax, pneumoperitoneum, and pneumopericardium. Xenon does not trigger malignant hyperthermia in susceptible swine.³⁰ Emergence from xenon anesthesia, regardless of the duration of anesthesia, is 2 to 3 times faster than that from equal-MAC nitrous oxide plus isoflurane or sevoflurane.³¹ Xenon is a potent hypnotic and analgesic, resulting in suppression of hemodynamic and catecholamine responses to surgical stimulation. Unlike other inhaled and injected anesthetics, xenon does not produce hemodynamic depression in healthy

adults. Neuromuscular-blocking effects of rocuronium are not different when given during propofol versus xenon anesthesia.³² A risk of recall would seem to be present but has not been observed in small numbers of patients. Like ketamine, xenon exerts antagonist effects at *N*-methyl-D-aspartate (NMDA) subtypes of glutamate receptors, which have been shown to have both neuroprotective and neurotoxic properties. Xenon is unique among known NMDA antagonists in exhibiting neuroprotection without coexisting psychotomimetic behavioral changes perhaps because it does not stimulate dopamine release from the nucleus accumbens.³³ The reason why ketamine and nitrous oxide, but not xenon, produce neurotoxicity may reflect actions on dopaminergic pathways that do not occur in the presence of xenon.

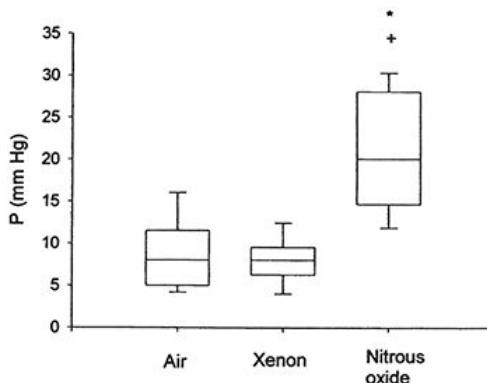

FIGURE 4.6 Pressures in obstructed bowel segments after 4 hours of air or anesthesia administration. After 4 hours of anesthesia, intraluminal pressures were significantly higher in the presence of nitrous oxide. Diffusion of xenon and nitrous oxide into the bowel. Anesthesiology. 2001;94(3):475-477. Copyright © 2001 American Society of Anesthesiologists, Inc.

Pharmacokinetics of Inhaled Anesthetics

The pharmacokinetics of inhaled anesthetics describes their (1) absorption (uptake) from alveoli into pulmonary capillary blood, (2) distribution in the body, (3) metabolism, and (4) elimination, principally via the lungs. The pharmacokinetics of volatile anesthetics may be influenced by aging, reflecting decreases in lean body mass and increases in body fat.³⁴ The volume of distribution of the central compartment (plasma volume) is smaller, whereas the apparent volume of distribution (steady state) for these drugs in the elderly is larger, especially for those anesthetics most soluble in fat. In addition, impaired pulmonary gas exchange may decrease anesthetic clearance with age. Furthermore, reduced cardiac output in the elderly decreases tissue perfusion, increases time constants, and may be associated with an altered regional distribution of anesthetics.

A series of partial pressure gradients beginning at the anesthetic machine serve to propel the inhaled anesthetic across various barriers (alveoli, capillaries, cell membranes) to their sites of action in the CNS. The principal objective of inhalation anesthesia is to achieve a constant and optimal brain partial pressure of the inhaled anesthetic.

The brain and all other tissues equilibrate with the partial pressures of inhaled anesthetics delivered to them by arterial blood (P_a). Likewise, arterial blood equilibrates with the alveolar partial pressures (P_A) of anesthetics. This emphasizes that the P_A of inhaled anesthetics mirrors the brain partial pressure (P_{BRAIN}) at steady state. This is the reason that P_A is used as an index of (1) depth of anesthesia, (2) recovery from anesthesia, and (3) anesthetic equal potency (MAC). It is important to recognize that equilibration between the two phases means the same partial pressure exists in both phases. Equilibration does not mean equality of concentrations in two biophases. Understanding those factors that determine the P_A and thus the P_{BRAIN} permits control of the doses of inhaled anesthetics delivered to the brain to maintain a constant and optimal depth of anesthesia. This relationship is applicable because volatile anesthetics are only minimally metabolized and as such are excreted from the lung. The availability of an “online” readout of end-tidal

partial pressure, which at equilibrium matches brain partial pressure, makes volatile anesthetic dosing easier than intravenous anesthetic dosing.

Determinants of Alveolar Partial Pressure

The PA and ultimately the P_{BRAIN} of inhaled anesthetics are determined by input (delivery) into alveoli minus uptake (loss) of the drug from alveoli into arterial blood ([Table 4.2](#)). Input of anesthetics into alveoli depends on the (1) inhaled partial pressure (PI), (2) alveolar ventilation, and (3) characteristics of the anesthetic breathing (delivery) system. Uptake of inhaled anesthetics from alveoli into the pulmonary capillary blood depends on (1) solubility of the anesthetic in body tissues, (2) cardiac output, and (3) alveolar-to-venous partial pressure differences (A-vD).

Inhaled Partial Pressure

A high PI delivered from the anesthetic machine is required during initial administration of the anesthetic. A high initial input offsets the impact of uptake, accelerating induction of anesthesia as reflected by the rate of rise in the PA and thus the P_{BRAIN} . With time, as uptake into the blood decreases, the PI should be decreased to match the decreased anesthetic uptake and therefore maintain a constant and optimal P_{BRAIN} . If the PI is maintained constant with time, the PA and P_{BRAIN} will increase progressively as uptake diminishes.

Concentration Effect

The impact of PI on the rate of rise of the PA of an inhaled anesthetic is known as the **concentration effect** ([Figure 4.7](#)).³⁵ The concentration effect states that the higher the PI, the more rapidly the PA approaches the PI. The higher PI provides anesthetic molecule input to offset uptake and thus speeds the rate at which the PA increases.

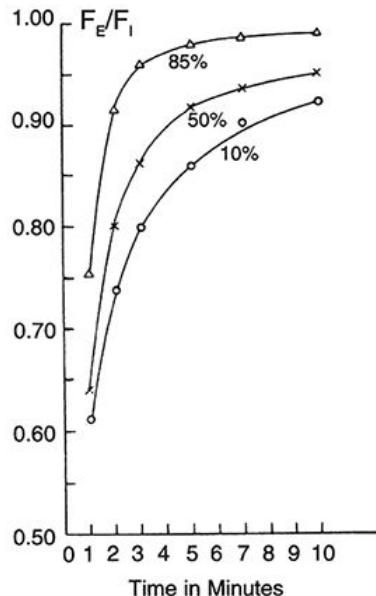

FIGURE 4.7 The impact of the inhaled concentration of an anesthetic on the rate at which the alveolar concentration increases toward the inspired (F_E/F_I) is known as the *concentration effect*. Reprinted with permission from Eger EI. Effect of inspired anesthetic concentration on the rate of rise of alveolar concentration. Anesthesiology. 1963;24(2):153-157. Copyright © 1963 American Society of Anesthesiologists, Inc.

The concentration effect results from (1) a concentrating effect and (2) an augmentation of tracheal inflow.³⁶ The concentrating effect reflects concentration of the inhaled anesthetic in a smaller lung volume due to uptake of all gases in the lung. At the same time, anesthetic input via tracheal inflow is increased to fill the space (void) produced by uptake of gases.

Second-Gas Effect

The second-gas effect reflects the ability of high-volume uptake of one gas (first gas) to accelerate the rate of increase of the PA of a concurrently administered “companion” gas (second gas) (Figure 4.8).³⁷ For example, the initial large-volume uptake of nitrous oxide accelerates the uptake of companion (second) gases such as oxygen and volatile anesthetics. This increased uptake of the second gas reflects increased tracheal inflow of all the inhaled gases (first and second gases) and higher concentration of the second gas or gases in a smaller lung volume (concentrating effect) due to the high-volume uptake of the first gas (Figure 4.9).³⁶ Conceptually, the loss of lung volume may be compensated for by decreased expired ventilation as well as increased inspired ventilation (increased tracheal inflow). The implication that extra gas is routinely drawn into the lungs to compensate for loss of lung volume is misleading if compensatory changes include decreased expired ventilation and/or a decrease in lung volume.³⁸

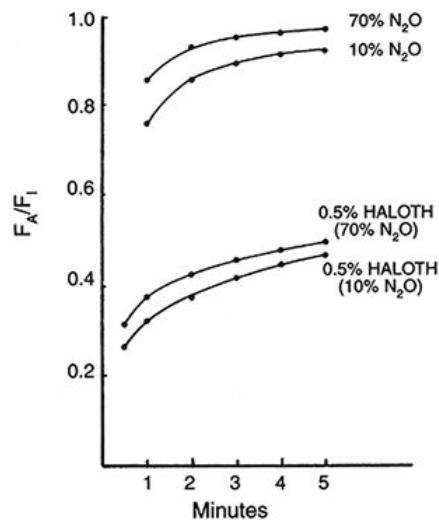

FIGURE 4.8 The second-gas effect is the accelerated increase in the alveolar concentration of a second gas, halothane (HALOTH), toward the inspired (F_A/F_I) in the presence of a high inhaled concentration of the first gas (nitrous oxide [N_2O]). Alveolar Ventilation

Increased alveolar ventilation, like PI, promotes input of anesthetics to offset uptake. The net effect is a more rapid rate of increase in the PA toward the PI and thus induction of anesthesia. In addition to the increased input, the decreased P_{CO_2} produced by hyperventilation of the lungs decreases cerebral blood flow (CBF). Conceivably, the impact of increased input on the rate of rise of the PA would be offset by decreased delivery of anesthetic to the brain. Decreased alveolar ventilation decreases input and thus slows the establishment of a PA and P_{BRAIN} necessary for the induction of anesthesia. The greater the alveolar ventilation to functional residual capacity (FRC) ratio, the more rapid is the rate of increase in the PA. In neonates, this ratio is approximately 5:1 compared with only 1.5:1 in adults, reflecting the greater metabolic rate in neonates compared with adults. As a result, the rate of increase of PA toward the PI and thus the induction of anesthesia is more rapid in neonates than in adults (Figure 4.10).³⁹

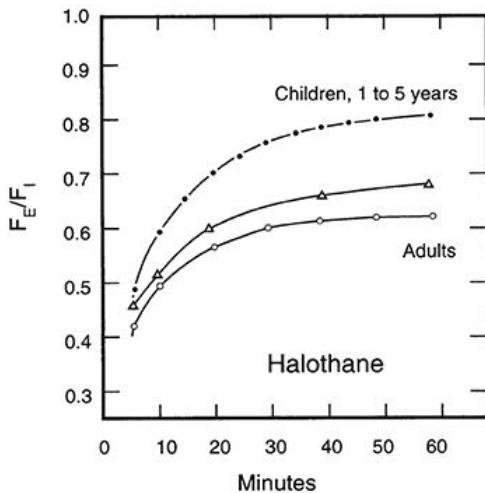

FIGURE 4.10 The rate at which the alveolar concentration (F_E) increases toward the inspired (F_I) for halothane (HALO 0.5%) in children 1 to 5 years of age is more rapid than in adults. *Reprinted with permission from Salanitre E, Rackow H. The pulmonary exchange of nitrous oxide and halothane in infants and children. Anesthesiology. 1969;30(4):388-394. Copyright © 1969 American Society of Anesthesiologists, Inc.*

Spontaneous Versus Mechanical Ventilation

Inhaled anesthetics influence their own uptake by virtue of dose-dependent depressant effects on alveolar ventilation. This, in effect, is a negative feedback protective mechanism that prevents establishment of an excessive depth of anesthesia (delivery of anesthesia is decreased when ventilation is decreased) when a high PI is administered during spontaneous breathing (Figure 4.11).⁴⁰ As anesthetic input decreases in parallel with decreased ventilation, anesthetic present in tissues is redistributed from tissues in which it is present in high concentrations (brain) to other tissues in which it is present in low concentrations (skeletal muscles). When the concentration (partial pressure) in the brain decreases to a certain threshold, ventilation increases and delivery of the anesthetic to the lungs increases. This protective mechanism against development of an excessive depth of anesthesia (anesthetic overdose) is lost when mechanical ventilation of the lungs replaces spontaneous breathing.

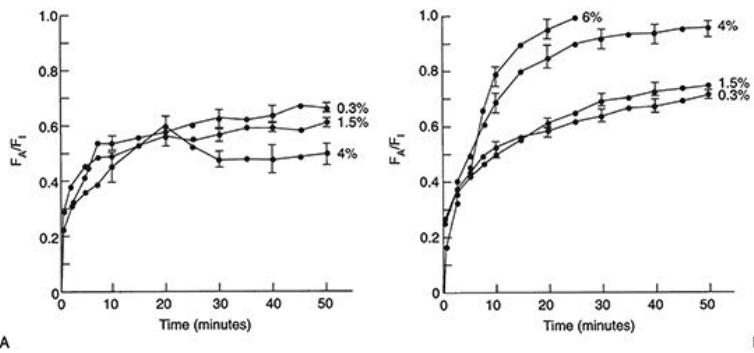

FIGURE 4.11 Effect of the mode of ventilation on the rate of increase of the alveolar concentration (F_A) of halothane toward the inspired concentration (F_I) as determined in an animal model. Negative feedback inhibition of spontaneous ventilation (A) limits the F_A/F_I to 0.6 for all the inspired concentrations of halothane. The positive feedback effect of controlled ventilation (B) results in ratios of the F_A/F_I that approach 1.0 and excessive depressant effects of halothane on the cardiovascular system at the higher inspired concentrations of the anesthetic. (Data are mean \pm standard deviation.) *Reprinted with permission from Gibbons RT, Steffey EP, Eger EI. The effect of spontaneous versus controlled ventilation on the rate of*

rise of the alveolar halothane concentration in dogs. Anest Analg. 1977;56(1):32-34. Copyright © 1977 International Anesthesia Research Society.

Impact of Solubility

The impact of changes in alveolar ventilation on the rate of increase in the PA toward the PI depends on the solubility of the anesthetic in blood. For example, changes in alveolar ventilation influence the rate of increase of the PA of a soluble anesthetic (halothane, isoflurane) more than a poorly soluble anesthetic (nitrous oxide, desflurane, sevoflurane). Indeed, the rate of increase in the PA of nitrous oxide is rapid regardless of the alveolar ventilation. This occurs because uptake of nitrous oxide is limited because of its poor solubility in blood. Conversely, uptake of a more blood-soluble anesthetic is larger, and increasing alveolar ventilation will accelerate the rate at which the PA of the soluble anesthetic approaches the PI. This emphasizes that changing from spontaneous breathing to mechanical (controlled) ventilation of the lungs, which also is likely to be associated with increased alveolar ventilation, will probably increase the depth of anesthesia (PA) produced by a more blood-soluble anesthetic.

Anesthetic Breathing System

Characteristics of the anesthetic breathing system that influence the rate of increase of the PA are the (1) volume of the external breathing system, (2) solubility of the inhaled anesthetics in the rubber or plastic components of the breathing system, and (3) gas inflow from the anesthetic machine. The volume of the anesthetic breathing system acts as a buffer to slow achievement of the PA. High gas inflow rates (5-10 L per minute) from the anesthetic machine negate this buffer effect. Solubility of inhaled anesthetics in the components of the anesthetic breathing system initially slows the rate at which the PA increases. At the conclusion of the administration of an anesthetic, however, reversal of the partial pressure gradient in the anesthetic breathing system results in elution of the anesthetic, which slows the rate at which the PA decreases.

Solubility

The solubility of the inhaled anesthetics in blood and tissues is denoted by the partition coefficient ([Table 4.3](#)).¹⁴¹ A partition coefficient is a distribution ratio describing how the inhaled anesthetic distributes itself between two phases at equilibrium (partial pressures equal in both phases). For example, a blood:gas partition coefficient of 0.5 means that the concentration of inhaled anesthetic in the blood is half that present in the alveolar gases when the partial pressures of the anesthetic in these two phases is identical. Similarly, a brain:blood partition coefficient of 2 indicates a concentration of anesthetic in the brain is twice that in the blood when the partial pressures of anesthetic are identical at both sites.

TABLE 4.3

Comparative solubilities of inhaled anesthetics^a

	Blood:gas partition coefficient	Brain:blood partition coefficient	Muscle:blood partition coefficient	Fat:blood partition coefficient	Oil:gas partition coefficient
Soluble					
Methoxyflurane	12	2	1.3	48.8	970
Intermediately soluble					
Halothane	2.54	1.9	3.4	51.1	224
Enflurane	1.90	1.5	1.7	36.2	98
Isoflurane	1.46	1.6	2.9	44.9	98
Poorly soluble					
Nitrous oxide	0.46	1.1	1.2	2.3	1.4
Desflurane	0.42	1.3	2.0	27.2	18.7

Sevoflurane	0.69	1.7	3.1	47.5	55
Xenon	0.115

Partition coefficients may be thought of as reflecting the relative capacity of each phase to accept anesthetic. Partition coefficients are temperature dependent such that the solubility of a gas in a liquid is decreased when the temperature of the liquid increases.

Blood:Gas Partition Coefficients

The rate of increase of the PA toward the PI (maintained constant by mechanical ventilation of the lungs) is inversely related to the solubility of the anesthetic in blood (see [Figure 4.3](#)).^{42,43} Based on their blood:gas partition coefficients, inhaled anesthetics are categorized traditionally as soluble, intermediately soluble, and poorly soluble (see [Table 4.3](#)).^{1,41} Blood can be considered a pharmacologically inactive reservoir, the size of which is determined by the solubility of the anesthetic in blood. When the blood:gas partition coefficient is high, a large amount of anesthetic must be dissolved in the blood before the Pa equilibrates with the PA. For example, the high blood solubility of methoxyflurane slows the rate at which the PA and Pa increase relative to the PI, and the induction of anesthesia is slow. The impact of high blood solubility on the rate of increase of the Pa can be offset to some extent by increasing the PI above that required for maintenance of anesthesia. This is termed the **overpressure** technique and may be used to speed the induction of anesthesia, recognizing that sustained delivery of a high PI will result in an anesthetic overdose.

When blood solubility is low, minimal amounts of inhaled anesthetic must be dissolved before equilibration is achieved; therefore, the rate of increase of PA and Pa, and thus onset-of-drug effects such as the induction of anesthesia, are rapid. For example, the inhalation of a constant PI of nitrous oxide, desflurane, or sevoflurane for about 10 minutes results in a PA that is $\geq 80\%$ of the PI (see [Figure 4.3](#)).^{42,43} Use of an overpressure technique with sevoflurane is more readily accepted by patients because this anesthetic is less pungent than desflurane. Indeed, one or more vital capacity breaths of high concentrations of sevoflurane (7% with 66% nitrous oxide) may result in loss of the eyelash reflex.⁴⁴

Associated with the rapid increase in the Pa of nitrous oxide is the absorption of several liters (up to 10 L during the first 10-15 minutes) of this gas, reflecting its common administration at inhaled concentrations of 60% to 70%. This high-volume absorption of nitrous oxide is responsible for several unique effects of nitrous oxide when it is administered in the presence of volatile anesthetics or air-containing cavities (see the sections “[Concentration Effect](#),” “[Second-Gas Effect](#),” and “[Nitrous Oxide Transfer to Closed Gas Spaces](#)”).

Percutaneous loss of inhaled anesthetics occurs but is too small to influence the rate of increase in the PA.⁴⁵ With the possible exception of methoxyflurane, the magnitude of metabolism of inhaled anesthetics is too small to influence the rate of increase of the PA. This lack of effect reflects the large excess of anesthetic molecules administered and the saturation, by anesthetic concentrations of inhaled drugs, of enzymes responsible for anesthetic metabolism.⁴⁶

Blood:gas partition coefficients are altered by individual variations in water, lipid, and protein content and by the hematocrit of whole blood.^{47,48} For example, blood:gas partition coefficients are about 20% less in blood with a hematocrit of 21% compared with blood with a hematocrit of 43%. Presumably, this decreased solubility reflects the decrease in lipid-dissolving sites normally provided by erythrocytes. Conceivably, decreased solubility of volatile anesthetics in anemic blood would manifest as an increased rate of increase in the PA and a more rapid induction of anesthesia. Ingestion of a fatty meal alters the composition of blood, resulting in an approximately 20% increase in the solubility of volatile anesthetics in blood.⁴⁹

The solubility of inhaled anesthetics in blood varies with age ([Figure 4.12](#)).⁵⁰ The blood solubilities of halothane, enflurane, methoxyflurane, and isoflurane are about 18% less in neonates and the elderly compared to young adults. In contrast, the solubility of the less soluble anesthetic sevoflurane (presumably also true for desflurane) is not different in neonates and adults.⁵¹

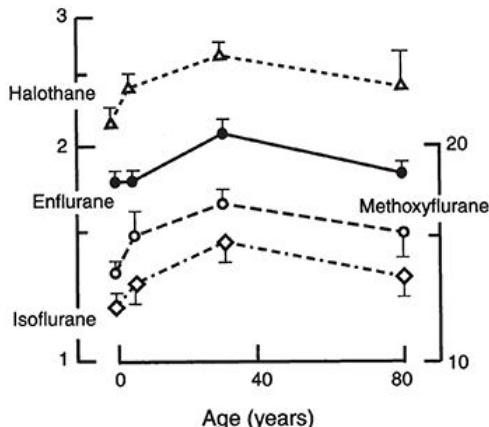

FIGURE 4.12 Blood:gas partition coefficients are 18% less in neonates compared with adults. (Data are mean \pm standard deviation.) Copyright © 1984 American Society of Anesthesiologists, Inc.

Tissue:Blood Partition Coefficients

Tissue:blood partition coefficients determine uptake of anesthetic into tissues and the time necessary for equilibration of tissues with the Pa. This time for equilibration can be estimated by calculating a time constant (amount of inhaled anesthetic that can be dissolved in the tissue divided by tissue blood flow) for each tissue. One time constant on an exponential curve represents 63% equilibration. Three time constants are equivalent to 95% equilibration. For volatile anesthetics, equilibration between the Pa and P_{BRAIN} depends on the anesthetic's blood solubility and requires 5 to 15 minutes (three time constants). Fat has an enormous capacity to hold anesthetic, and this characteristic, combined with low blood flow to this tissue, prolongs the time required to narrow anesthetic partial pressure differences between arterial blood and fat. For example, equilibration of fat with isoflurane (three time constants) based on this drug's fat:blood partition coefficient and an assumed fat blood flow of 2 to 3 mL per minute per 100 g fat is estimated to be 25 to 46 hours. Fasting before elective operations results in transport of fat to the liver, which could increase anesthetic uptake by this organ and modestly slow the rate of increase in the PA of a volatile anesthetic during induction of anesthesia.⁵²

Oil:Gas Partition Coefficients

Oil:gas partition coefficients parallel anesthetic requirements. For example, an estimated MAC can be calculated as 150 divided by the oil:gas partition coefficient. The constant, 150, is the average value of the product of oil:gas solubility and MAC for several inhaled anesthetics with widely divergent lipid solubilities. Using this constant, the calculated MAC for a theoretical anesthetic with an oil:gas partition coefficient of 100 would be 1.5%.

Nitrous Oxide Transfer to Closed Gas Spaces

As discussed earlier, one downside of using nitrous oxide is that it has the capacity to accumulate in closed spaces where it can cause damage by increasing pressure. The blood:gas partition coefficient of nitrous oxide (0.46) is about 34 times greater than that of nitrogen (0.014). This differential solubility means that nitrous oxide can leave the blood to enter an air-filled cavity 34 times more rapidly than nitrogen can leave the cavity to enter blood. As a result of this preferential transfer of nitrous oxide, the volume or pressure of an air-filled cavity increases. Passage of nitrous oxide into an air-filled cavity surrounded by a compliant wall (intestinal gas, pneumothorax, pulmonary blebs, air bubbles) causes the gas space to expand ([Figure 4.13](#)).⁵³ Conversely, passage of nitrous oxide into an air-filled cavity surrounded by a noncompliant wall (middle ear, cerebral ventricles, supratentorial space) causes an increase in intracavitary pressure.

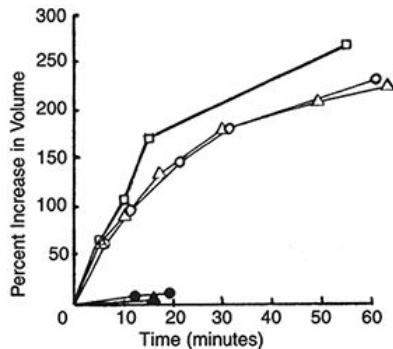

FIGURE 4.13 Inhalation of 75% nitrous oxide rapidly increases the volume of a pneumothorax (open symbols). Inhalation of oxygen (solid symbols) does not alter the volume of the pneumothorax. *Reprinted with permission from Eger EI II, Saidman LJ. Hazards of nitrous oxide anesthesia in bowel obstruction and pneumothorax. Anesthesiology. 1965;26(1):61-66. Copyright © 1965 American Society of Anesthesiologists, Inc.*

The magnitude of volume or pressure increase is influenced by (1) partial pressure of nitrous oxide, (2) blood flow to the air-filled cavity, and (3) duration of nitrous oxide administration. In an animal model, the inhalation of 75% nitrous oxide doubles the volume of a pneumothorax in 10 minutes.⁵³ The finding emphasizes the high blood flow to this area. Likewise, air bubbles (emboli) expand rapidly when exposed to nitrous oxide (Figure 4.14).⁵⁴ Nevertheless, in neurosurgical patients operated on in the sitting position, 50% nitrous oxide has no measurable effect on the incidence or severity of venous air embolism if its administration is discontinued immediately upon Doppler detection of venous air embolism.⁵⁵ In contrast to the rapid expansion of a pneumothorax, the increase in bowel gas volume produced by nitrous oxide is slow but can result in an increase in distention and postoperative pain after a 3-hour surgery.

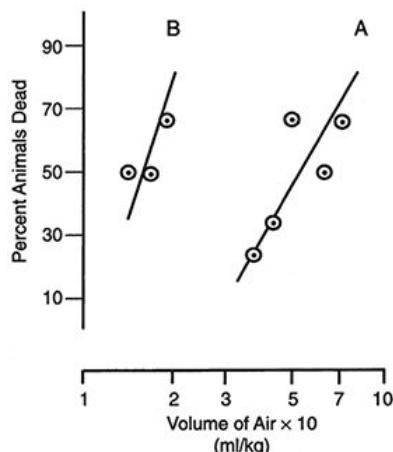

FIGURE 4.14 Nitrous oxide rapidly expands air bubbles as reflected by the volume of injected air necessary to produce 50% mortality in animals breathing nitrous oxide (0.16 mL/kg) (A) compared with animals breathing oxygen (0.55 mL/kg) (B). *Reprinted with permission from Munson ES, Merrick HC. Effect of nitrous oxide on venous air embolism. Anesthesiology. 1966;27(6):783-787. Copyright © 1966 American Society of Anesthesiologists, Inc.*

The middle ear is an air-filled cavity that vents passively via the Eustachian tube when pressure reaches 20 to 30 cm H₂O. Nitrous oxide diffuses into the middle ear more rapidly than nitrogen leaves, and middle ear pressures may increase if Eustachian tube patency is compromised by inflammation or edema. Indeed, tympanic membrane rupture has been attributed to this mechanism after administration of nitrous oxide. Negative middle ear pressures may develop after discontinuation of nitrous oxide, leading to serous otitis.

Nausea and vomiting that may follow general anesthesia may be due to multiple mechanisms, but the role of altered middle ear pressures as a result of nitrous oxide is a consideration.

Intraocular gas bubbles as used for internal retinal tamponade (retinal detachment, macular hole repair, complicated vitrectomy) may persist in the eye for up to 10 weeks following ocular surgery. Administration of nitrous oxide for periods as brief as 1 hour during this time period may result in rapid increases in the volume of intraocular gas within the rigid closed eye that is sufficient to compress the retinal artery with resulting visual loss.⁵⁶

Cardiopulmonary Bypass

Cardiopulmonary bypass produces changes in blood-gas solubility that depend on the constituents of the priming solution and temperature.⁵⁷ Nevertheless, the overall effect of hypothermic cardiopulmonary bypass and a crystalloid prime on blood-gas solubility is only 2%. Volatile anesthetics initiated during cardiopulmonary bypass take longer to equilibrate, whereas the same drugs already present when cardiopulmonary bypass is initiated are diluted, potentially decreasing the depth of anesthesia.

Cardiac Output

Cardiac output (pulmonary blood flow) influences uptake and therefore PA by carrying away either more or less anesthetic from the alveoli. An increased cardiac output results in more rapid uptake, so the rate of increase in the PA and thus the induction of anesthesia are slowed. A decreased cardiac output speeds the rate of increase of the PA because there is less uptake to oppose input.

The effect of cardiac output on the rate of increase in the PA may seem paradoxical. For example, the uptake of more drugs by an increased cardiac output should speed the rate of increase of partial pressures in tissues and thus narrow the A-vD for anesthetics. Indeed, an increase in cardiac output does hasten equilibration of tissue anesthetic partial pressures with the Pa. Nevertheless, the Pa is lower than it would be if cardiac output were normal. Conceptually, a change in cardiac output is analogous to the effect of a change in solubility. For example, doubling cardiac output increases the capacity of blood to hold anesthetic, just as solubility increases the capacity of the same volume of blood.

As with alveolar ventilation, changes in cardiac output most influence the rate of increase of the PA of a soluble anesthetic. Conversely, the rate of increase of the PA of a poorly soluble anesthetic, such as nitrous oxide, is rapid regardless of physiologic deviations of the cardiac output around its normal value. As a result, changes in cardiac output exert little influence on the rate of increase of the PA of nitrous oxide. In contrast, doubling the cardiac output will greatly increase the uptake of soluble anesthetic from alveoli, slowing the rate of increase of the PA. Conversely, a low cardiac output, as with shock, could produce an unexpectedly high PA of a soluble anesthetic.

Volatile anesthetics that depress cardiac output can exert a positive feedback response that contrasts with the negative (protective) feedback response on spontaneous breathing exerted by these drugs. For example, decreases in cardiac output due to an excessive dose of volatile anesthetic results in an increase in the PA, which further increases anesthetic depth and thus cardiac depression. The administration of a volatile anesthetic that depresses cardiac output, plus controlled ventilation of the lungs, results in a situation characterized by unopposed input of anesthetic via alveolar ventilation combined with decreased uptake because of decreased cardiac output. The net effect of this combination of events can be an unexpected, abrupt increase in the PA and an excessive depth of anesthesia.

Distribution of cardiac output will influence the rate of increase of the PA of an anesthetic. For example, increases in cardiac output are not necessarily accompanied by proportional increases in blood flow to all tissues. Preferential perfusion of vessel-rich group tissues when the cardiac output increases results in a more rapid increase in the PA of anesthetic than would occur if the increased cardiac output was distributed equally to all tissues. Indeed, infants have a relatively greater perfusion of vessel-rich group tissues than do adults and, consequently, show a faster rate of increase of the PA toward the PI (see [Figure 4.10](#)).³⁹

Impact of a Shunt

In the absence of an intracardiac or intrapulmonary right-to-left shunt, it is valid to assume that the Pa and Pa_a of inhaled anesthetics are essentially identical. When a right-to-left shunt is present, the diluting effect of the shunted blood on the partial pressure of anesthetic in blood coming from ventilated alveoli results in a decrease in the Pa and a slowing in the induction of anesthesia. Monitoring the end-tidal concentration of anesthetic or carbon dioxide reveals a gradient between the PA and Pa in which the PA underestimates the Pa. A similar mechanism is responsible for the decrease in PaO₂ and the gradient between the PA and Pa in the presence of a right-to-left shunt.

The relative impact of a right-to-left shunt on the rate of increase in the Pa depends on the solubility of the anesthetic. For example, a right-to-left shunt slows the rate of increase of the Pa of a poorly soluble anesthetic more than that of a soluble anesthetic.⁵⁸ This occurs because uptake of a soluble anesthetic offsets dilutional effects of shunted blood on the Pa. Uptake of a poorly soluble drug is minimal, and dilutional effects on the Pa are relatively unopposed. This impact of solubility in the presence of a right-to-left shunt is opposite to that observed with changes in cardiac output and alveolar ventilation. All factors considered, it seems unlikely that a right-to-left shunt alone will alter the speed of induction of anesthesia significantly.

Left-to-right tissue shunts (arteriovenous fistulas, volatile anesthetic-induced increases in cutaneous blood flow) result in delivery to the lungs of blood containing a higher partial pressure of anesthetic than that present in blood that has passed through tissues. As a result, left-to-right shunts offset the dilutional effects of a right-to-left shunt on the Pa. Indeed, the effect of a left-to-right shunt on the rate of increase in the Pa is detectable only if there is a concomitant presence of a right-to-left shunt. Likewise, the effect of a right-to-left shunt on the rate of increase in the PA is maximal in the absence of a left-to-right shunt.

Alveolar-to-Venous Partial Pressure Differences

The A-vD reflects tissue uptake of the inhaled anesthetic. Tissue uptake affects uptake at the lung by controlling the rate of increase of the mixed venous partial pressure of anesthetic. Factors that determine the fraction of anesthetic removed from blood traversing a tissue parallel those factors that determine uptake at the lungs (tissue solubility, tissue blood flow, and arterial-to-tissue partial pressure differences).

Highly perfused tissues (brain, heart, kidneys) in the adult account for <10% of body mass but receive 75% of the cardiac output (**Table 4.4**). As a result of the small mass and high blood flow, these tissues, known as **vessel-rich group tissues**, equilibrate rapidly with the Pa. Indeed, after about three time constants, approximately 75% of the returning venous blood is at the same partial pressure as the PA. For this reason, uptake of a volatile anesthetic is decreased greatly after three time constants (5-15 minutes, depending on the blood solubility of the inhaled anesthetic), as reflected by a narrowing of the inspired-to-alveolar partial pressure difference. Continued uptake of anesthetic after saturation of vessel-rich group tissues reflects principally the entrance of anesthetic into skeletal muscles and fat. Skeletal muscles and fat represent about 70% of the body mass but receive only about 25% of the cardiac output (see **Table 4.4**). As a result of the large tissue mass, sustained tissue uptake of the inhaled anesthetic continues and the effluent venous blood is at a lower partial pressure than the PA. For this reason, the A-vD difference for anesthetic is maintained and uptake from the lungs continues, even after several hours of continuous administration of inhaled anesthetics.

TABLE 4.4

Body tissue composition

	Body mass (% of 70-kg adult)	Blood flow (% of cardiac output)
Vessel-rich group	10	75
Muscle group	50	19
Fat group	20	6
Vessel-poor group	20	<1

The time for equilibration of vessel-rich group tissues is more rapid for neonates and infants than for adults. This difference reflects the greater cardiac output to vessel-rich group tissues in the very young as well

as decreased solubility of anesthetics in the tissues of neonates. Furthermore, skeletal muscle bulk comprises a small fraction of body weight in neonates and infants.

Recovery From Anesthesia

Recovery from anesthesia is depicted by the rate of decrease in the P_{BRAIN} as reflected by the PA (Figure 4.15).^{42,43} The rate of washout of anesthetic from the brain should be rapid because inhaled anesthetics are not highly soluble in brain and the brain receives a large fraction of the cardiac output. Although similarities exist between the rate of induction and recovery, as reflected by changes in the PA of the inhaled anesthetic, there are important differences between the two events. In contrast to induction of anesthesia, which may be accelerated by the concentration effect, it is not possible to speed the decrease in PA by this mechanism (you cannot administer less than zero). Furthermore, at the conclusion of every anesthetic, the concentration of the inhaled anesthetic in tissues depends highly on the solubility of the inhaled drug and the duration of its administration. This contrasts with tissue concentrations of zero at the initiation of induction of anesthesia. The failure of certain tissues to reach equilibrium with the PA of the inhaled anesthetic during maintenance of anesthesia means that the rate of decrease of the PA during recovery from anesthesia will be more rapid than the rate of increase of the PA during induction of anesthesia (see Figures 4.3 and 4.15).^{42,43} Indeed, even after a prolonged anesthetic, skeletal muscles probably, and fat almost certainly, will not have equilibrated with the PA of the inhaled anesthetic. Thus, when the PI of an anesthetic is abruptly decreased to zero at the conclusion of an anesthetic, these tissues initially cannot contribute to the transfer of drug back to blood for delivery to the liver for metabolism or to the lungs for exhalation. As long as gradients exist between the Pa and tissues, the tissues will continue to take up anesthetic. Thus, during recovery from anesthesia, the continued passage of anesthetic from blood to tissues, such as fat, acts to speed the rate of decrease in the PA of that anesthetic. Continued tissue uptake of anesthetic will depend on the solubility of the inhaled anesthetic and the duration of anesthesia, with the impact being most important with soluble anesthetics.⁵⁹ For example, time to recovery is prolonged in proportion to the duration of anesthesia for soluble anesthetics (halothane and isoflurane), whereas the impact of duration of administration on time to recovery is minimal with poorly soluble anesthetics (sevoflurane and desflurane) (Figure 4.16).¹ The importance of these differences depend on the context of the administration, thus called context-sensitive half-time.

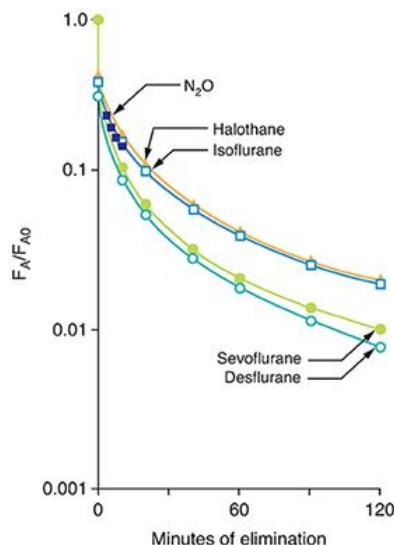

FIGURE 4.15 Elimination of inhaled anesthetics is defined as the ratio of the end-tidal anesthetic concentration (F_A) to the F_A immediately before the beginning of elimination (F_{AO}). The rate of decrease (awakening from anesthesia) in the F_A/F_{AO} is most rapid with the anesthetics that are least soluble in blood (nitrous oxide [N_2O], desflurane, sevoflurane). *Reprinted with permission from Yasuda N, Lockhart SH, Eger*

EI, et al. Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth Analg. 1991;72(3):316-324. Copyright © 1991 International Anesthesia Research Society.

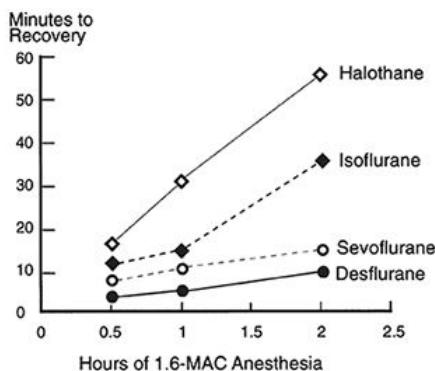

FIGURE 4.16 An increase in the duration of anesthesia during a constant dose of anesthetic (1.6 MAC) is associated with increases in the time to recovery (motor coordination in an animal model), with the greatest increases occurring with the most blood-soluble anesthetics. *Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.*

Anesthetic that has been absorbed into the components of the anesthetic breathing system will pass from the components back into the gases of the breathing circuit at the conclusion of anesthesia and retard the rate of decrease in the PA of the anesthetic. Likewise, exhaled gases of the patient contain anesthetic that will be rebreathed unless fresh gas flow rates are increased (at least 5 L per minute of oxygen) at the conclusion of anesthesia.

Context-Sensitive Half-Time

The pharmacokinetics of the elimination of inhaled anesthetics depends on the length of administration and the blood-gas solubility of the inhaled anesthetic. As with injected anesthetics, it is possible to use computer simulations to determine context-sensitive half-times for volatile anesthetics.⁶⁰ For example, [Figure 4.17](#) shows the times for decrements in the vessel-rich group of 80%, 88%, 90%, 92%, and 95% for isoflurane, sevoflurane, and desflurane. The figures provide mathematical quantification of two obvious clinical observations. First, recovery is always fastest for desflurane, the most insoluble anesthetic, and always slowest for isoflurane, the most soluble anesthetic. Second, the greater the percentage decrease required for anesthesia, the longer duration required for recovery from anesthetic.

However, [Figure 4.17](#) provides more detailed insight as well. A typical anesthetic might require 90% decrease in inhaled concentration after maintaining 1 MAC. This is the decrement in [Figure 4.17C](#). If the anesthetic is about 30 minutes' duration, then there will be no difference in recovery time between desflurane, sevoflurane, or isoflurane. This makes it clear why the argument that desflurane has an advantage in short procedures is nonsense. Any of the three volatile anesthetics will provide a faster recovery. Indeed, one has to get to an anesthetic of about 2 hours to see an appreciable benefit of desflurane over sevoflurane. (As discussed in the section that follows, one has to weigh the benefit of a few minutes faster recovery against the consequential greenhouse gas contribution of desflurane.) [Figure 4.17C](#) provides guidance on how to administer sevoflurane and get a rapid recovery: Turn it off early! If the anesthetic is 3 to 4 hours' duration, then about 30 minutes before the end of the case, turn off sevoflurane and replace it with 70% nitrous oxide. This will give the sevoflurane adequate time to decrease 90%, ensuring rapid recovery once the nitrous is discontinued at the end of surgery.

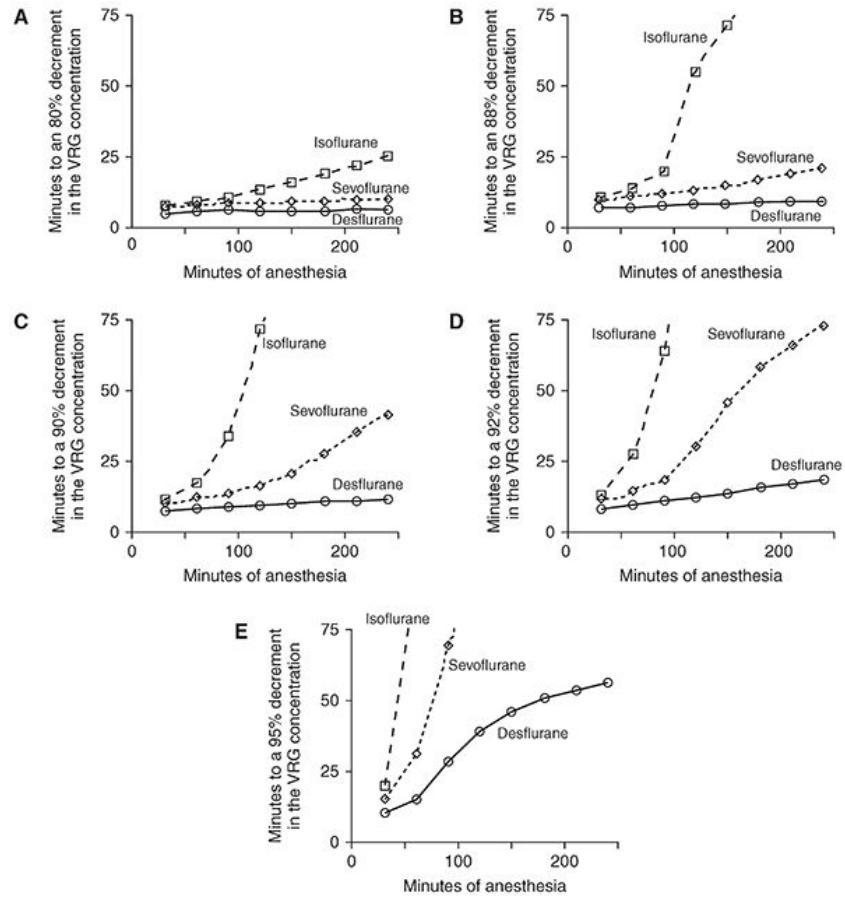

FIGURE 4.17 Graphs A, B, C, D, and E show the times required for decrements in the vessel-rich group (VRG) concentration of inhaled anesthetic of 80%, 88%, 90%, 92%, and 95%, respectively. As can be seen by comparing the individual graphs, the decrement times can become exceptionally long if a large decrement in anesthetic concentration is required to awaken from anesthesia. This quantifies the obvious clinical observation that rapid emergence is facilitated by administering the lowest concentration of an inhaled anesthetic necessary to maintain unconsciousness. *Reprinted with permission from Eger EI II, Shafer SL. Tutorial: context-sensitive decrement times for inhaled anesthetics. Anesth Analg. 2005;101(3):688-696. Copyright © 2005 International Anesthesia Research Society.*

In this regard, the time needed for a 50% decrease in anesthetic concentration of enflurane, isoflurane, desflurane, and sevoflurane is <5 minutes and does not increase significantly with increasing duration of anesthesia.⁶¹ Presumably, this is a reflection of the initial phase of elimination, which is primarily a function of alveolar ventilation. Determination of other decrement times (80% and 90%) reveals differences between various inhaled anesthetics. For example, the 80% decrement times of desflurane and sevoflurane are <8 minutes and do not increase significantly with the duration of anesthesia, whereas 80% decrement times for enflurane and isoflurane increase significantly after about 60 minutes, reaching plateaus of approximately 30 to 35 minutes. The 90% decrement time of desflurane increases slightly from 5 minutes after 30 minutes of anesthesia to 14 minutes after 6 hours of anesthesia, which is significantly less than sevoflurane (65 minutes), isoflurane (86 minutes), and enflurane (100 minutes) after 6 hours of administration. Based on the simulated context-sensitive half-times and assuming that MAC-awake is 0.5 MAC, there would be little difference in recovery time among these volatile anesthetics when a pure inhalation anesthetic technique is used. The major differences in the rates at which desflurane, sevoflurane, isoflurane, and enflurane are eliminated occur in the final 20% of the elimination process.

Diffusion Hypoxia

Diffusion hypoxia occurs when inhalation of nitrous oxide is discontinued abruptly, leading to a reversal of partial pressure gradients such that nitrous oxide leaves the blood to enter alveoli.⁶² This initial high-volume outpouring of nitrous oxide from the blood into the alveoli can so dilute the PAO_2 that the PaO_2 decreases. In addition to dilution of the PAO_2 by nitrous oxide, there is also dilution of the PACO_2 , which decreases the stimulus to breathe.⁶³ This decreased stimulus to breathe exaggerates the impact on PaO_2 of the outpouring of nitrous oxide into the alveoli. Outpouring of nitrous oxide into alveoli is greatest during the first 1 to 5 minutes after its discontinuation at the conclusion of anesthesia. Thus, it is common practice to fill the lungs with oxygen at the end of anesthesia to ensure that arterial hypoxemia will not occur as a result of dilution of the PAO_2 by nitrous oxide.

Pharmacodynamics of Inhaled Anesthetics

Minimal Alveolar Concentration

The MAC of an inhaled anesthetic is defined as that concentration at 1 atm that prevents skeletal muscle movement in response to a supramaximal painful stimulus (surgical skin incision) in 50% of patients.⁶⁴ The MAC is anesthetic 50% effective dose (ED_{50}). Immobility produced by inhaled anesthetics as measured by MAC is mediated principally by effects of these drugs on the spinal cord and only a minor component of immobility results from cerebral effects.⁶⁵ For example, in animals, MAC for isoflurane is 1.2% when delivered to the intact animal but delivery of inhaled anesthetic only to the brain results in isoflurane MAC increasing to nearly 3%.⁶⁶ Further evidence that MAC reflects effects of the inhaled anesthetics at the spinal cord is the observation that decerebration does not change MAC (Figure 4.18).⁶⁷

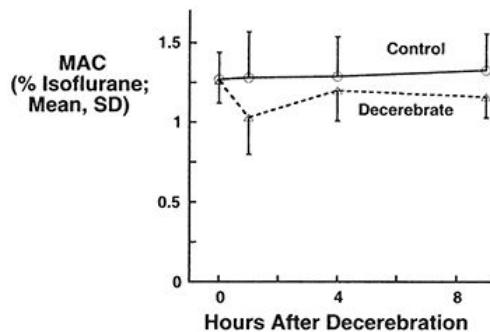

FIGURE 4.18 Decerebration does not change the minimum alveolar anesthetic concentration of isoflurane in rats confirming that the effects of volatile anesthetics on the spinal cord determine minimal alveolar concentration (MAC). Abbreviation: SD, standard deviation. Reprinted with permission from Rampil IJ, Mason P, Singh H. Anesthetic potency (MAC) is independent of forebrain structures in the rat. *Anesthesiology*. 1993;78(4):707-712. Copyright © 1993 American Society of Anesthesiologists, Inc.

The MAC is among the most useful concepts in anesthetic pharmacology as it establishes a common measure of potency (partial pressure at steady state) for inhaled anesthetics. This concept is used to provide uniformity in dosages of inhaled anesthetics, to establish relative amounts of inhaled anesthetics to reach specific endpoints (MAC-aware), and to guide the search for mechanisms responsible for mechanisms of anesthetic action.⁶⁸ A unique feature of MAC is its consistency varying only 10% to 15% among individuals. This small degree of pharmacodynamic variability for inhaled anesthetics is unique in pharmacology. The use of equally potent doses (comparable MAC) of inhaled anesthetics is mandatory for comparing effects of these drugs not only at the spinal cord but also at all other organs (Table 4.5). For example, similar MACs of inhaled anesthetics produce equivalent depression of the spinal cord, whereas effects on cardiopulmonary parameters may be different for each drug (see Chapter 2). This emphasizes that MAC represents only one point on the dose-response curve of effects produced by inhaled anesthetics and that these dose-response curves are not parallel. It is remarkable though that MAC-aware, the concentration of anesthetic that prevents

consciousness in 50% of persons, is reliably about half of MAC and that MAC-memory, the concentration of anesthetic that is associated with amnesia in 50% of patients, is significantly less than MAC-aware. If this were not the case, an ED₅₀ would not be satisfactory end point for clinical anesthesia! A surgeon may tolerate 50% of his or her patients moving but having 50% of patients have awareness under anesthesia would clearly not be acceptable.

TABLE 4.5

Comparative minimal alveolar concentration (MAC) of inhaled anesthetics

	MAC (% , 30-55 years old at 37°C, PB 760 mm Hg)
Nitrous oxide ^a	104
Halothane	0.75
Enflurane	1.63
Isoflurane	1.17
Desflurane	6.6
Sevoflurane	1.80
Xenon	63-71

Abbreviation: P_B, brain partial pressure.

^aDetermined in a hyperbaric chamber in males 21 to 55 years old.

Factors That Alter Minimal Alveolar Concentration

Inhalation anesthetic requirements are remarkably uniform in humans, mainly being affected by age and body temperature. The MAC allows a quantitative analysis of the effect, if any, of various physiologic and pharmacologic factors on anesthetic requirements ([Table 4.6](#)).⁵⁹⁻⁸¹ For example, increasing age results in a progressive decrease in MAC of about 6% per decade that is similar for all inhaled anesthetics ([Figures 4.19](#) and [4.20](#)).^{82,83} The MAC is decreased nearly 30% during pregnancy and in the early postpartum period, returning to normal values in 12 to 72 hours.^{84,85} However, the incidence of postoperative awareness is higher after cesarean section than most surgeries aside from cardiothoracic surgery. The MAC, the concentration of anesthetic required to prevent movement, is mediated predominantly by a spinal reflex.^{66,67} Although MAC is reduced in parturients, there is evidence that the concentration response in the brain is not changed. For example, the dose of volatile anesthetic required to induce the electroencephalogram (EEG) changes expected with hypnosis are not changed in pregnancy.⁸⁶ Anesthetic concentrations required to reduce awareness reflect those in the brain.

TABLE 4.6

Impact of physiologic and pharmacologic factors on minimal alveolar concentration (MAC)

Increases in MAC

Hyperthermia

Excess pheomelanin production (red hair)

Gender does not influence MAC (see [Figure 4.19](#)).^{87,88} The MAC is increased in women with natural red hair, presumably reflecting mutations of the melanocortin-1 receptor gene and increased pheomelanin concentrations (see [Figure 4.20](#)).⁸⁹ Although most reports describe MAC as independent of the duration of anesthesia, there is evidence that MAC for isoflurane decreases during the administration of anesthesia and the performance of surgery ([Figure 4.21](#)).⁹⁰ The effect of cardiopulmonary bypass on MAC is uncertain, with some studies showing a decrease, whereas others fail to demonstrate any change.⁵⁷ Despite prolongation of sleeping times in animals, cyclosporine increases rather than decreases isoflurane MAC.⁹¹ A MAC is defined by the response to a surgical incision, which is considered to be a supramaximal stimulus. The MAC values may vary with the type of stimulus; tetanic stimulation and trapezius squeeze are considered noninvasive stimulation patterns that are relatively equivalent to surgical skin incision, although in contrast to skin incision, these events can be repeated ([Figure 4.22](#)).⁹² Tracheal intubation requires the highest MAC to prevent skeletal muscle responses and may represent a true supramaximal stimulation (see [Figure 4.22](#)).⁹²

The MAC values for inhaled anesthetics are additive.⁹³ For example, 0.5 MAC of nitrous oxide plus 0.5 MAC isoflurane has the same effect at the brain as does a 1 MAC of either anesthetic alone. The strict additivity of the interactions among inhaled anesthetics implies either a common site of action or that anesthetic action occurs with only a small fraction of the binding sites occupied.⁹⁴

Opioids synergistically decrease anesthetic requirements for volatile anesthetics. For example, 25 minutes after the administration of fentanyl, 3 or 6 µg/kg intravenously (IV), MAC for desflurane is decreased 48% and 68%, respectively.⁹⁵ Similar decreases in isoflurane MAC are also produced by these doses of fentanyl.⁹⁶ The MAC values for volatile anesthetics and ED₅₀ concentrations for intravenous anesthetics are for the most part not additive but synergistic. As a general rule, drugs that act on different receptors or by different mechanisms are typically not additive.^{94,97} Dose-response curves for inhaled anesthetics, although not parallel, are all steep. This is emphasized by the fact that a 1 MAC dose prevents skeletal muscle movement in response to a painful stimulus in 50% of patients, whereas a modest increase to about 1.3 MAC prevents movement in at least 95% of patients.

Mechanisms of Anesthetic Action

Meyer-Overton Theory (Critical Volume Hypothesis)

The mechanism of volatile anesthetic action is one of the great unsolved mysteries of our time. We know quite exactly how most systemically administered drugs work, often down to the specific molecular binding sites. Volatile anesthetics have been a hard nut to crack. Various theories have held precedence over the years, but no consensus has been reached that explains the ability of volatile anesthetics to induce unconsciousness.

Correlation between the lipid solubility of inhaled anesthetics (oil:gas partition coefficient) and anesthetic potency has historically been presumed to be evidence that inhaled anesthetics act by disrupting

the structure or dynamic properties of the lipid portions of nerve membranes. For example, when a sufficient number of molecules dissolve (critical concentration) in crucial hydrophobic sites such as lipid cell membranes, there is distortion of channels necessary for ion flux and the subsequent development of action potentials needed for synaptic transmission. Likewise, changes in the lipid matrix produced by dissolved anesthetic molecules could alter the function of proteins in cell membranes, thus decreasing sodium conductance. Evidence supporting distortion of sodium channels by dissolved anesthetic molecules is the observation that high pressures (40–100 atm) partially antagonize the action of inhaled anesthetics (pressure reversal), presumably by returning (compressing) lipid membranes and their sodium channels to their “awake” contour.⁹⁸

The most compelling evidence against the Meyer-Overton theory of anesthesia is the fact that effects of inhaled anesthetics on the fluidity of lipid bilayers is implausibly small and can generally be mimicked by temperature changes of 1°C.⁹⁹ Furthermore, not all lipid-soluble drugs are anesthetics, and, in fact, some are convulsants. For example, the observation that, among *n*-alcohols, dodecanol is anesthetic and decanol is not (for *n*-alkanes the cutoff is after octane) suggests that anesthetic binding to protein pockets or clefts and not lipid membranes is important in the mechanism of anesthesia. Based on these negative observations, lipid theories have been refined to postulate that specialized domains in membranes (boundary membranes surrounding proteins) are not only particularly sensitive to anesthetics but also are critical to membrane function. Indeed, either binding to proteins or dissolving in lipids could account for the Meyer-Overton correlation.

Stereoselectivity

The effects of inhaled anesthetics on ion channels responsible for neuronal action are readily demonstrated (**Figure 4.23**).⁹⁹ The most definitive evidence that general anesthetics act by binding directly to proteins and not a lipid bilayer comes from observations of stereoselectivity.¹⁰⁰ Inhalation anesthetics exist as isomers, and isoflurane has been shown to act stereoselectively on neuronal channels, with the levoisomer being more potent than the dextroisomer in enhancing potassium conductance in neurons¹⁰¹ and in with respect to the loss of righting reflex in animals.¹⁰² The relevance to anesthetic mechanisms of the differing effects of enantiomers of volatile anesthetics on *in vitro* nerve conduction would be supported by parallel changes in MAC in the intact animal. Indeed, in rats, MAC for the levoisomer of isoflurane was 60% more potent than the dextroisomer.¹⁰³ In contrast, others have not found a significant difference in the effects of the enantiomers of isoflurane and desflurane on anesthetic effects in animals.¹⁰⁴ Receptor specificity is also suggested by conversion of an anesthetic to a nonanesthetic by increasing the molecular volume, despite corresponding increases in lipid solubility. Nevertheless, there is evidence that molecular shape (bulkiness) and size provide limited insight into the structure of the anesthetic site of action.¹⁰⁵

Potential Mediators of Anesthetic Action

Ionotropic and Metabotropic Receptors

Neurotransmitters signal through two families of receptors designated as ionotropic and metabotropic. Ionotropic receptors are also known as **ligand-gated ion channels** because the neurotransmitter binds directly to ion channel proteins and this interaction causes opening (gating) of the ion channels allowing transmission of specific ions resulting in changes in membrane potential. Ionotropic receptors are often composed of several subunits. Indeed the γ -aminobutyric acid receptor type A (GABA_A) and nicotinic acetylcholine receptors are constructed from large families of evolutionarily related subunits that come together to make pleomorphic receptors. In contrast, metabotropic receptors are usually monomeric receptors consisting of seven transmembrane segments. Binding of neurotransmitters (acetylcholine) to metabotropic receptors causes activation of guanosine triphosphate binding proteins (G proteins) associated with the receptors, and these G proteins act as second messengers to activate other signaling molecules such as protein kinases or potassium or calcium channels.⁶⁵

Inhaled anesthetics do not seem to stimulate the release of endogenous opioids and do not suppress ventilatory responses to surgical stimulation at concentrations that suppress movement. The fact that small doses of opioids decrease MAC reflects their ability to provide an effect (analgesia) that is not present with inhaled anesthetics alone.

Inhibitory Ligand-Gated and Voltage-Gated Channels (Glycine and GABA_A Receptors)

Glycine receptors are major mediators of inhibitory neurotransmission in the spinal cord and may mediate part of the immobility produced by inhaled anesthetics.¹⁰⁶ Their spinal localization and potentiation by volatile anesthetics at clinical concentrations is consistent with their being a target for mediating immobility as defined by MAC.

Although β_3 -subunit-containing GABA_A receptors mediate hypnosis and part of the immobility produced by injected anesthetics (propofol, etomidate),¹⁰⁷ there is evidence that GABA_A receptors do not mediate immobility produced by inhaled anesthetics. In this regard, although GABA_A receptors are potentiated at MACs of all clinically used volatile anesthetics, their enhancement of GABA_A receptor activation minimally influences MAC.¹⁰⁸

Glutamate (NMDA, AMPA, and Kainate Receptors)

Inhaled anesthetics decrease excitatory neurotransmission in the CNS. Glutamate is the principal excitatory neurotransmitter in the mammalian CNS. Glutamate receptors include G protein-coupled receptors and the ligand-gated receptors (NMDA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA], and kainate). The NMDA receptors may mediate some important behavioral effects of inhaled anesthetics. Volatile anesthetics separate into two different classes in terms of their efficacy for NMDA blockade. At 1 MAC, different volatile anesthetics inhibit NMDA receptors by between 14% (sevoflurane) and 39% (Xenon) with those anesthetics having cation-p interactions having the greatest NMDA blockade.¹⁰⁹

Two-Pore Potassium Channels

Two-pore potassium channels are intrinsic membrane receptor/ion channels that normally act to maintain the cell's resting potential and responds to internal stimuli such as a change in pH. Several members of this family have been found to be sensitive to volatile anesthetics at clinically used concentrations. The TREK and TASK channel activity is potentiated by volatile anesthetics in an agent-specific manner.¹¹⁰ The TASK-3 receptors are anesthetic-sensitive receptors that play a role in maintaining theta oscillations in the EEG that are associated with anesthesia and the duration of natural deep sleep.^{111,112} Anesthetic interaction with TASK channels may contribute to anesthetic induced neuroprotective effects in ischemia-reperfusion injury.¹¹³

Voltage-Gated Sodium Channels

It is now clear that there are many subtypes of sodium channels. Although sodium channels that mediate axonal conduction are not significantly effected at MACs of volatile anesthetics, those that modulate the release of neurotransmitter may be more sensitive to anesthetics. There is evidence that by interacting with specific subtypes of sodium channel that are expressed at the presynaptic junction, these drugs can inhibit the release of neurotransmitters, particularly glutamate.¹¹⁴ Indeed, intravenous administration of lidocaine, which is a nonspecific sodium channel blocker, decreases MAC.

Hyperpolarization-Activated Cyclic Nucleotide–Gated Channels

Hyperpolarization-activated cyclic nucleotide–gated channels are voltage-gated ion channels that are expressed throughout the body but are particularly important in regulating rhythmogenicity in heart and brain. There is some suggestion that halothane may affect hyperpolarization-activated cyclic nucleotide–gated channels in motor neurons to induce anesthetic immobility.¹¹⁵

Mechanism of Immobility

The MAC is based on the characteristic ability of inhaled drugs to produce immobility by virtue of actions of these drugs principally on the spinal cord rather than on higher centers.⁶⁵ The observation that immobility during noxious stimulation does not correlate with electroencephalographic activity reflects the fact that cortical electrical activity does not control motor responses to noxious stimulation. Effects of inhaled anesthetics on the spinal cord leading to immobility are diverse. In this regard, inhaled anesthetics depress excitatory AMPA and NMDA receptor–mediated currents by actions independent of inhibitory GABA_A and glycine receptor–mediated currents. Actions on two-pore potassium channels may also be important in producing immobility. Conversely, nicotinic acetylcholine receptors do not seem to exert a significant role in anesthetic-induced immobility at the spinal cord level.¹¹⁶ Likewise, although opioids and stimulation of α₂-adrenergic receptors (clonidine) decrease MAC, it is unlikely that immobility produced by inhaled anesthetics is due to activation of these receptors.⁸⁷ Inhaled anesthetics do not act via opioid receptors. Overall, no inhaled anesthetic action on a single group of receptors yet described can explain immobility, and immobility as a result of concurrent actions on many receptors is unlikely.^{65,117}

Mechanism of Anesthesia-Induced Unconsciousness

A comprehensive explanation of the mechanism by which volatile anesthetics cause loss of consciousness (suppression of awareness) is not known.¹¹⁸ Hypnosis is typically studied in animal models as loss of righting reflex. In human studies, it can be measured as loss of response to command, and in the presence of neuromuscular blockers, the spared arm technique uses a tourniquet to block muscle relaxant access to an arm, which is then used to indicate consciousness. Subtle differences in the clinical effects of inhaled anesthetics may be attributed to distinct actions on a number of critical molecular targets. There is evidence that loss of consciousness (hypnosis), amnesia, and the response to skin incision (immobility as defined by MAC) are not a single continuum of increasing anesthetic depth but rather separate phenomena.^{119,120} Combining these two observations, it has been proposed that general anesthesia is a process requiring a state of unconsciousness of the brain (produced by volatile or injected anesthetics) plus immobility in response to a noxious stimulus (surgical skin incision) that is mediated by the action of volatile anesthetics on the spinal cord administered at concentrations equivalent to MAC for that drug.

It has been proposed that clinical anesthesia is a hierarchical process in which afferent sensory impulses are diminished by some drugs (opioids, regional anesthesia, ketamine) while the central activating systems are depressed by another mechanism and sometimes other drugs (benzodiazepines, barbiturates, propofol, etomidate, ketamine, and volatile anesthetics) and motor reflexes are depressed by yet another mechanism (volatile anesthetics, propofol, etomidate, barbiturates). According to the definition of MAC, only agents that depress motor reflexes in addition to the other actions can be properly considered general anesthetics, but many agents are able to provide one or the other behavioral outcome and can be used as part of a general anesthetic regimen. Volatile anesthetics have been called **total anesthetics** because they can be used as a

single agent to provide general anesthesia. It was long assumed that they decreased pain transmission, but after more thorough consideration, it appears that volatile anesthetics have a biphasic dose response for nociceptive influences such that they are increased at very low volatile anesthetic concentrations (about 10% MAC) and they diminish thereafter.¹²¹ The pronociceptive activity of volatile anesthetics can be attributed to inhibition of heteromeric nicotinic receptors that is complete at very low concentrations around 1 MAC.¹²² This mechanism has been shown to impact emergence from isoflurane but not propofol anesthetics in humans.¹²³

Presynaptic inhibition of neurotransmitter release may explain how certain inhaled anesthetics can inhibit synaptic transmission. Many mechanisms have been proposed for the inhibition of neurotransmitter release by inhaled anesthetics. The mechanism by which anesthetics act to inhibit neurotransmitter release might reflect actions at ion channels that regulate the probability of neurotransmitter release or could act on the machinery of release itself. Recent evidence in rodents supports this view.¹²⁴ As mentioned earlier, halogenated volatile anesthetics inhibit some types of sodium channels in native neurons and in heterologous expression systems.¹²⁵ Although sodium channels can presynaptically modulate the release of both glutamate and GABA, their effect on the release of glutamate is greater than on the release of GABA.¹²⁶ There is recent evidence that isoflurane inhibits presynaptic neurotransmitter release inhibiting both the machinery required for neurotransmitter release.

Comparative Pharmacology of Gaseous Anesthetic Drugs

Inhaled anesthetics evoke different pharmacologic effects at comparable percentages of MACs, emphasizing that dose-response curves for these drugs are not necessarily parallel. Measurements obtained from normothermic volunteers exposed to equal potent concentrations of inhaled anesthetics during controlled ventilation of the lungs to maintain normocapnia have provided the basis of comparison for pharmacologic effects of these drugs on various organ systems.¹²⁷ In this regard, it is important to recognize that surgically stimulated patients who have other confounding variables may respond differently than healthy volunteers (**Table 4.7**).

TABLE 4.7

Variables that influence pharmacologic effects of inhaled anesthetics

Anesthetic concentration
Rate of increase in anesthetic concentration
Spontaneous versus controlled ventilation
Variations from normocapnia
Surgical stimulation
Patient age
Coexisting disease
Concomitant drug therapy
Intravascular fluid volume
Preoperative medication
Injected drugs to induce and/or maintain anesthesia or skeletal muscle relaxation
Alterations in body temperature

Desflurane and sevoflurane provide one specific advantage over other currently available potent inhaled anesthetics.⁴ Their lower blood and tissue solubility permit more precise control over the induction of anesthesia and a more rapid recovery when the drug is discontinued. Most of the other properties of these new volatile anesthetics resemble their predecessors, especially at concentrations of ≤ 1 MAC.

Central Nervous System Effects

Mental impairment is not detectable in volunteers breathing 1,600 ppm (0.16%) nitrous oxide or 16 ppm (0.0016%) halothane.¹²⁸ It is therefore unlikely that impairment of mental function in the personnel who work in the operating room using modern anesthetic scavenging techniques can result from inhaling trace concentrations of anesthetics. Reaction times do not increase significantly until 10% to 20% nitrous oxide is inhaled.¹²⁹

Cerebral metabolic oxygen requirements are decreased in parallel with drug-induced decreases in cerebral activity. Drug-induced increases in CBF may increase intracranial pressure (ICP) in patients with space-occupying lesions. The effects of desflurane and sevoflurane on the CNS do not differentiate these inhaled anesthetics from the older inhaled drugs.

Electroencephalogram

Volatile anesthetics in concentrations of <0.4 MAC similarly increase the frequency and voltage on the EEG. This enhancement is representative of the “excitement stage” of anesthesia. At about 0.4 MAC, there is an abrupt shift of high-voltage activity from posterior to anterior portions of the brain.¹³⁰ Cerebral metabolic oxygen requirements also begin to decrease abruptly at about 0.4 MAC. It is likely that these changes reflect a transition from wakefulness to unconsciousness. Furthermore, amnesia probably occurs at this dose of volatile anesthetic. As the dose of volatile anesthetic approaches 1 MAC, the frequency on the EEG decreases and maximum voltage occurs. During administration of isoflurane, burst suppression appears on the EEG at about 1.5 MAC, and at 2 MAC, electrical silence predominates.¹³¹ Electrical silence does not occur with enflurane, and only unacceptably high concentrations of halothane (>3.5 MAC) produce this effect. The effects of nitrous oxide on the EEG are similar to those produced by volatile anesthetics. Slower frequency and higher voltage develop on the EEG as the dose of nitrous oxide is increased or when nitrous oxide is added to a volatile anesthetic to provide a greater total MAC.

Desflurane and sevoflurane cause dose-related changes in the EEG similar to those that occur with isoflurane.⁴ With desflurane, the EEG progresses from an initial increase in frequency and lowering of voltage at low anesthetic concentrations to increased voltage at anesthetizing concentrations. Higher concentrations of desflurane produce decreasing voltage and increasing periods of electrical silence with an isoelectric EEG at 1.5 to 2.0 MAC. The addition of nitrous oxide to a given level of anesthesia with desflurane causes little or no change in the EEG.

Seizure Activity

Enflurane can produce fast frequency and high voltage on the EEG that often progresses to spike wave activity that is indistinguishable from changes that accompany a seizure. This EEG activity may be accompanied by tonic-clonic twitching of skeletal muscles in the face and extremities. The likelihood of enflurane-induced seizure activity is increased when the concentration of enflurane is >2 MAC or when hyperventilation of the lungs decreases the PaCO_2 to <30 mm Hg. Repetitive auditory stimuli can also initiate seizure activity during the administration of enflurane. There is no evidence of anaerobic metabolism in the brain during seizure activity produced by enflurane. Furthermore, in an animal model, enflurane does not enhance preexisting seizure foci, with the possible exception being certain types of myoclonic epilepsy and photosensitive epilepsy.¹³²

Isoflurane does not evoke seizure activity on the EEG, even in the presence of deep levels of anesthesia, hypocapnia, or repetitive auditory stimulation. Indeed, isoflurane possesses anticonvulsant properties; it is able to suppress seizure activity produced by flurothyl.¹³³ An undocumented speculation is that the greater MAC value for enflurane compared with its isomer, isoflurane, reflects the need for a higher concentration to suppress the stimulating effects of enflurane in the CNS.

Desflurane and sevoflurane, like isoflurane, do not produce evidence of convulsive activity on the EEG either at deep levels of anesthesia or in the presence of hypocapnia or auditory stimulation. Nevertheless, there are reports of pediatric patients with epilepsy and otherwise healthy adults who developed EEG evidence of seizure activity during sevoflurane anesthesia.^{134,135} Sevoflurane can suppress convulsive activity induced with lidocaine.

The administration of nitrous oxide may increase motor activity with clonus and opisthotonus even in clinically used concentrations.¹³⁶ When nitrous oxide is administered in high concentrations in a hyperbaric chamber, abdominal muscle rigidity, catatonic movements of extremities, and periods of skeletal muscle activity may alternate with periods of skeletal muscle relaxation, clonus, and opisthotonus.¹³⁷ Although very rare, tonic-clonic seizure activity has been described after administration of nitrous oxide to an otherwise healthy child.¹³⁸ Animals suspended by their tails may experience seizures in the first 15 to 90 minutes after discontinuation of nitrous oxide but not of volatile anesthetics.¹³⁹ It is possible that these withdrawal seizures reflect acute nitrous oxide dependence. In patients, delirium or excitement during recovery from anesthesia that included nitrous oxide could reflect this phenomenon.

Evoked Potentials

Volatile anesthetics cause dose-related decreases in the amplitude and increases in the latency of the cortical component of median nerve somatosensory evoked potentials, visual evoked potentials, and auditory evoked potentials.^{140,141} Decreases in amplitude are more marked than increases in latencies. In the presence of 60% nitrous oxide, waveforms adequate for monitoring cortical somatosensory evoked potentials are present during administration of 0.50 to 0.75 MAC halothane and 0.5 to 1.0 MAC enflurane and isoflurane.¹⁴² Peri-MACs of desflurane (0.5-1.5 MAC) increasingly depress somatosensory evoked potentials in patients.⁴ Even nitrous oxide alone may decrease the amplitude of cortical somatosensory evoked potentials.

Mental Function and Awareness

By definition, inhaled anesthetics cause loss of response to verbal command at MAC-awake concentrations. Subtle effects on mental function (learning) may occur at lower anesthetic concentrations (0.2 MAC).¹⁴³ Gaseous anesthetics may not be equally effective in preventing awareness. For example, 0.4 MAC isoflurane prevents recall and responses to commands, whereas nitrous oxide requires greater than 0.5 to 0.6 MAC to produce similar effects. Surgical stimulation may increase the anesthetic requirement to prevent awareness.

Cerebral Blood Flow

Volatile anesthetics produce dose-dependent increases in CBF. The magnitude of this increase is dependent on the balance between the drug's intrinsic vasodilatory actions and vasoconstriction secondary to flow-metabolism coupling. Volatile anesthetics administered during normocapnia in concentrations of >0.6 MAC produce cerebral vasodilation, decreased cerebral vascular resistance, and resulting dose-dependent increases in CBF (Figure 4.24).¹²⁷ This drug-induced increase in CBF occurs despite concomitant decreases in cerebral metabolic requirements. Sevoflurane has an intrinsic dose-dependent cerebral vasodilatory effect, but this effect is less than that of isoflurane.¹⁴⁴ Desflurane and isoflurane are similar in terms of increases in CBF and the preservation of reactivity to carbon dioxide (Figure 4.25).¹⁴⁵ Nitrous oxide also increases CBF, but its restriction to concentrations of <1 MAC limits the magnitude of this change. In fact, nitrous oxide may be a more potent cerebral vasodilator than an equipotent dose of isoflurane alone in humans.¹⁴⁶

Anesthetic-induced increases in CBF occur within minutes of initiating administration of the inhaled drug and whether blood pressure is unchanged or decreased, emphasizing the cerebral vasodilating effects of these drugs. Animals exposed to halothane demonstrate a time-dependent return to baseline from the previously increased CBF beginning after about 30 minutes and reaching predrug levels after about 150 minutes.¹⁴⁷ This normalization of CBF reflects a concomitant increase in cerebral vascular resistance that is not altered by α - or β -adrenergic blockade and is not the result of changes in the pH of the cerebrospinal fluid.¹⁴⁸

Unlike the decay in CBF with time observed in animals, CBF remains increased relative to cerebral metabolic oxygen requirements for as long as 4 hours during administration of halothane, isoflurane, or sevoflurane to patients during surgery (see [Figure 4.25](#)).¹⁴⁹ Furthermore, in these patients, isoflurane possesses greater capability to maintain global CBF relative to cerebral metabolic oxygen requirements than does halothane or sevoflurane (see [Figure 4.24](#)).¹⁴⁹ An unchanging EEG during this period suggests that CBF is increased over time without decay rather than a parallel change in CBF and cerebral metabolic oxygen requirements.

Autoregulation of CBF in response to changes in systemic blood pressure is retained during administration of 1 MAC isoflurane but not halothane ([Figure 4.26](#)).¹²⁷ Inhaled anesthetics including desflurane and sevoflurane do not alter autoregulation of CBF as reflected by the responsiveness of the cerebral circulation to changes in PaCO_2 .^{144,150,151} For example, cerebrovascular carbon dioxide reactivity is described as intact during administration of 1 MAC desflurane.¹⁵² Nevertheless, others describe impairment of autoregulation by desflurane with 1.5 MAC nearly abolishing autoregulation.¹⁵³

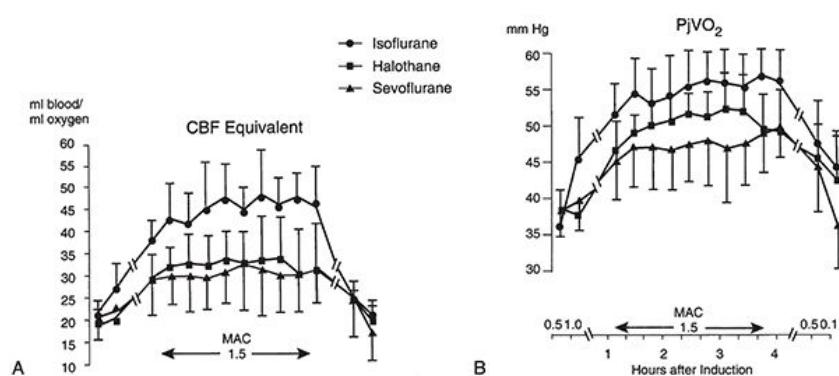

FIGURE 4.26 A, When compared at 1.5 minimal alveolar concentration (MAC), the average increase in cerebral blood flow (CBF) in the patients receiving isoflurane is greater than in those receiving halothane or sevoflurane. B, Likewise, the average value of the internal jugular venous oxygen tension ($PjVO_2$) is higher in patients receiving isoflurane. The increased CBF present at 1.5 MAC was sustained over time. *Reprinted with permission from Kuroda Y, Murakami M, Tsuruta J, et al. Preservation of the ratio of cerebral blood flow/metabolic rate for oxygen during prolonged anesthesia with isoflurane, sevoflurane, and halothane in humans. Anesthesiology. 1996;84(3):555-561. Cerebral Metabolic Oxygen Requirements

Inhaled anesthetics produce dose-dependent decreases in cerebral metabolic oxygen requirements that are greater during the administration of isoflurane than with an equivalent MAC of halothane.¹⁵⁴ When the EEG becomes isoelectric, an additional increase in the concentration of the volatile anesthetics does not produce further decreases in cerebral metabolic oxygen requirements. The greater decrease in cerebral metabolic oxygen requirements produced by isoflurane may explain why CBF is not predictably increased by this anesthetic at concentrations lower than 1 MAC. For example, decreased cerebral metabolism means less carbon dioxide is produced, which thus opposes any increase in CBF. It is conceivable that isoflurane could evoke unexpected increases in CBF if administered to a patient in whom cerebral metabolic oxygen requirements were already decreased by drugs. Desflurane and sevoflurane decrease cerebral metabolic oxygen requirements similar to isoflurane.

Cerebral Protection

Although neurologic outcome is not different based on the volatile anesthetic administered, these data suggest that relative to enflurane and halothane, isoflurane may offer a degree of cerebral protection (blunts necrotic processes resulting from cerebral ischemia) from transient incomplete regional cerebral ischemia during carotid endarterectomy.¹⁵⁵ Unchanged CBF and decreased cerebral metabolic oxygen requirements during isoflurane-induced controlled hypotension for clipping of cerebral aneurysms indicates that global cerebral oxygen supply-demand balance is favorably altered in patients anesthetized with this anesthetic.¹⁵⁶

Intracranial Pressure

Inhaled anesthetics produce increases in ICP that parallel increases in CBF produced by these drugs. Patients with space-occupying intracranial lesions are most vulnerable to these drug-induced increases in ICP. In hypocapnic humans with intracranial masses, desflurane concentrations of <0.8 MAC do not increase ICP, whereas 1.1 MAC increases ICP by 7 mm Hg.¹⁵⁷ Hyperventilation of the lungs to decrease the $Paco_2$ to about 30 mm Hg opposes the tendency for inhaled anesthetics to increase ICP.¹⁵⁸ With enflurane, it must be remembered that hyperventilation of the lungs increases the risk of seizure activity, which could lead to increased cerebral metabolic oxygen requirements and carbon dioxide production. These enflurane-induced changes will tend to increase CBF, which could further increase ICP. The ability of nitrous oxide to increase ICP is probably less than that of volatile anesthetics, reflecting the restriction of the dose of this drug to <1 MAC.

Cerebrospinal Fluid Production

Isoflurane does not alter production of CSF and, at the same time, decreases resistance to reabsorption.¹⁵⁹ These observations are consistent with minimal increases in ICP observed during the administration of isoflurane. Increases in ICP associated with administration of nitrous oxide presumably reflect increases in CBF because enhanced production of CSF does not occur in the presence of this inhaled anesthetic.¹⁶⁰

Circulatory Effects

Inhaled anesthetics produce dose-dependent and drug-specific circulatory effects. The circulatory effects of desflurane and sevoflurane parallel many of the characteristics of older inhaled anesthetics with desflurane

most closely resembling isoflurane, whereas sevoflurane has characteristics of both isoflurane and halothane.⁴¹⁶¹

Drug-induced circulatory effects manifest as changes in systemic blood pressure, heart rate, cardiac output, stroke volume, right atrial pressure, systemic vascular resistance, cardiac rhythm, and coronary blood flow. Circulatory effects of inhaled anesthetics may be different in the presence of (1) controlled ventilation of the lungs compared with spontaneous breathing, (2) preexisting cardiac disease, or (3) drugs that act directly or indirectly on the heart. The mechanisms of circulatory effects are diverse but often reflect the effects of inhaled anesthetics on (1) myocardial contractility, (2) peripheral vascular smooth muscle tone, and (3) autonomic nervous system activity (see the section “[Mechanisms of Circulatory Effects](#)”).

Mean Arterial Pressure

Halothane, isoflurane, desflurane, and sevoflurane produce similar and dose-dependent decreases in mean arterial pressure when administered to healthy human volunteers ([Figure 4.27](#)).¹⁶² The magnitude of decrease in mean arterial pressure in volunteers is greater than that which occurs in the presence of surgical stimulation. Likewise, artificially increased preoperative levels of systemic blood pressure, as may accompany apprehension, may be followed by decreases in blood pressure that exceed the true pharmacologic effect of the volatile anesthetic. In contrast with volatile anesthetics, nitrous oxide produces either no change or modest increases in systemic blood pressure.^{127,163} Substitution of nitrous oxide for a portion of the volatile anesthetic decreases the magnitude of blood pressure decrease produced by the same MAC of the volatile anesthetic alone ([Figure 4.28](#)).¹²⁷ The decrease in blood pressure produced by halothane is, in part or in whole, a consequence of decreases in myocardial contractility and cardiac output, whereas with isoflurane, desflurane, and sevoflurane, the decrease in systemic blood pressure results principally from a decrease in systemic vascular resistance (see the section “[Mechanism of Anesthesia-Induced Unconsciousness](#)”).

Heart Rate

Isoflurane, desflurane, and sevoflurane, but not halothane, increase heart rate when administered to healthy human volunteers (Figure 4.29).¹⁶² Sevoflurane increases heart rate only at concentrations of >1.5 MAC, whereas isoflurane and desflurane tend to increase heart rate at lower concentrations. Heart rate effects seen in patients undergoing surgery may be quite different than those documented in volunteers because so many confounding variables influence heart rate. For example, a small dose of opioid (morphine in the preoperative medication or fentanyl intravenously immediately before induction of anesthesia) can prevent the heart rate increase associated with isoflurane and presumably the other volatile anesthetics (Figure 4.30).¹⁶⁴ Increased sympathetic nervous system activity, as accompanies apprehension, may artificially increase heart rate and the magnitude of the true pharmacologic effect of the volatile anesthetic. Similarly, excessive parasympathetic nervous system activity may result in unexpected increases in heart rate when anesthesia is established.

The common observation of an unchanged heart rate despite a decrease in blood pressure during the administration of halothane may reflect depression of the carotid sinus (baroreceptor reflex response) by halothane as well as drug-induced decreases in the rate of sinus node depolarization. Junctional rhythm and associated decreases in systemic blood pressure most likely reflect suppression of sinus node activity by halothane. Halothane also decreases the speed of conduction of cardiac impulses through the atrioventricular node and His-Purkinje system. At 0.5 MAC, desflurane produces decreases in systemic blood pressure similar to those caused by isoflurane but does not evoke an increased heart rate as does isoflurane. This difference is not explained by disparate effects of these anesthetics on the baroreceptor-reflex response.¹⁶⁵ In neonates, administration of isoflurane is associated with attenuation of the carotid sinus reflex response, as reflected by drug-induced decreases in blood pressure that are not accompanied by increases in heart rate.¹⁶⁶ Heart rate responses during administration of isoflurane also seem to be blunted in elderly patients, whereas isoflurane-induced increases in heart rate are more likely to occur in younger patients and may be accentuated by the presence of other drugs (atropine, pancuronium) that exert vagolytic effects. Nitrous oxide also depresses the carotid sinus, but quantitating this effect is difficult because of its limited potency and its frequent simultaneous administration with other injected or inhaled drugs.

Cardiac Output and Stroke Volume

Halothane, but not isoflurane, desflurane, and sevoflurane, produces dose-dependent decreases in cardiac output when administered to healthy human volunteers (Figure 4.31).¹⁶⁷ Sevoflurane did decrease cardiac output at 1 and 1.5 MAC, but at 2 MAC, cardiac output had recovered to nearly awake values. Sevoflurane causes a smaller decrease in cardiac output than does halothane when administered to infants.¹⁶⁷ Due to different effects on heart rate (halothane causes no change and heart rate increases in the presence of the other volatile anesthetics), the calculated left ventricular stroke volume was similarly decreased 15% to 30% for all the volatile anesthetics. In patients, the increase in heart rate may tend to offset drug-induced decreases in cardiac output. Cardiac output is modestly increased by nitrous oxide, possibly reflecting the mild sympathomimetic effects of this drug.

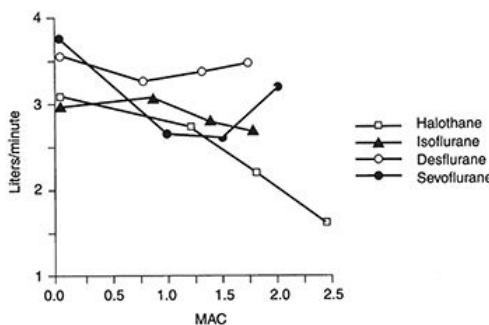

FIGURE 4.31 The effects of increasing concentrations (minimal alveolar concentration [MAC]) of halothane, isoflurane, desflurane, and sevoflurane on cardiac index (liters per minute) when administered to healthy volunteers. Reprinted with permission from Cahalan MK. Hemodynamic Effects of Inhaled Anesthetics [Review Courses]. Cleveland, OH: International Anesthesia Research Society; 1996:14-18.

In addition to better maintenance of heart rate, isoflurane's minimal depressant effects on cardiac output could reflect activation of homeostatic mechanisms that obscure direct cardiac depressant effects. Indeed, volatile anesthetics, including isoflurane, produce similar dose-dependent depression of myocardial contractility when studied in vitro using isolated papillary muscle preparations. The vasodilating effects of the ether-derivative volatile anesthetics make the direct myocardial depression produced by these drugs less

apparent than that of halothane. Indeed, excessive concentrations of these drugs administered to patients can produce cardiovascular collapse. In vitro depression of myocardial contractility produced by nitrous oxide is about one-half that produced by comparable concentrations of volatile anesthetics. Direct myocardial depressant effects *in vivo* are most likely offset by mild sympathomimetic effects of nitrous oxide.

Another possible explanation for the lesser impact of isoflurane on myocardial contractility may be its greater anesthetic potency relative to that of halothane.¹²⁷ For example, the multiple of MAC times the oil:gas partition coefficient for halothane is 168 and 105 for isoflurane. The implication is that isoflurane may more readily depress the brain and thus, at a given MAC value, appear to spare the heart. Indeed, in animals, the lesser myocardial depression associated with the administration of isoflurane manifests as a greater margin of safety between the dose that produces anesthesia and that which produces cardiovascular collapse.¹⁶⁸

Right Atrial Pressure

Halothane, isoflurane, and desflurane, but not sevoflurane, increase right atrial pressure (central venous pressure) when administered to healthy human volunteers but the changes are minimal at 1 MAC ([Figure 4.32](#)).¹⁶² These differences are not predictable based on the many other similarities between sevoflurane, desflurane, and isoflurane. The peripheral vasodilating effects of volatile anesthetics would tend to minimize the effects of direct myocardial depression on right atrial pressure produced by these drugs. Increased right atrial pressure during administration of nitrous oxide most likely reflects increased pulmonary vascular resistance due to the sympathomimetic effects of this drug.¹⁶⁹

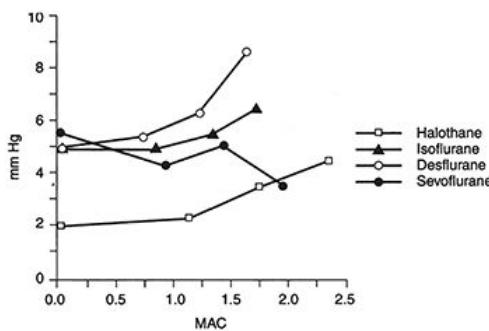

FIGURE 4.32 The effects of increasing concentrations (minimal alveolar concentration [MAC]) of halothane, isoflurane, desflurane, and sevoflurane on central venous pressure (mm Hg) when administered to healthy volunteers. Reprinted with permission from Cahalan MK. Hemodynamic Effects of Inhaled Anesthetics [Review Courses]. Cleveland, OH: International Anesthesia Research Society; 1996:14-18.

Systemic Vascular Resistance

Isoflurane, desflurane, and sevoflurane, but not halothane, decrease systemic vascular resistance when administered to healthy human volunteers ([Figure 4.33](#)).¹⁶² Thus, although these four volatile anesthetics decrease systemic blood pressure comparably, only halothane does so principally by decreasing cardiac output. For example, the absence of changes in systemic vascular resistance during administration of halothane emphasizes that decreases in systemic blood pressure produced by this drug parallelly decreases in myocardial contractility. The other volatile anesthetics decrease blood pressure principally by decreasing systemic vascular resistance. Nitrous oxide does not change systemic vascular resistance.

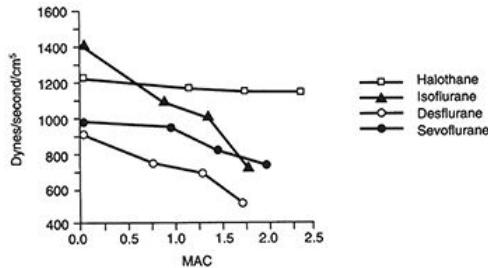

FIGURE 4.33 The effects of increasing concentrations (minimal alveolar concentration [MAC]) of halothane, isoflurane, desflurane, and sevoflurane on systemic vascular resistance (dynes/second/cm⁵) when administered to healthy volunteers. *Reprinted with permission from Cahalan MK. Hemodynamic Effects of Inhaled Anesthetics [Review Courses]. Cleveland, OH: International Anesthesia Research Society; 1996:14-18.*

Decreases in systemic vascular resistance during administration of isoflurane principally reflect substantial (up to fourfold) increases in skeletal muscle blood flow.¹⁷⁰ Cutaneous blood flow is also increased by isoflurane. The implications of these alterations in blood flow may include (1) excess (wasted) perfusion relative to oxygen needs, (2) loss of body heat due to increased cutaneous blood flow, and (3) enhanced delivery of drugs, such as muscle relaxants, to the neuromuscular junction.

Failure of systemic vascular resistance to decrease during administration of halothane does not mean that this drug lacks vasodilating effects on some organs. Clearly, halothane is a potent cerebral vasodilator and cutaneous vasodilation is prominent. These vasodilating effects of halothane, however, are offset by absent changes or vasoconstriction in other vascular beds such that the overall effect is unchanged calculated systemic vascular resistance.

The increase in cutaneous blood flow produced by all volatile anesthetics arterializes peripheral venous blood, providing an alternative to sampling arterial blood for evaluation of pH and Paco₂ (Figure 4.34).¹⁷¹ These drug-induced increases in cutaneous blood flow most likely reflect a central inhibitory action of these anesthetics on temperature-regulating mechanisms.

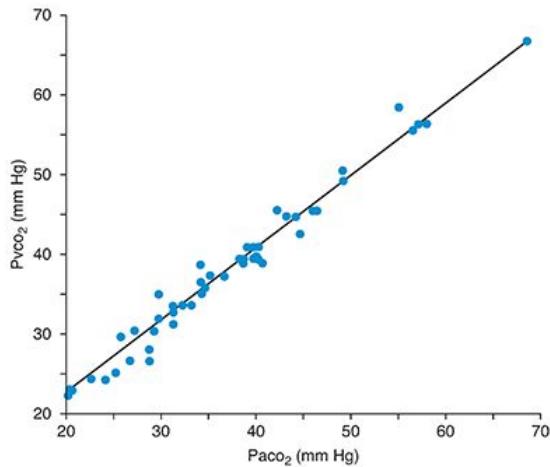

FIGURE 4.34 There is a linear relationship between PvCO₂ measured in “arterialized” peripheral venous blood and the Paco₂. *Reprinted with permission from Williamson DC III, Munson ES. Correlation of peripheral venous and arterial blood gas values during general anesthesia. Anesth Analg. 1982;61(11):950-952. Copyright © 1982 International Anesthesia Research Society.*

Pulmonary Vascular Resistance

Volatile anesthetics appear to exert little or no predictable effect on pulmonary vascular smooth muscle. Conversely, nitrous oxide may produce increases in pulmonary vascular resistance that is exaggerated in patients with preexisting pulmonary hypertension.^{172,173} The neonate with or without preexisting pulmonary hypertension may also be uniquely vulnerable to the pulmonary vascular vasoconstricting effects of nitrous oxide.¹⁷⁴ In patients with congenital heart disease, these increases in pulmonary vascular resistance may increase the magnitude of right-to-left intracardiac shunting of blood and further jeopardize arterial oxygenation.

Cardiac Dysrhythmias

The ability of volatile anesthetics to decrease the dose of epinephrine necessary to evoke ventricular cardiac dysrhythmias is greatest with the alkane derivative halothane and minimal to nonexistent with the ether derivatives isoflurane, desflurane, and sevoflurane (**Figure 4.35**).^{175–177}

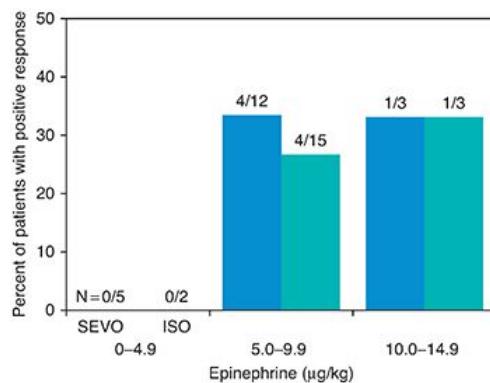

FIGURE 4.35 Responses to submucosally injected epinephrine in patients receiving sevoflurane (SEVO) or isoflurane (ISO) anesthesia. Reprinted with permission from Navarro R, Weiskopf RB, Moore MA, et al. Humans anesthetized with sevoflurane or isoflurane have similar arrhythmic response to epinephrine. Anesthesiology. 1994;80(3):545-549. Copyright © 1994 American Society of Anesthesiologists, Inc.

QTc Interval

Halothane, enflurane, and isoflurane prolong the QTc interval on the electrocardiogram in healthy patients.¹⁷⁸ Nevertheless, similar changes may not occur in patients with idiopathic long QTc interval syndrome suggesting that generalizations from healthy patients to patients with long QTc interval syndrome may not be valid. Conversely, there are reports of patients with long QTc syndrome of prolongation of the QT interval in response to the administration of sevoflurane.^{179,180} Furthermore, in healthy patients, administration of sevoflurane, but not propofol, results in prolongation of the QTc interval on the electrocardiogram.¹⁸¹

Accessory Pathway Conduction

The technology that underlies electrophysiologic studies and treatments is beyond the purview of this text but is covered in a recent review.¹⁸² The choice of anesthetic and monitoring depends on the pathophysiology underlying the arrhythmia being treated. Sympathetically driven arrhythmias such as supraventricular tachycardia and ventricular tachycardia are challenging because they are suppressed by most anesthetic agents as they reduce adrenergic tone. Volatile anesthetics are the most commonly used and cause minimal interference. Propofol can suppress atrial fibrillation in children and can be used to suppress electrical storm. There is no evidence that ketamine inhibits arrhythmias. It does not alter sinoatrial or atrioventricular node function but stimulates hemodynamics through adrenergic stimulation.

Spontaneous Breathing

Circulatory effects produced by volatile anesthetics during spontaneous breathing are different from those observed during normocapnia and controlled ventilation of the lungs. This difference reflects the impact of

sympathetic nervous system stimulation due to accumulation of carbon dioxide (respiratory acidosis) and improved venous return during spontaneous breathing. In addition, carbon dioxide may have direct relaxing effects on peripheral vascular smooth muscle. Indeed, systemic blood pressure, and heart rate are increased and systemic vascular resistance is decreased compared with measurements during administration of volatile anesthetics in the presence of controlled ventilation of the lungs to maintain normocapnia.^{183–185}

Coronary Blood Flow

Volatile anesthetics induce coronary vasodilation by preferentially acting on vessels with diameters from 20 to 50 microns, whereas adenosine, in addition, has a pronounced impact on the small precapillary arterioles.¹⁸⁶ It has been suggested that isoflurane as well as other coronary vasodilators (adenosine, dipyridamole, nitroprusside) that preferentially dilate the small coronary resistance coronary vessels would be capable of redistributing blood from ischemic to nonischemic areas, producing the phenomenon known as **coronary steal syndrome**. Nevertheless, this phenomenon is not clinically significant and volatile anesthetics, including isoflurane, are cardioprotective (see the section “[Cardiac Protection \[Anesthetic Preconditioning\]](#)”).

Neurocirculatory Responses

The solubility characteristics of desflurane make this volatile anesthetic a good choice to treat abrupt increases in systemic blood pressure and/or heart rate as may occur in response to sudden changes in the intensity of surgical stimulation. Nevertheless, abrupt increases in the alveolar concentrations of isoflurane and desflurane from 0.55 (0.71% isoflurane and 4% desflurane) to 1.66 MAC (2.12% isoflurane and 12% desflurane) increase sympathetic nervous system and renin-angiotensin activity and cause transient increases in mean arterial pressure and heart rate ([Figures 4.36](#) to [4.38](#)).¹⁸⁷ Desflurane causes significantly greater increases than isoflurane. The magnitude of the response to a rapid increase from 4% to 8% desflurane was similar to that produced by a rapid increase from 4% to 12%, suggesting that the stimulus provided by 8% desflurane produced a maximum response. Small (1%) increases in the desflurane concentration also transiently increase systemic blood pressure and heart rate, but the magnitude is less than those same changes that occur with an increase from 4% to 12%.¹⁸⁸ Sites mediating sympathetic nervous system activation in response to desflurane are present in the upper airway (larynx and above) and in the lungs.¹⁸⁹ These sites may respond to direct irritation. The increase in basal levels of sympathetic nervous system activity that accompany increasing inhaled concentrations of desflurane does not reflect the effects of drug-induced hypotension or alterations in baroreceptor activity.

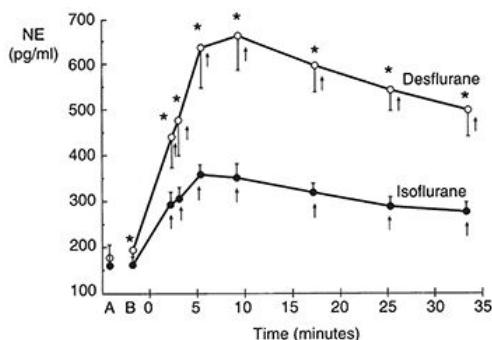

FIGURE 4.36 Plasma norepinephrine (NE) concentrations increased from awake levels (A) and those present during administration of 0.55 minimal alveolar concentration (MAC) desflurane or isoflurane (B) when the anesthetic concentrations were abruptly increased to 1.66 MAC (0). The increase was greater in the presence of desflurane than isoflurane (* $P < .05$). (Data are mean \pm standard error.) Reprinted with permission from Weiskopf RB, Moore MA, Eger EI II, et al. Rapid increase in desflurane concentration is associated with greater transient cardiovascular stimulation than with rapid increase in isoflurane concentration in humans. Anesthesiology. 1994;80(5):1035-1045. Copyright © 1994 American Society of Anesthesiologists, Inc.

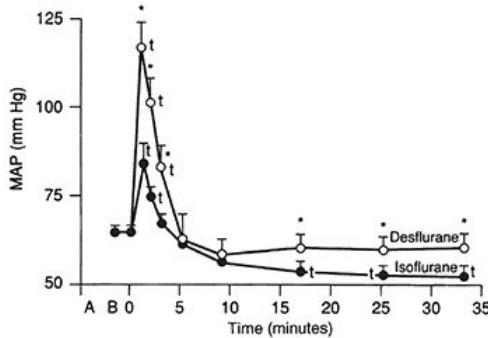

FIGURE 4.37 An abrupt and sustained increase in the concentration of desflurane from 0.55 to 1.66 minimal alveolar concentration (MAC) (0) resulted in a substantial but transient increase in mean arterial pressure (MAP). A similar increase in isoflurane MAC produced an increase in MAP that was substantially less than that observed in patients receiving desflurane. Within 5 minutes after increasing the anesthetic concentration, the MAP had decreased below awake (A) and 0.55 MAC values (B) reflecting the greater depth of anesthesia present at this time (t , $P < .05$ compared with the value at 0.55 MAC of the same anesthetic; * $P < .05$ compared with isoflurane at the same time point). *Reprinted with permission from Weiskopf RB, Moore MA, Eger EI II, et al. Rapid increase in desflurane concentration is associated with greater transient cardiovascular stimulation than with rapid increase in isoflurane concentration in humans. In contrast to desflurane and isoflurane, neurocirculatory responses do not accompany abrupt increases in the delivered concentration of sevoflurane ([Figure 4.39](#)).¹⁹⁰

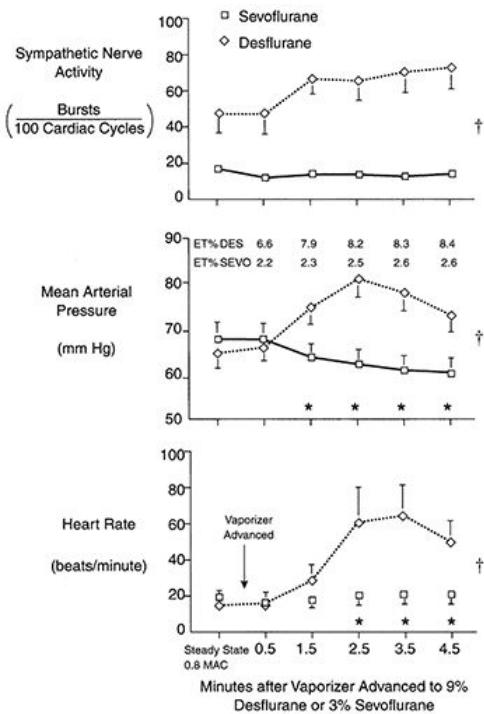

FIGURE 4.39 A rapid increase in the inspired concentration of sevoflurane (SEVO) from 0.8 minimal alveolar concentration (MAC) to 3% did not alter sympathetic nerve activity, mean arterial pressure, or heart rate. Conversely, a rapid increase in the inspired concentration of desflurane (DES) from 0.8 MAC to 9% significantly increased sympathetic nerve activity, mean arterial pressure, and heart rate. (Data are mean \pm standard error; * $P < .05$.) Abbreviation: ET, end-tidal. Reprinted with permission from Ebert TJ, Muzi M, Lopatka CW. Neurocirculatory responses to sevoflurane in humans: a comparison to desflurane. Anesthesiology. 1995;83(1):88-95. Copyright © 1995 American Society of Anesthesiologists, Inc.

Fentanyl (1.5–4.5 $\mu\text{g}/\text{kg}$ IV administered 5 minutes before the abrupt increase in desflurane concentration), esmolol (0.75 $\mu\text{g}/\text{kg}$ IV 1.5 minutes before), and clonidine (4.3 $\mu\text{g}/\text{kg}$ orally 90 minutes before) blunt the transient cardiovascular responses to rapid increases in desflurane concentration.¹⁹¹ Fentanyl may be the most clinically useful of these drugs because it blunts the increase in heart rate and blood pressure, has minimal cardiovascular depressant effects, and imposes little postanesthetic sedation. Alfentanil, 10 $\mu\text{g}/\text{kg}$ IV, in conjunction with the induction of anesthesia, also blunts the hemodynamic responses to an abrupt increase in the delivered concentration of desflurane; however, the increase in plasma norepinephrine concentrations that accompany the abrupt increase in desflurane concentration are not predictably prevented by the prior administration of opioids.¹⁹²

Preexisting Diseases and Drug Therapy

Preexisting cardiac disease may influence the significance of circulatory effects produced by inhaled anesthetics. For example, volatile anesthetics decrease myocardial contractility of normal and failing cardiac muscle by similar amounts, but the significance is greater in diseased cardiac muscle because contractility is decreased even before administration of depressant anesthetics. Neurocirculatory responses evoked by abrupt increases in the concentration of desflurane may be undesirable in patients with coronary artery disease. In patients with coronary artery disease, administration of 40% nitrous oxide produces evidence of myocardial depression that does not occur in patients without heart disease.¹⁹³ Valvular heart disease may influence the significance of anesthetic-induced circulatory effects. For example, peripheral vasodilation produced by isoflurane (presumably also desflurane and sevoflurane) is undesirable in patients with aortic stenosis but may be beneficial by providing afterload reduction in those with mitral or aortic regurgitation. Arterial hypoxemia may enhance the cardiac depressant effects of volatile anesthetics.

Prior drug therapy that alters sympathetic nervous system activity (antihypertensives, β -adrenergic antagonists) may influence the magnitude of circulatory effects produced by volatile anesthetics. Calcium entry blockers decrease myocardial contractility and thus render the heart more vulnerable to direct depressant effects of inhaled anesthetics.

Mechanisms of Circulatory Effects

There is no known single mechanism that explains the cardiovascular depressant effects of volatile anesthetics, just as there is none for the neurobehavioral effects. Proposed mechanisms include (1) direct myocardial depression, (2) inhibition of CNS sympathetic activity, (3) peripheral autonomic ganglion blockade, (4) attenuated carotid sinus reflex activity, (5) decreased formation of cyclic adenosine monophosphate, (6) decreased release of catecholamines, and (7) decreased influx of calcium ions through slow channels. Indeed, negative inotropic, vasodilating, and depressant effects on the sinoatrial node produced by volatile anesthetics are similar to the effects produced by calcium entry blockers.¹⁹⁴ However, voltage-gated calcium channels are only inhibited to a small extent by inhalational anesthetics.¹⁹⁵ Plasma catecholamine concentrations typically do not increase during administration of volatile anesthetics except during the initiation of desflurane anesthesia and isoflurane anesthesia to some extent, which is evidence that these drugs do not activate and may even decrease activity of the central and peripheral sympathetic nervous systems.

Isoflurane may be unique among the volatile anesthetics in possessing mild β -adrenergic agonist properties. This effect is consistent with the maintenance of cardiac output, increased heart rate, and decreased systemic vascular resistance that may accompany administration of isoflurane.¹⁷⁰ The increase in blood pressure that is associated with rapid increases in desflurane concentration is accompanied by a significant increase in plasma epinephrine suggesting enhanced release from the adrenal gland.¹⁹¹

Nitrous oxide administered alone or added to unchanging concentrations of volatile anesthetics produces signs of mild sympathomimetic stimulation characterized by (1) increases in the plasma concentrations of catecholamines, (2) mydriasis, (3) increases in body temperature, (4) diaphoresis, (5) increases in right atrial pressure, and (6) evidence of vasoconstriction in the systemic and pulmonary circulations. Sympathetic nervous system stimulation may also result because nitrous oxide can inhibit uptake of norepinephrine by the lungs, making more neurotransmitter available to receptors.¹⁹⁶ Interestingly, nitrous oxide shares its sympathomimetic aspect with another NMDA-blocking anesthetic, ketamine.

In contrast to sympathomimetic effects observed with the administration of nitrous oxide alone or added to volatile anesthetics, the inhalation of nitrous oxide in the presence of opioids results in evidence of profound circulatory depression, characterized by decreases in systemic blood pressure and cardiac output and increases in left ventricular end-diastolic pressure and systemic vascular resistance.^{197,198} It is possible that opioids inhibit the centrally mediated sympathomimetic effects of nitrous oxide, thus unmasking its direct depressant effects on the heart.

Cardiac Protection (Anesthetic Preconditioning)

Brief episodes of myocardial ischemia occurring before a subsequent longer period of myocardial ischemia providing protection against myocardial dysfunction and necrosis is termed *ischemic preconditioning*.¹⁹⁹ The molecular mechanism that underlies this phenomenon has been defined for more than 20 years because each step in the pathway represents a target for cardiac protection. Over the years, thousands of molecules have been defined that induce interaction between myocardial organelles and other cells including neurons, lymphocytes (**Figure 4.40**).²⁰⁰ It has been difficult to define a succinct description because of the voluminous number of players that interact over an almost instantaneous time course. See Heursh²⁰⁰ for review. However, these findings brought forth the concept of ischemic preconditioning that has been demonstrated in other organs including the kidneys.

Ventilation Effects

Inhaled anesthetics produce dose-dependent and drug-specific effects on the (1) pattern of breathing, (2) ventilatory response to carbon dioxide, (3) ventilatory response to arterial hypoxemia, and (4) airway resistance. The PaO_2 predictably declines during administration of inhaled anesthetics in the absence of supplemental oxygen.

Pattern of Breathing

Inhaled anesthetics, except for isoflurane, produce dose-dependent increases in the frequency of breathing.²⁰¹ Isoflurane increases the frequency of breathing similarly to other inhaled anesthetics up to a dose of 1 MAC. At a concentration of >1 MAC, however, isoflurane does not produce a further increase in the frequency of breathing. Nitrous oxide increases the frequency of breathing more than other inhaled anesthetics at concentrations of >1 MAC. The effect of inhaled anesthetics on the frequency of breathing presumably reflects CNS stimulation. Volatile anesthetics stimulate central respiratory chemoreceptor neurons likely through activation of THIK-1 (potassium channel subfamily K member 13; K2p13.1) receptors, a two-pore potassium channel that is responsible for a background potassium current.²⁰² Activation of pulmonary stretch receptors by inhaled anesthetics has not been demonstrated. The exception may be nitrous oxide, which, at anesthetic concentrations of >1 MAC, may also stimulate pulmonary stretch receptors.

Tidal volume is decreased in association with anesthetic-induced increases in the frequency of breathing. The net effect of these changes is a rapid and shallow pattern of breathing during general anesthesia. The increase in frequency of breathing is insufficient to offset decreases in tidal volume, leading to decreases in minute ventilation and increases in Paco_2 . The pattern of breathing during general anesthesia is also characterized as regular and rhythmic in contrast to the awake pattern of intermittent deep breaths separated by varying intervals.

Ventilatory Response to Carbon Dioxide

Volatile anesthetics produce dose-dependent depression of ventilation characterized by decreases in the ventilatory response to carbon dioxide and increases in the Paco_2 (Figure 4.41).¹ Desflurane and sevoflurane depress ventilation, producing profound decreases in ventilation leading to apnea between 1.5 and 2.0 MAC.

Both of these volatile anesthetics increase Paco_2 and decrease the ventilatory response to carbon dioxide. Depression of ventilation produced by anesthetic concentrations up to 1.24 MAC desflurane are similar to the depression produced by isoflurane.²⁰³

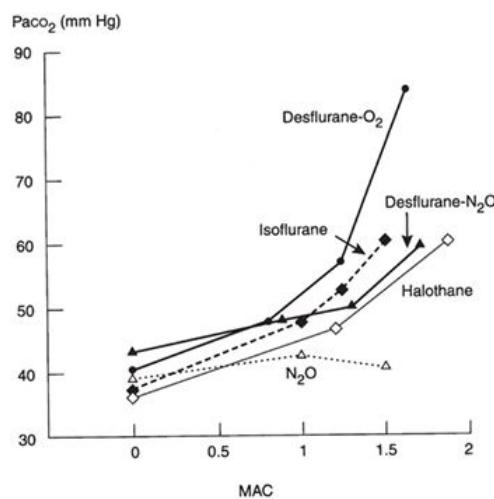

FIGURE 4.41 Inhaled anesthetics produce drug-specific and dose-dependent increases in Paco_2 . Abbreviations: MAC, minimal alveolar concentration; O₂, oxygen; N₂O, nitrous oxide. *Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.*

The presence of chronic obstructive pulmonary disease (COPD) may accentuate the magnitude of increase in Paco_2 produced by volatile anesthetics.²⁰⁴ Nitrous oxide does not increase the Paco_2 , suggesting that substitution of this anesthetic for a portion of the volatile anesthetic would result in less depression of ventilation. Indeed, nitrous oxide combined with a volatile anesthetic produces less depression of ventilation and increase in Paco_2 than does the same MAC of the volatile drug alone.²⁰⁵ This ventilatory depressant-sparing effect of nitrous oxide is detectable with all volatile anesthetics.¹

Despite the apparent benign effect of nitrous oxide on ventilation, the slope of the carbon dioxide response curve is decreased similarly and shifted to the right by anesthetic concentrations of all inhaled anesthetics (**Figure 4.42**).¹ Subanesthetic concentrations (0.1 MAC) of inhaled anesthetics, however, do not alter the ventilatory response to carbon dioxide. In addition to nitrous oxide, painful stimulation (surgical skin incision) and duration of drug administration influence the magnitude of increase in Paco_2 produced by volatile anesthetics.

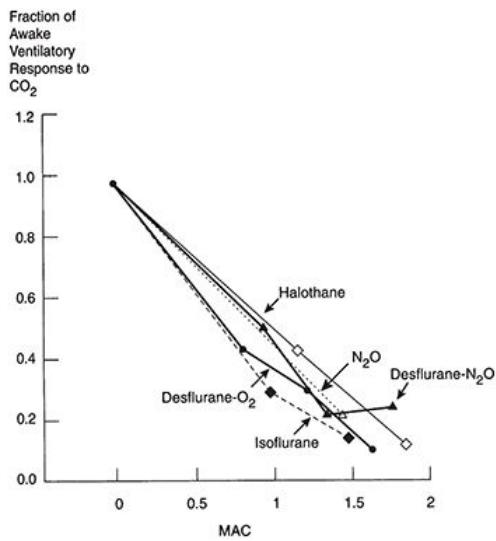

FIGURE 4.42 All inhaled anesthetics produce similar dose-dependent decreases in the ventilatory response to carbon dioxide (CO_2). Abbreviations: MAC, minimal alveolar concentration; O_2 , oxygen; N_2O , nitrous oxide. *Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.*

Surgical Stimulation

Surgical stimulation increases minute ventilation by about 40% because of increases in tidal volume and frequency of breathing. The PaCO_2 , however, decreases only about 10% (4-6 mm Hg) despite the larger increase in minute ventilation (Figure 4.43).¹²⁷ The reason for this discrepancy is speculated to be an increased production of carbon dioxide resulting from activation of the sympathetic nervous system in response to painful surgical stimulation. Increased production of carbon dioxide is presumed to offset the impact of increased minute ventilation on PaCO_2 .

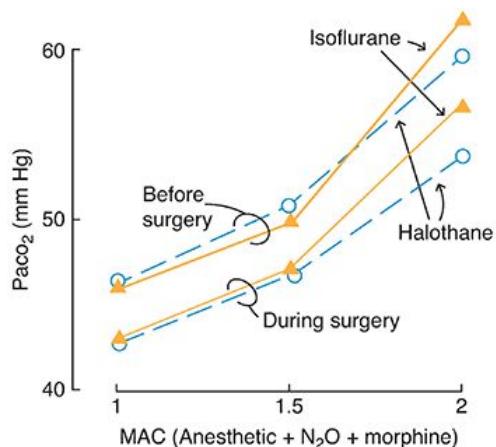

FIGURE 4.43 Impact of surgical stimulation on the resting PaCO_2 (mm Hg) during administration of isoflurane or halothane. Abbreviations: MAC, minimal alveolar concentration; N_2O , nitrous oxide. *Reprinted with permission from Eger EI. Isoflurane (Forane): A Compendium and Reference. 2nd ed. Madison, WI: Ohio Medical Products; 1981:1-110.*

Duration of Administration

After about 5 hours of administration, the increase in Paco_2 produced by spontaneous breathing of a volatile anesthetic is less than that present during administration of the same concentration for 1 hour (**Table 4.8**).¹⁸⁴ Likewise, the slope and position of the carbon dioxide response curve returns toward normal after about 5 hours of administration of the volatile anesthetics.²⁰⁵ The reason for this apparent recovery from the ventilatory depressant effects of volatile anesthetics with time is not known.

TABLE 4.8

Metabolism of volatile anesthetics as assessed by metabolite recovery versus mass balance studies^a

Anesthetic	Magnitude of metabolism	
	Metabolite recovery (%)	Mass balance (%)
Nitrous oxide	0.004	
Halothane	15-20	46.1
Enflurane	3	8.5
Isoflurane	0.2	0 ^b
Desflurane	0.02	
Sevoflurane	5	

^aData adapted from Carpenter RL, Eger EI II, Johnson BH, Unadkat JD, Sheiner LB. The extent of metabolism of inhaled anesthetics in humans. *Anesthesiology*. 1986;65:201-205.

^bMetabolism of isoflurane assumed to be 0 for this calculation.

Mechanism of Depression

Anesthetic-induced depression of ventilation as reflected by increases in the Paco_2 most likely reflects the direct depressant effects of these drugs on the medullary ventilatory center. An additional mechanism may be the ability of halothane and possibly other inhaled anesthetics to selectively interfere with intercostal muscle function, contributing to loss of chest wall stabilization during spontaneous breathing.²⁰⁶ This loss of chest wall stabilization could interfere with expansion of the chest in response to chemical stimulation of ventilation as normally produced by increases in the Paco_2 or arterial hypoxemia. Furthermore, this loss of chest wall stabilization means the descent of the diaphragm tends to cause the chest to collapse inward during inspiration, contributing to decreases in lung volumes, particularly the FRC. It is thus likely that halothane-induced depression of ventilation reflects both central and peripheral effects of the drug. The ventilatory depression associated with sevoflurane may result from a combination of central depression of medullary inspiratory neurons and depression of diaphragmatic function and contractility.²⁰⁷

Management of Ventilatory Depression

The predictable ventilatory depressant effects of volatile anesthetics are most often managed by institution of mechanical (controlled) ventilation of the patient's lungs. In this regard, the inherent ventilatory depressant effects of volatile anesthetics facilitate the initiation of controlled ventilation.²⁰⁸

Ventilatory Response to Hypoxemia

All inhaled anesthetics, including nitrous oxide, profoundly depress the ventilatory response to hypoxemia that is normally mediated by the carotid bodies. For example, 0.1 MAC produces 50% to 70% depression, and 1.1 MAC produces 100% depression of this response.^{209,210} This contrasts with the absence of significant depression of the ventilatory response to carbon dioxide during administration of 0.1 MAC of volatile anesthetics. Inhaled anesthetics also attenuate the usual synergistic effect of arterial hypoxemia and hypercapnia on stimulation of ventilation. Sevoflurane-induced decreases in hypoxic responses are not different in men and women that contrasts with morphine, which produces greater depression of the ventilatory response to hypoxia in women.²¹¹ Sevoflurane is useful during thoracic surgery as it is a potent

bronchodilator, its low blood-gas solubility permits rapid adjustment of the depth of anesthesia, and effects on hypoxic pulmonary vasoconstriction are small.²¹²

Airway Resistance and Irritability

Risk factors for developing bronchospasm during anesthesia include young age (<10 years), perioperative respiratory infection, endotracheal intubation, and the presence of COPD.²¹³ Nevertheless, isoflurane and sevoflurane produce bronchodilation in patients with COPD (**Figure 4.44**).²¹⁴ Sevoflurane causes moderate bronchodilation that is not observed in patients receiving desflurane or thiopental (**Figure 4.45**).²¹⁵ Bronchoconstriction produced by desflurane is most likely to occur in patients who smoke (**Figure 4.46**).²¹⁵ Administration of fentanyl 1 µg/kg IV or morphine 100 µg/kg IV prior to inhalation induction with desflurane and nitrous oxide significantly decreases airway irritability associated with desflurane.²¹⁶ After tracheal intubation in patients without asthma, airway resistance decreased in the presence of 1.1 MAC isoflurane, halothane, or sevoflurane (**Figure 4.47**).²¹⁷ Sevoflurane and desflurane have been administered without evidence of bronchospasm to patients with bronchial asthma.⁴

The assessment of the cough response to tracheal stimulation by endotracheal tube cuff inflation is a reliable and clinically meaningful measure of upper airway reactivity. At 1 MAC, sevoflurane is superior to desflurane for suppressing moderate and severe responses to this stimulus (Figure 4.48).²¹⁸ However, the irritant effects of desflurane are thought to be as a result of stimulation of TRPA1 receptors in the airways.²¹⁹ Administration of desflurane, 1.8% to 5.4%, does not produce secretions, coughing, or breath holding in human volunteers.¹

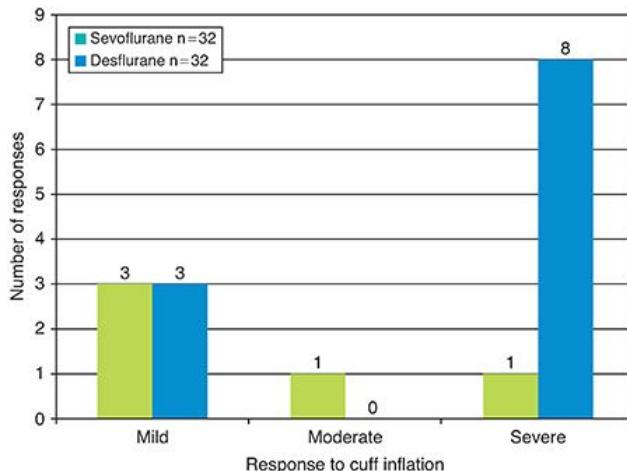

FIGURE 4.48 Responses to tracheal tube cuff inflation during 1 minimal alveolar concentration anesthesia with sevoflurane or desflurane. Reprinted with permission from Klock PA Jr, Czeslick EG, Klafta JM, et al. The effect of sevoflurane and desflurane on upper airway reactivity. Anesthesiology. 2001;94(6):963-967. Copyright © 2001 American Society of Anesthesiologists, Inc.

Despite the typical lack of irritant effects of sevoflurane on the airways, there is evidence that exposure of sevoflurane to desiccated carbon dioxide absorbents, especially those containing potassium hydroxide, may result in production of toxic gases and subsequent inhalation of these products causing airway irritation and impaired gas exchange.^{18,220} This airway irritation may be caused by formaldehyde, which is generated in isomolar concentrations with methanol. Compound A is not an airway irritant.

In the absence of bronchoconstriction, the bronchodilating effects of volatile anesthetics are difficult to demonstrate because normal bronchomotor tone is low and only minimal additional relaxation is possible. Like other inhaled anesthetics, nitrous oxide decreases FRC.

Neurologic Effects

Since the 1960s—largely sparked by the work of Wells and Keats²²¹ and their association of general anesthesia with a resultant increase in tolerance to cerebral ischemia during carotid occlusion—inhaled anesthetics have been considered to be neuroprotective agents. Multiple studies have been performed, and the results yielded positive association between neuroprotective characteristics of inhaled anesthetics.^{155,222} These findings were not replicated in high-quality, prospective studies; however, these findings brought forth the concept of ischemic preconditioning that has been demonstrated in other organs including the kidneys.

More recently, concern that the inverse may be true, that the administration of inhaled agents may be associated with neurotoxic effects was strongly supported by animal, including primate, models.²²³ These effects are the most reproducible at the extremes of age in animal models. A variety of potential mechanisms have been presented,²²⁴ with a demonstration of postexposure increases in neuronal and glial apoptosis associated with calcium dysregulation and many downstream effects in animal models.²²⁵⁻²²⁸ Behavior results in the elderly may include postoperative delirium and postoperative cognitive dysfunction that affects 20% to 40% of patients older than 60 years after anesthesia and surgery.²²⁹

Neurotoxicity in young children has been extensively studied by the SmartTots initiative and other groups.²³⁰ Early exposure to common anesthetic agents causes widespread neurodegeneration in the developing rat brain and persistent learning deficits.²²⁸ The widespread neuronal degeneration that results is thought to be a natural programmed response to synaptic silencing. Prolonged anesthesia with ketamine in neonatal monkeys (more than 9 hours) results in neuronal degeneration in the frontal cortex.²³¹ Whether normal exposures of young children to anesthesia for typical time periods could have neurodevelopmental effects has not been well supported by clinical studies. However, multiple large observational studies have suggested that multiple prolonged exposures to anesthesia may affect learning and development.²³²⁻²³⁷ These

concerns have led to a controversial U.S. Food and Drug Administration warning on anesthesia and brain development.²³⁸

Hepatic Effects

Hepatic Blood Flow

In patients receiving 1.5% end-tidal isoflurane, total hepatic blood flow and hepatic artery blood flow were maintained while portal vein blood flow was increased confirming that isoflurane was a vasodilator of the hepatic circulation providing beneficial effects on hepatic oxygen delivery.²³⁹ In contrast, halothane acts as a vasoconstrictor on the hepatic circulation. In another report, patients receiving 1 MAC isoflurane plus nitrous oxide demonstrated increases in hepatic blood flow and increased hepatic venous oxygen saturation, whereas hepatic blood flow did not change in patients receiving 1 MAC halothane plus nitrous oxide.²⁴⁰ Hepatic blood flow during administration of desflurane and sevoflurane is maintained similar to isoflurane in dogs (**Figure 4.49**).^{4,241} Maintenance of hepatic oxygen delivery relative to demand during exposure to anesthetics is uniquely important in view of the evidence that hepatocyte hypoxia is a significant mechanism in the multifactorial etiology of postoperative hepatic dysfunction.

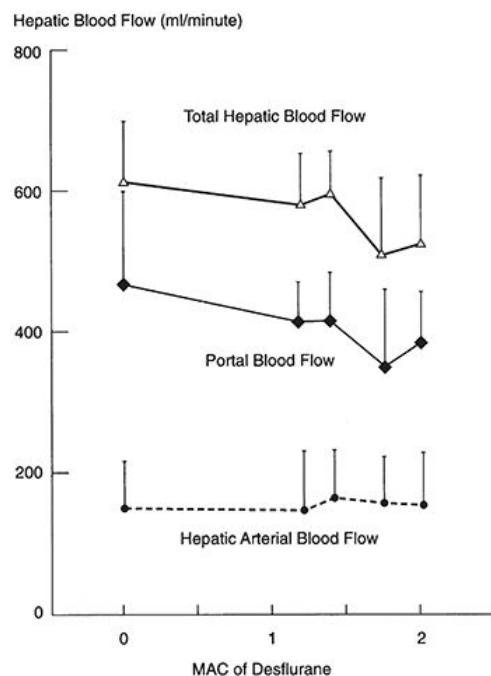

FIGURE 4.49 Administration of desflurane to dogs does not significantly alter hepatic perfusion. (Data are mean \pm standard deviation.) Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.

Drug Clearance

Volatile anesthetics may interfere with clearance of drugs from the plasma. Intrinsic clearance by hepatic metabolism of drugs such as propranolol is decreased by 54% to 68% by inhaled anesthetics.²⁴² In the overall hepatic clearance of drugs anesthetic-induced inhibition of hepatic drug-metabolizing enzymes is most often implicated.²⁴³

Liver Function Tests

Transient increases in the plasma alanine aminotransferase activity follow administration of desflurane, but not isoflurane administration, to human volunteers (**Figure 4.50**).^{1,241} Transient increases in plasma concentrations of α -glutathione transferase (sensitive indicator of hepatocellular injury) follow administration

of isoflurane or desflurane for surgical anesthesia.²⁴⁴ In the presence of surgical stimulation, bromsulphalein retention and increases in liver enzymes follow transiently the administration of even isoflurane, suggesting that changes in hepatic blood flow evoked by painful stimulation can adversely alter hepatic function independent of the volatile anesthetic.

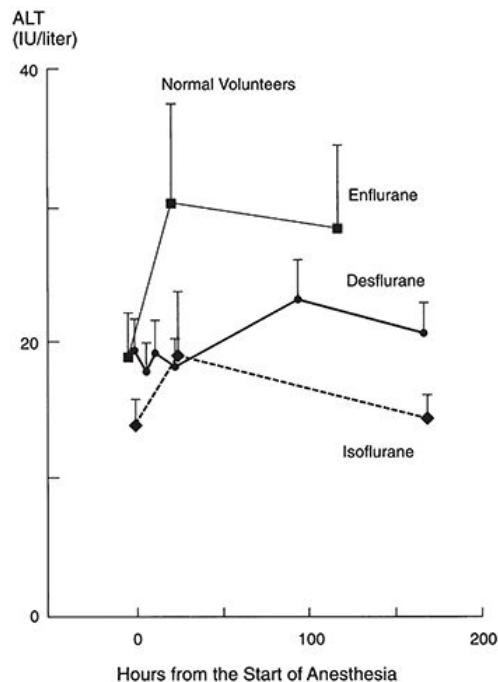

FIGURE 4.50 Plasma alanine aminotransferase (ALT) levels do not change significantly when enflurane, desflurane, or isoflurane are administered to healthy volunteers. (Data are mean \pm standard error.) Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.

Hepatotoxicity

Postoperative liver dysfunction has been associated with most volatile anesthetics, but halothane has caused the most frequent and clinically relevant cases.²⁴⁵ Metabolism of halothane can produce free radicals that can alter hepatic proteins, creating antigens that stimulate the immune system.²⁴⁶ Preexisting liver disease, such as hepatic cirrhosis, may be associated with marginal hepatocyte oxygenation, which would be further jeopardized by the depressant effects of anesthetics on hepatic blood flow and/or arterial oxygenation. Hypothermia, which decreases hepatic oxygen demand, may protect the liver from drug-induced events that decrease hepatic oxygen delivery.

Halothane

Halothane produces two types of hepatotoxicity in susceptible patients. An estimated 20% of adult patients receiving halothane develop a mild, self-limited postoperative hepatotoxicity that is characterized by nausea, lethargy, fever, and minor increases in plasma concentrations of liver transaminase enzymes.²⁴⁷ The other and rarer type of hepatotoxicity (halothane hepatitis) is estimated to occur in 1 in 10,000 to 1 in 30,000 adult patients receiving halothane and may lead to massive hepatic necrosis and death.²⁴⁸ Children seem to be less susceptible to this type of hepatotoxicity than adults.^{249,250} It is likely that the more common self-limited form of hepatic dysfunction following halothane is a nonspecific drug effect due to changes in hepatic blood flow that impair hepatic oxygenation. Conversely, the rarer, life-threatening form of hepatic dysfunction characterized as halothane hepatitis is most likely an immune-mediated hepatotoxicity.²⁴⁵

Halothane Hepatitis

Clinical manifestations of halothane hepatitis that suggest an immune-mediated response include eosinophilia, fever, rash, arthralgia, and prior exposure to halothane. Risk factors commonly associated with halothane hepatitis include female gender, middle age, obesity, and multiple exposures to halothane. The predominant histologic feature is acute hepatitis. The most compelling evidence for an immune-mediated mechanism is the presence of circulatory immunoglobulin G antibodies in at least 70% of those patients with the diagnosis of halothane hepatitis.²⁴⁵ These antibodies are directed against liver microsomal proteins on the surface of hepatocytes that have been covalently modified by the reactive oxidative trifluoroacetyl halide metabolite of halothane to form neoantigens (Figure 4.51).²⁵¹ This acetylation of liver proteins in effect changes these proteins from self to nonself (neoantigens), resulting in the formation of antibodies against this new protein. It is presumed that the subsequent antigen-antibody interaction is responsible for the liver injury characterized as halothane hepatitis. The possibility of a genetic susceptibility factor is suggested by case reports of halothane hepatitis in closely related relatives.^{252,253} Indeed, metabolism of halothane appears to be under genetic influence in humans (Figure 4.52).²⁵⁴

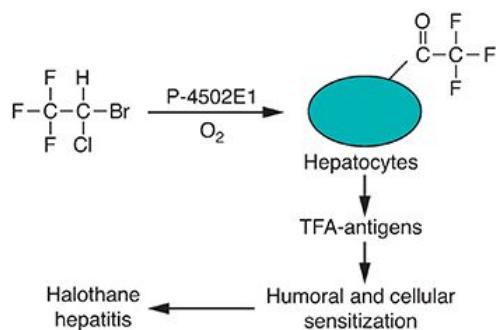

FIGURE 4.51 Halothane is metabolized to a trifluoroacetylated (TFA) adduct that binds to liver proteins. In susceptible patients, this adduct (altered protein) is seen as nonself (neoantigen), generating an immune response (production of antibodies). Subsequent exposure to halothane may result in hepatotoxicity. A similar process may occur in genetically susceptible individuals after anesthetic exposure to other fluorinated volatile anesthetics (enflurane, isoflurane, desflurane) that also generate a TFA adduct. *Reprinted with permission from Njoku D, Lesser MJ, Gong DH, et al. Biotransformation of halothane, enflurane, isoflurane, and desflurane to trifluoroacetylated liver proteins: association between protein acylation and hepatic injury. FIGURE 4.52 Pathways for the oxidative metabolism of fluorinated volatile anesthetics by cytochrome P450 enzymes to form acetylated protein adducts. In genetically susceptible individuals, the resulting trifluoroacetylates are thought to produce an immune response manifesting clinically as drug-induced hepatitis. *Reprinted with permission from Martin JL, Plevak DJ, Flannery KD, et al. Hepatotoxicity after desflurane anesthesia. Anesthesiology. 1995;83(5):1125-1129. Copyright © 1995 American Society of Anesthesiologists, Inc.*

Several observations suggest that reductive metabolism is not the primary mechanism in the development of halothane hepatitis. For example, neither enflurane nor isoflurane undergoes reductive metabolism; yet, these drugs both produce centrilobular necrosis in the hypoxic rat model. Furthermore, metabolites produced by reductive metabolism of halothane do not themselves produce hepatotoxicity. Finally, fasting does not alter metabolism but enhances hepatotoxicity by volatile anesthetics.

Enflurane, Isoflurane, and Desflurane

The mild, self-limited postoperative hepatic dysfunction that is associated with all the volatile anesthetics most likely reflect anesthetic-induced alterations in hepatic oxygen delivery relative to demand that results in inadequate hepatocyte oxygenation. More disturbing, however, is the realization that enflurane, isoflurane, and desflurane are oxidatively metabolized by liver cytochrome P450 enzymes to form acetylated liver protein adducts by mechanisms similar to that of halothane.²⁵¹⁻²⁵⁶ As a result, acetylated liver proteins capable of evoking an antibody response could occur after exposure to halothane, enflurane, isoflurane, or desflurane. Indeed, trifluoroacetyl-modified proteins have been described in a patient with hepatitis associated with isoflurane.²⁵⁷ This raises the possibility that enflurane, isoflurane, and desflurane could produce hepatotoxicity by a mechanism similar to that of halothane but at a lower incidence because the degree of anesthetic metabolism appears to be directly related to the potential for hepatic injury. Considering the magnitude of metabolism of these volatile anesthetics, it is predictable that the incidence of anesthetic-induced hepatitis would be greatest with halothane, intermediate with enflurane, and rare with isoflurane.²⁵⁸⁻
²⁶⁰ Desflurane is metabolized even less than isoflurane, and from the standpoint of immune-mediated

hepatotoxicity, desflurane should be very safe because it would have the lowest level of adduct formation. Nevertheless, even very small amounts of adduct may be able to precipitate massive hepatotoxicity, particularly if the patient was previously sensitized against trifluoroacetyl proteins. Indeed, hepatotoxicity after desflurane anesthesia has been described in a patient who may have been previously sensitized by exposure to halothane 18 and 12 years previously.²⁵⁶ Fulminant hepatic failure accompanied by high plasma concentrations of CYP2A6 autoantibodies has been observed in a patient 22 years following exposure to enflurane.²⁶¹ Similarly, halothane may be able to sensitize patients against protein adducts formed by other fluorinated volatile anesthetics.^{255,262}

The risk of fulminant hepatic failure after exposure to enflurane, isoflurane, or desflurane after previous exposure to halothane is probably less than the overall risk associated with anesthesia.²⁴⁵

Environmental exposure of operating room personnel to trace concentrations of volatile anesthetics could stimulate antibody production. Indeed, measurement of plasma autoantibody concentrations demonstrated increased levels in pediatric anesthesiologists (especially females) compared with general anesthesiologists and controls.²⁶³ It is presumed that pediatric anesthesiologists experience greater occupational exposure to trace concentrations of volatile anesthetics due to the frequent use of nonrebreathing anesthesia delivery systems and use of uncuffed endotracheal tubes. Despite these higher antibody levels, pediatric anesthesiologists did not have increased liver transaminase enzymes compared with general anesthesiologists, suggesting these antibodies may be insufficient to cause appreciable damage to normal hepatic cells.^{264,265}

Sevoflurane

The chemical structure of sevoflurane, unlike that of other fluorinated volatile anesthetics, dictates that it cannot undergo metabolism to an acetyl halide (**Figure 4.53**).^{266,267} Sevoflurane metabolism does not result in the formation of trifluoroacetylated liver proteins and therefore cannot stimulate the formation of antitrifluoroacetylated protein antibodies. In this regard, sevoflurane differs from halothane, enflurane, and desflurane, all of which are metabolized to reactive acetyl halide metabolites. Therefore, unlike all the other fluorinated volatile anesthetics, sevoflurane would not be expected to produce immune-mediated hepatotoxicity or to cause cross-sensitivity in patients previously exposed to halothane. Rare reported cases of sevoflurane hepatotoxicity are without explanation or proven cause and effect.^{4,268,269}

Copyright © 1992 International Anesthesia Research Society.

Compound A, a product of sevoflurane interaction with carbon dioxide absorbents, is hepatotoxic in animals at above clinically relevant concentrations. Nevertheless, small increases in the plasma alanine aminotransferase have been observed in volunteers receiving sevoflurane for prolonged periods of time during which the compound A concentration averaged 41 ppm. Similar changes in the plasma transaminase concentrations did not occur in volunteers receiving desflurane, suggesting that mild transient hepatic injury

was limited to the sevoflurane-treated individuals.²⁷⁰ Conversely, others have not observed differences in liver function enzyme changes in patients receiving sevoflurane compared with isoflurane.²⁷¹

Renal Effects

Volatile anesthetics produce similar dose-related decreases in renal blood flow, glomerular filtration rate, and urine output. These changes are not a result of the release of arginine vasopressin hormone but rather most likely reflect the effects of volatile anesthetics on systemic blood pressure and cardiac output. Preoperative hydration attenuates or abolishes many of the changes in renal function associated with volatile anesthetics. Volatile anesthetics appear to induce a protective activity on the kidney similar to that of the heart due to antiinflammatory and antiapoptotic activity at least in preclinical studies.²⁷²

Fluoride-Induced Nephrotoxicity

Fluoride-induced nephrotoxicity (polyuria, hypernatremia, hyperosmolarity, increased plasma creatinine, inability to concentrate urine) was first recognized in patients after the administration of methoxyflurane, which undergoes extensive metabolism (70% of the absorbed dose) to inorganic fluoride, which acts as a renal toxin. The methoxyflurane nephrotoxicity theory had been extended to other fluorinated volatile anesthetics despite the absence of data to support this extrapolation. As earlier, current studies suggest that newer volatile anesthetics may be protective against acute kidney injury.

Sevoflurane

Prolonged sevoflurane anesthesia does not impair renal concentrating function as evaluated with desmopressin testing 1 and 5 days postanesthesia in healthy volunteers.^{273,274}

Despite reports failing to show renal impairment after the administration of sevoflurane, there are observations of transient impairment of renal concentrating ability and increased urinary excretion of β -N-acetylglucosaminidase in patients exposed to sevoflurane and developing peak plasma inorganic fluoride concentrations $>50 \mu\text{mol/L}$ (**Figures 4.54** and **4.55**).²⁷⁵ Urinary excretion of β -N-acetylglucosaminidase is considered an indicator of acute proximal renal tubular injury. Despite these changes, the blood urea nitrogen and plasma creatinine did not change, and the authors concluded that clinically significant renal damage did not accompany administration of sevoflurane to patients with no preexisting renal disease. Concern that administration of sevoflurane to patients with preexisting renal disease could accentuate renal dysfunction was not confirmed when this volatile anesthetic was administered to patients with chronic renal disease as reflected by increased plasma creatinine concentrations.^{273,276} Likewise, administration of desflurane or isoflurane did not aggravate renal impairment in patients with preexisting chronic renal insufficiency (**Figure 4.56**).²⁷⁷

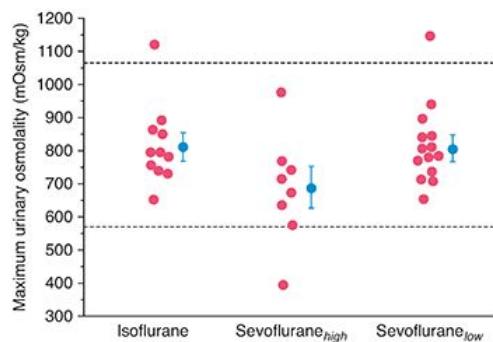

FIGURE 4.54 Maximum urinary osmolality in response to vasopressin 16.5 hours after cessation of anesthesia was not significantly different between the three anesthesia groups. Sevoflurane_{high} included only patients with a peak plasma inorganic fluoride concentration $>50 \mu\text{mol/L}$. Solid circles and bars represent mean \pm standard error. It has been postulated that intrarenal production of inorganic fluoride may be a more important factor for nephrotoxicity than hepatic metabolism that causes increased plasma fluoride concentrations.^{266,278} This would explain why patients with increased plasma concentrations of fluoride after administration of sevoflurane occasionally experience less renal dysfunction than patients receiving enflurane and manifesting lower plasma fluoride concentrations.^{273,274,279} Presumably, inhaled anesthetics such as methoxyflurane and enflurane undergo greater intrarenal metabolism to fluoride than sevoflurane, whereas sevoflurane undergoes greater hepatic metabolism, thus accounting for the higher plasma concentrations of fluoride.

Vinyl Halide Nephrotoxicity

Carbon dioxide absorbents containing potassium and sodium hydroxide react with sevoflurane and eliminate hydrogen fluoride from its isopropyl moiety to form breakdown products (**Figure 4.57**).^{5,280} The degradation product produced in greatest amounts is fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether (compound A). During closed-circuit anesthesia with sevoflurane administered to patients undergoing operations lasting longer than 5 hours, the average concentration of compound A in the anesthesia circuit was <20 ppm and no evidence of renal dysfunction occurred based on measurements of blood urea nitrogen and plasma creatinine concentrations (**Figure 4.58**).²⁴ Higher concentrations of compound A occurred in the presence of Baralyme (no longer clinically available) probably as a result of higher absorbent temperatures compared with soda lime.^{5,104} Similarly, carbon dioxide production increases the absorbent temperature and thus the production of compound A.

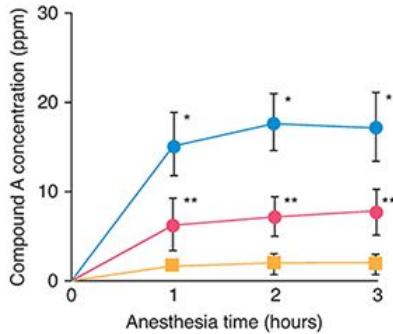

FIGURE 4.57 Inhaled compound A concentrations during administration of sevoflurane at fresh gas flow rates of 1 L per minute (blue circles), 3 L per minute (red circles), and 6 L per minute (squares) (* $P < .05$ vs 3 L per minute; ** $P < .05$ vs 6 L per minute). *Reprinted from Bito H, Ikeda K. Effect of total flow rate on the concentration of degradation products generated by reaction between sevoflurane and soda lime. Br J Anaesth. 1995;74(6):667-669. Copyright © 1995 Elsevier. With permission.*

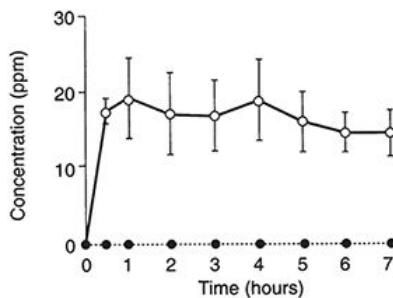

FIGURE 4.58 Inhaled compound A concentrations (open circles) and compound B concentrations (solid circles) during closed-circuit sevoflurane anesthesia. Closed-circuit anesthesia with sevoflurane in humans: effects of renal and hepatic function and concentrations of breakdown products with soda lime in the circuit. Anesthesiology. 1994;80(1):71-76. Copyright © 1994 American Society of Anesthesiologists, Inc.*

The rationale for the limitation of gas flow to at least 2 L per minute when administering sevoflurane is intended to minimize the concentration of compound A that may accumulate in the anesthesia breathing circuit. To assess the adequacy of this recommendation, the nephrotoxicity of 2, 4, or 8 hours of anesthesia with 1.25 MAC sevoflurane has been compared with a similar exposure to desflurane.^{270,281} Compound A concentrations ranged from 40 to 42 ppm during the three different durations of sevoflurane administration. In patients receiving 1.25 MAC sevoflurane for 8 hours or 4 hours, there was transient evidence of injury to the glomeruli (albuminuria), proximal renal tubules (glucosuria and increased urinary excretion of glutathione-S-transferase), and distal renal tubules (increased urinary excretion of glutathione-S-transferase) that was greater in the 8-hour group. Urine-concentrating ability and plasma creatinine were not altered

despite these findings in the patients receiving sevoflurane. Desflurane administered at 1.25 MAC for 2, 4, or 8 hours or sevoflurane exposure for 2 hours did not produce any evidence of renal injury. Conversely, comparisons of the renal effects of sevoflurane and isoflurane using fresh gas flows of 1 L per minute or less demonstrated no difference between these drugs based on measurement of indices of renal function.²⁸²⁻²⁸³ In children, sevoflurane anesthesia lasting 4 hours using total fresh gas flows of 2 L per minute produced concentrations of compound A of <15 ppm, and there was no evidence of renal dysfunction.²⁸⁴

Skeletal Muscle Effects

Neuromuscular Junction

Volatile anesthetics inhibit muscle type nicotinic receptors incompletely at MACs.²⁸⁵ Ether derivative fluorinated volatile anesthetics (isoflurane, sevoflurane, and desflurane) produce skeletal muscle relaxation that is about twofold greater than that associated with a comparable dose of halothane. Nitrous oxide does not relax skeletal muscles, and in doses of >1 MAC (delivered in a hyperbaric chamber), it may produce skeletal muscle rigidity.¹⁶³ This is not clinically relevant except perhaps in hyperbaric medicine. This effect of nitrous oxide is consistent with enhancement of skeletal muscle rigidity produced by opioids when low concentrations of nitrous oxide are administered. The ability of skeletal muscles to sustain contractions in response to continuous stimulation (such as with a nerve muscle stimulator) is impaired in the presence of increasing concentrations of ether derivative volatile anesthetics but not in the presence of halothane or nitrous oxide ([Figure 4.59](#)).¹

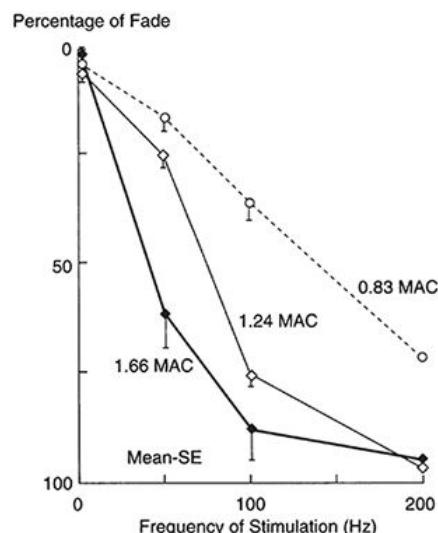

FIGURE 4.59 Increases in fade with tetanic stimulation accompany increasing doses of desflurane or increasing frequency of stimulation. Abbreviations: MAC, minimal alveolar concentration; SE, standard error. *Derived from Eger EI. Desflurane (Suprane): A Compendium and Reference. Nutley, NJ: Anaquest; 1993:1-119.*

Volatile anesthetics produce dose-dependent enhancement of the effects of neuromuscular-blocking drugs, with the effects of isoflurane, desflurane, and sevoflurane being similar and greater than halothane. In vitro, isoflurane and halothane produce similar potentiation of the effects of neuromuscular-blocking drugs.²⁸⁶ Nitrous oxide does not significantly potentiate the in vivo effects of neuromuscular-blocking drugs.

Malignant Hyperthermia

All volatile anesthetics including desflurane and sevoflurane can trigger malignant hyperthermia in genetically susceptible patients even in the absence of concomitant administration of succinylcholine.²⁸⁷⁻²⁸⁹ In one report, malignant hyperthermia did not manifest until 3 hours following uneventful desflurane anesthesia.²⁹⁰ Among the volatile anesthetics, however, halothane is the most potent trigger. Despite previous

data from animal models, nitrous oxide does not trigger malignant hyperthermia in humans. Xenon²⁹¹ can also be given safely to a patient with a history of malignant hyperthermia, although current anesthesia machines need longer flushing times than earlier simpler machines and manufacturer's instructions should be followed. Malignant Hyperthermia Association of the United States (MHAUS) is a nonprofit organization designed to promote best practices and scientific understanding of malignant hyperthermia. It currently runs a hotline for emergency recommendations for health care professionals in the management of an acute suspected case of malignant hyperthermia.²⁹²

Obstetric Effects

Volatile anesthetics produce similar and dose-dependent decreases in uterine smooth muscle contractility and blood flow (**Figure 4.60**).^{127,293,294} These changes are modest at 0.5 MAC (analgesic concentrations) and become substantial at concentrations of >1 MAC as such, nitrous oxide is particularly useful in obstetrical anesthesia to reduce the need to volatile anesthetic that promotes uterine atony while avoiding opioids and benzodiazepines that may cause prolonged depression of the newborn.

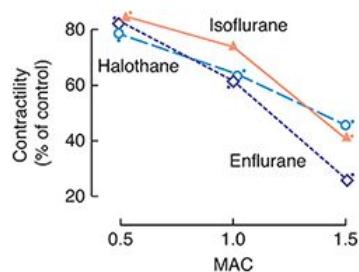

FIGURE 4.60 Impact of volatile anesthetics on contractility of uterine smooth muscle strips studied in vitro (*P > .05). Abbreviation: MAC, minimal alveolar concentration. *Reprinted with permission from Eger EI. Isoflurane (Forane): A Compendium and Reference. Madison, WI: Ohio Medical Products; 1981:1-110.*

In some settings, anesthetic-induced uterine relaxation may be desirable to facilitate removal of retained placenta; nitroglycerine can also be used for this purpose. Conversely, uterine relaxation produced by volatile anesthetics may contribute to blood loss due to uterine atony. Indeed, blood loss during therapeutic abortion is greater in patients anesthetized with a volatile anesthetic compared with that in patients receiving propofol.^{295,296} Propofol inhibits uterine contractility only slightly at anesthetic concentrations.²⁹⁷

There is a higher risk of awareness in women undergoing cesarean section compared to those who undergo other general surgery.²⁹⁸ Volatile anesthetics at about 0.5 MACs combined with 50% nitrous oxide provide a reasonable assurance of amnesia during cesarean section and do not produce detectable effects in the neonate.²⁹⁹ However, remember that MAC is defined as the concentration of an inhaled anesthetic that prevents movement in 50% of patients. Clearly, a 50% incidence of memory under general anesthesia is unacceptable! One MAC of an anesthetic is more reasonable, as the concentration of volatile anesthetic required for amnesia is approximately one-third of that required to prevent movement and dose response curves are very steep putting the likelihood of awareness during cesarean section considerably lower than 50%.³⁰⁰⁻³⁰² Another consideration is that MAC is thought to be primarily due to inhibition of a spinal reflex.⁶⁶ Awareness clearly requires a supratentorial contribution. When possible, absence of movement in response to surgical stimulus while avoiding muscle relaxation after intubation provides some assurance that at least a MAC is being used.

Inhaled anesthetics rapidly cross the placenta to enter the fetus, but these drugs are likewise rapidly exhaled by the newborn infant. Nitrous oxide-induced analgesia for vaginal delivery develops more rapidly than with most volatile anesthetics (desflurane and sevoflurane may be exceptions), but, after about 10 minutes, all inhaled drugs provide comparable analgesia. It is not known over what period of time the analgesic properties recover. These topics are discussed more fully in [Chapter 45](#).

Resistance to Infection

Many normal functions of the immune system are depressed after patient exposure to the combination of anesthesia and surgery.³⁰³ It would seem that many of the immune changes seen in surgical patients are primarily the result of surgical trauma and the subsequent endocrine (catecholamines and corticosteroids) and inflammatory responses (cytokines and chemokines) rather than the result of the anesthetic exposure itself. However, inhaled anesthetics, particularly nitrous oxide, produce dose-dependent inhibition of polymorphonuclear leukocytes and their subsequent migration (chemotaxis) for phagocytosis, which is necessary for the inflammatory response to infection. Nevertheless, decreased resistance to bacterial infection due to inhaled anesthetics seems unlikely, considering the duration of administration and dose of these drugs. Furthermore, when leukocytes reach the site of infection, their ability to phagocytize bacteria appears to be normal. Inhaled anesthetics do not have bacteriostatic effects at clinically used concentrations.

Genetic Effects

The Ames test, which identifies chemicals that act as mutagens and carcinogens, is negative for isoflurane, desflurane, sevoflurane, and nitrous oxide, and their known metabolites.^{23,304,305} Compound A, which is formed from sevoflurane degradation by carbon dioxide absorbents, might be expected to be an alkylating agent (and thus a mutagen), but tests of this product do not reveal mutagenicity.³⁰⁶ Halothane also results in a negative Ames test, but some of its potential metabolites may be positive.³⁰⁷

Nitrous oxide irreversibly oxidizes the cobalt atom of vitamin B₁₂ such that the activity of vitamin B₁₂-dependent enzymes (methionine synthetase and thymidylate synthetase) is decreased. In patients undergoing laparotomy with general anesthesia including 70% nitrous oxide, the half-time for inactivation of methionine synthetase is about 46 minutes (**Figure 4.61**).³⁰⁸ Volatile anesthetics do not alter activity of vitamin B₁₂-dependent enzymes.

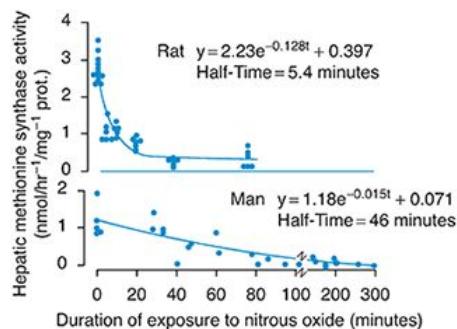

FIGURE 4.61 Time course of inactivation of hepatic methionine synthase (synthetase) activity during administration of 50% nitrous oxide to rats or 70% nitrous oxide to humans. Reprinted with permission from Royston BD, Nunn JF, Weinbren HK, et al. Rate of inactivation of human and rodent hepatic methionine synthase by nitrous oxide. Anesthesiology. 1988;68(2):213-216. Copyright © 1988 American Society of Anesthesiologists, Inc.

A 1995 trial designed to evaluate the effect of nitrous oxide among dental assistants on the rate of spontaneous abortion found a relative risk of 2.6 in women who worked with nitrous oxide for more than 3 hours a week without scavenging equipment, whereas the risk was not elevated among women working in offices that used scavenging equipment.³⁰⁹ The speculated role of trace concentrations of nitrous oxide in the production of spontaneous abortions led to the use of scavenging systems designed to remove waste anesthetic gases, including nitrous oxide, from the ambient air of the operating room. Health care workers exposed to nitrous oxide have lower levels of vitamin B₁₂ in proportion to their exposure.³¹⁰ Methionine synthetase converts homocysteine to methionine, which is necessary for the formation of myelin. Thymidylate synthetase is important for DNA synthesis. Interference with myelin formation and DNA synthesis could have significant effects on the rapidly growing fetus, manifesting as spontaneous abortions or congenital anomalies. Inhibition of these enzymes could also manifest as depression of bone marrow function and neurologic disturbances. Women do not normally choose to have elective surgery during the first

trimester of pregnancy when the risk is highest for spontaneous abortion. As discussed earlier, in animal models, all general anesthetics with the exception of Xenon that readily available cause neuroapoptosis in animals and there is no evidence that one is worse than the other. The lowest safe anesthetic doses for the shortest period of time are recommended for urgent surgery during the first trimester.³¹¹

Bone Marrow Function

Interference with DNA synthesis is responsible for the megaloblastic changes and agranulocytosis that may follow prolonged administration of nitrous oxide. Megaloblastic changes in bone marrow are consistently found in patients who have been exposed to anesthetic concentrations of nitrous oxide for 24 hours.³¹² Exposure to nitrous oxide lasting 4 days or longer results in agranulocytosis. This is not a common clinical occurrence. These bone marrow effects occur as a result of nitrous oxide–induced interference with activity of vitamin B₁₂–dependent enzymes, which are necessary for synthesis of DNA and the subsequent formation of erythrocytes (see the section “[Genetic Effects](#)”). Despite these potential adverse effects on bone marrow function, the administration of nitrous oxide to patients undergoing bone marrow transplantation does not influence bone marrow viability ([Figure 4.62](#)).³¹³

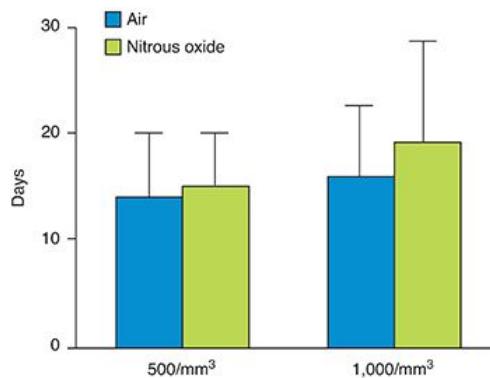

FIGURE 4.62 Nitrous oxide administered during bone marrow harvest did not alter the subsequent number of days needed for cultures to grow 500 to 1,000 cells/mm³. (Data are mean \pm standard deviation.) Reprinted with permission from Lederhaas G, Brock-Utne JG, Negrin RS, et al. Is nitrous oxide safe for bone marrow harvest? *Anesth Analg*. 1995;80(4):770-772. Copyright © 1995 International Anesthesia Research Society.

It is presumed that a healthy surgical patient could receive nitrous oxide for 24 hours without harm. Because the inhibition of methionine synthetase is rapid and its recovery is slow, it is to be expected that repeated exposures at intervals of <3 days may result in a cumulative effect. This relationship may be further complicated by other factors influencing levels of methionine synthetase and tetrahydrofolate (necessary for the transmethylation reaction) that might be important in critically ill patients receiving nitrous oxide. Nevertheless, the contradiction between the serious biochemical effects of nitrous oxide and the apparent absence of adverse clinical effects in routine use of this inhaled anesthetic makes it difficult to draw firm conclusions.

Peripheral Neuropathy

Animals exposed to 15% nitrous oxide for up to 15 days develop ataxia and exhibit evidence of spinal cord and peripheral nerve degeneration. Humans who chronically inhale nitrous oxide for nonmedical purposes may develop a neuropathy characterized by sensorimotor polyneuropathy that is often combined with signs of posterior lateral spinal cord degeneration resembling pernicious anemia.³¹⁴ The speculated mechanism of this neuropathy is the ability of nitrous oxide to oxidize irreversibly the cobalt atom of vitamin B₁₂ such that activity of vitamin B₁₂–dependent enzymes is decreased (see the section “[Genetic Effects](#)”).

Total Body Oxygen Requirements

Total body oxygen requirements are decreased by similar amounts by different volatile anesthetics. The oxygen requirements of the heart decrease more than those of other organs, reflecting drug-induced decreases in cardiac work associated with decreases in systemic blood pressure and myocardial contractility. Therefore, decreased oxygen requirements would protect tissues from ischemia that might result from decreased oxygen delivery due to drug-induced decreases in perfusion pressure. Decreases in total body oxygen requirements probably reflect metabolic depressant effects as well as decreased functional needs in the presence of anesthetic-produced depression of organ function.

Metabolism

Metabolism of modern drugs does not significantly affect either the onset or offset of drug effect. Based on mass balance studies, it is concluded that alveolar ventilation is principally responsible for the elimination of enflurane and isoflurane (presumably also desflurane and sevoflurane). Metabolism plays an important role for elimination of halothane that increases the risk for halothane hepatitis in susceptible individuals.^{315,316}

Environmental Impact of Inhaled Anesthetics

Greenhouse gases absorb and emit thermal radiation. They trap reflected sunlight and other terrestrial sources of infrared radiation within the atmosphere. A greenhouse gas must be present in sufficient quantities to potentially alter the equilibration between radiant energy absorbed from the sun and radiant energy dissipated into space from the Earth. The most important greenhouse gas, carbon dioxide, is taken up by plants and potentially by chemical reactions that can capture carbon dioxide. Most other greenhouse gases linger in the atmosphere for years (**Table 4.9**). This combination allows for the interference with the escape of such radiation from the earth's lower atmosphere. The resultant absorption of such radiant energy rather than its free release into space contributes to the "greenhouse effect": the process by which atmospheric radiation progressively warms the surface and lower atmosphere of the planet.

TABLE 4.9

Atmospheric lifetimes, radiative efficiencies, ozone depletion potentials, and global warming potentials of inhaled anesthetics^a

Compound	AL (years)	RE (W m^{-2} ppb $^{-1}$)	ODP	GWP ₂₀	GWP ₁₀₀
Nitrous oxide (N ₂ O)	114	0.00303	0.017	289	298

All inhaled anesthetics are well-documented contributors to the greenhouse effect. Additionally, many of the inhaled anesthetics are known to deplete the stratospheric ozone layer as well. Specifically, isoflurane, enflurane, and halothane are known to participate in the chlorine-mediated catalytic destruction of the ozone layer. Desflurane and sevoflurane are known to produce CF₃O₂ radicals, although they are not associated with direct ozone destruction.³¹⁷ Nitrous oxide is a prominent contributor to both ozone destruction as well as the greenhouse effect.³¹⁸

To evaluate the relative potential contribution of a particular greenhouse gas to climate change, the global warming potential has been developed. The global warming potential is the ratio of time-integrated

radiative efficiency and the atmospheric lifetime of a forcing agent, relative to a reference gas (eg, carbon dioxide). In comparing global warming potentials, clinical equivalences have been referenced in relation to automotive emissions.³¹⁹ In a single 8-hour day of anesthetic usage, desflurane run at 1 to 2 L of fresh gas flow produces 58 to 116 days' worth of average auto emissions. Sevoflurane (2 L fresh gas flow) and isoflurane (1-2 L fresh gas flow) produce the equivalents of 4.3 and 4.8 to 9.6 days of average auto emissions, respectively. When all are used at 2 L fresh gas flow, desflurane demonstrates roughly 26 and 13 times the global warming potential of sevoflurane and isoflurane, respectively. Furthermore, the vaporization of a single bottle of desflurane produces the same global warming effect as 886 kg of carbon dioxide (**Table 4.9**).³²⁰

Proposed mechanisms for limiting the environmental impact of inhalational agents include closed-circuit anesthetics, low-flow administration of the less environmentally detrimental inhalational agents, and total intravenous anesthetic techniques. The use of propofol in place of inhalational agents, for example, was demonstrated to produce nearly four orders of magnitude less greenhouse gas than nitrous or desflurane. Of note, the greenhouse gas effects of propofol result specifically from energy requirements for medication administration (ie, operation of pump systems) rather than environmental release of the medication.³²¹

Intravenous Sedatives and Hypnotics*

Updated by: James P. Rathmell • Albert Dahan

Overview

No other class of pharmacologic agents is more central to the practice of anesthesiology than the intravenous (IV) sedatives and hypnotics. It is this group of agents that we rely upon to provide everything through the spectrum from anxiolysis to light and deep sedation all the way to general anesthesia. The term **sedative** refers to a drug that induces a state of calm or sleep. The term **hypnotic** refers to drug that induces hypnosis or sleep. There is significant overlap in the two terms as well as with the related term **anxiolytic**, which refers to any agent that reduces anxiety; nearly all such substances have sedation as a side effect. For practical purposes, we generally combine the terms and refer to all of these drugs as **sedative-hypnotics**, drugs that reversibly depress the activity of the central nervous system (CNS). Depending on the specific agent, the dose, and the rate of administration, many sedative-hypnotics can be used to allay anxiety with minimal sedation, produce varying degrees of sedation, or rapidly induce drug-induced unconsciousness, which we call **general anesthesia**. We review the pharmacology of these important agents in this chapter.

γ -Aminobutyric Acid Agonists

Propofol

Propofol is a substituted isopropylphenol (2,6-diisopropylphenol) that is administered intravenously as a 1% solution in an aqueous solution of 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide.¹⁻³ This drug is chemically distinct from all other drugs that act as IV sedative-hypnotics. Administration of propofol, 1.5 to 2.5 mg/kg IV (equivalent to thiopental, 4-5 mg/kg IV, or methohexitol, 1.5 mg/kg IV) as a rapid IV injection (<15 seconds), produces unconsciousness within about 30 seconds. Awakening is more rapid and complete than that after induction of anesthesia with all other drugs used for rapid IV induction of anesthesia. The more rapid return of consciousness with minimal residual CNS effects is one of the most important advantages of propofol compared with alternative drugs administered for the same purpose.

Commercial Preparations

Propofol is an insoluble drug that requires a lipid vehicle for emulsification. Soybean oil holds the propofol in a medium that can be stabilized and dispersed; lecithin serves as an emulsifier to stabilize the small propofol–soybean oil droplets in aqueous dispersion, and glycerol maintains the formulation isotonic with blood.^{4,5} This formulation supports bacterial growth and causes increased plasma triglyceride concentrations when prolonged IV infusions are used. Diprivan and generic propofol differ with respect to the preservatives used and the pH of the formulation. Diprivan uses the preservative disodium edetate (0.005%) with sodium hydroxide to adjust the pH to 7 to 8.5. A generic formulation of propofol incorporates sodium metabisulfite (0.25 mg/mL) as the preservative and has a lower pH (4.5-6.4). Propofol, unlike thiopental, etomidate, and ketamine, is not a chiral compound. The mixing of propofol with any other drug is not recommended, although lidocaine has been frequently added to propofol in attempts to prevent pain with IV injection. However, mixing of lidocaine with propofol may result in coalescence of oil droplets, which may pose the risk of pulmonary embolism.⁶

A low-lipid emulsion of propofol (Ampofol) contains 5% soybean oil and 0.6% egg lecithin but does not require a preservative or microbial growth retardant.⁷ This formulation is equipotent to Diprivan but is associated with a higher incidence of pain on injection.

An alternative to emulsion formulations of propofol and associated side effects (pain on injection, risk of infection, hypertriglyceridemia, pulmonary embolism) is creation of a prodrug (Aquavan, fospropofol) by cleaving groups to the parent compound that increase its water solubility (phosphate monoesters, hemisuccinates). Propofol is liberated after hydrolysis by endothelial cell surface alkaline phosphatases. In

this regard, injection of the water-soluble propofol phosphate prodrug results in propofol and dose-dependent sedative effects.^{8,9} However, although the absence of lipid emulsion obviates pain on injection, the release of a small amount of formaldehyde byproduct causes an unpleasant dysesthesia or burning sensation often in the perineal area. Compared with propofol, this prodrug has a slower onset, larger volume of distribution (V_d), and higher potency.¹⁰ This drug was under active development in the late 2000s; publication of phase I and phase II clinical results were retracted in 2010 due to inaccuracies with the assays used and further development was halted.¹¹

Another nonlipid formulation of propofol uses cyclodextrins as a solubilizing agent.^{12,13} Cyclodextrins are ring sugar molecules that form guest (propofol)-host complexes migrating between the hydrophilic center of the cyclodextrin molecule and the water-soluble phase. This allows propofol, which is poorly soluble in water, to be presented in an injectable form. After injection, propofol migrates out of the cyclodextrin into the blood. This preparation has not been released for general human use.

Mechanism of Action

Propofol is a relatively selective modulator of γ -aminobutyric acid type A ($GABA_A$) receptors. Propofol is presumed to exert its sedative-hypnotic effects through a $GABA_A$ receptor interaction, although potentiation of activity at glycine receptors partially contributes to propofol-induced hypnosis.^{14,15} The $GABA$ is the principal inhibitory neurotransmitter in the brain. When $GABA_A$ receptors are activated, transmembrane chloride conductance increases, resulting in hyperpolarization of the postsynaptic cell membrane and functional inhibition of the postsynaptic neuron. The interaction of propofol (also etomidate and barbiturates) with specific components of $GABA_A$ receptors appears to decrease the rate of dissociation of the inhibitory neurotransmitter $GABA$ from the receptor, thereby increasing the duration of the $GABA$ -activated opening of the chloride channel with resulting hyperpolarization of cell membranes. In contrast to volatile anesthetics, spinal motor neuron excitability, as measured by H reflexes, is not altered by propofol, suggesting that immobility during propofol anesthesia is not caused by drug-induced spinal cord depression.¹⁶

Pharmacokinetics

Clearance of propofol from the plasma exceeds hepatic blood flow, emphasizing that tissue uptake (possibly into the lungs), as well as hepatic oxidative metabolism by cytochrome P450, is important in removal of this drug from the plasma (Figure 5.1) (Table 5.1).¹⁷ Hepatic metabolism is rapid and extensive, resulting in inactive, water-soluble sulfate and glucuronic acid metabolites that are excreted by the kidneys.¹⁸ Propofol may also undergo ring hydroxylation by cytochrome P450 to form 4-hydroxypropofol which is then glucuronidated or sulfated. Although the glucuronide and sulfate conjugates of propofol appear to be pharmacologically inactive, 4-hydroxypropofol has about one-third the hypnotic activity of propofol. Less than 0.3% of a dose is excreted unchanged in urine. The elimination half-time is 0.5 to 1.5 hours, but more important, the context-sensitive half-time for propofol infusions lasting up to 8 hours is less than 40 minutes.¹⁹ The context-sensitive half-time of propofol is only minimally influenced by the duration of the infusion at surgical durations (hours) relevant for most surgery. When the infusion is discontinued, drug returns from tissue storage sites to the circulation. Once in the circulation, propofol is rapidly metabolized and cleared, and little of the drug is available to slow the decline in plasma concentration. However, when used as a sedative for prolonged intensive care unit (ICU) care (days), the context-sensitive half-time becomes highly relevant and may lead to prolonged effects when the drug is discontinued. Propofol, like thiopental and remifentanil, has a short effect-site equilibration time such that effects on the brain occur promptly after IV administration.

TABLE 5.1

Comparative characteristics of common induction drugs

	Elimination half-time (hour)	Volume of distribution (L/kg)	Clearance (mL/kg/minute)	Systemic blood pressure	Heart rate
Propofol	0.5-1.5	3.5-4.5	30-60	Decreased	Decreased
Etomidate	2-5	2.2-4.5	10-20	No change to decreased	No change
Ketamine	2-3	2.5-3.5	16-18	Increased	Increased

The fact that total body clearance of propofol exceeds hepatic blood flow is consistent with extrahepatic clearance (pulmonary uptake and first-pass elimination, renal excretion) of propofol.¹⁸⁻²⁰ Pulmonary uptake of propofol is significant and influences the initial availability of propofol. Although propofol can be transformed in the lungs to 2,6-diisopropyl-1,4-quinol, most of the drug that undergoes pulmonary uptake during the first pass is released back into the circulation.^{21,22} Glucuronidation is the major metabolic pathway for propofol, and uridine 5'-diphospho-glucuronosyltransferase isoforms are expressed in the kidneys and brain.

Despite the rapid clearance of propofol by metabolism, there is no evidence of impaired elimination in patients with cirrhosis of the liver. Plasma concentrations of propofol at the time of awakening are similar in alcoholic and normal patients.²³ Extrahepatic elimination of propofol occurs during the anhepatic phase of orthotopic liver transplantation. Renal dysfunction does not influence the clearance of propofol despite the observation that nearly three-fourths of propofol metabolites are eliminated in urine in the first 24 hours.²⁴ Patients older than 60 years of age exhibit a decreased rate of plasma clearance of propofol compared with younger adults. The rapid clearance of propofol confirms this drug can be administered as a continuous infusion during surgery without an excessive cumulative effect. Propofol readily crosses the placenta but is rapidly cleared from the neonatal circulation.²⁵ The effect of instituting cardiopulmonary bypass on the plasma propofol concentration is unpredictable, with some studies reporting a decrease, whereas other observations fail to document any change.²⁶

Clinical Uses

Propofol has become the induction drug of choice for many forms of anesthesia, especially when rapid awakening is considered desirable.³ Continuous IV infusion of propofol, with or without other anesthetic drugs, has become a commonly used method for producing IV sedation or as part of a balanced or total IV anesthetic.^{1,3} Administration of propofol as a continuous infusion may be used for sedation of patients in the

ICU.² In this regard, a 2% solution may be useful to decrease the volume of lipid emulsion administered with long-term sedation. A computer-controlled infusion pump is available to allow the clinician to select the propofol target concentration and calculates the infusion rates that are necessary to achieve this target concentration based on the pharmacokinetics of propofol.²⁷ Sadly, introduction of such target-controlled infusion pumps has been met with significant concerns by the U.S. Food and Drug Administration (FDA) over interpatient variability in actual plasma drug concentrations, and they remain unavailable for clinical use in the United States.²⁸

Induction of Anesthesia

The induction dose of propofol in healthy adults is 1.5 to 2.5 mg/kg IV, with blood levels of 2 to 6 µg/mL producing unconsciousness depending on associated medications and the patient's age. As with barbiturates, children require higher induction doses of propofol on a milligram per kilogram basis, presumably reflecting a larger central distribution volume and higher clearance rate. Elderly patients require a lower induction dose (25%-50% decrease) as a result of a smaller central distribution volume and decreased clearance rate and increased pharmacodynamic activity.³ Awakening typically occurs at plasma propofol concentrations of 1.0 to 1.5 µg/mL. Awakening without residual CNS effects that is characteristic of propofol is the principal reason this drug has replaced thiopental for induction of anesthesia in many clinical situations. Thiopental is not currently available for use in the United States.

Intravenous Sedation

The short context-sensitive half-time of propofol, combined with the short effect-site equilibration time, make this a readily titratable drug for production of IV sedation.¹ The prompt recovery without residual sedation and low incidence of nausea and vomiting make propofol particularly well suited to ambulatory conscious sedation techniques. The typical conscious sedation dose of 25 to 100 µg/kg/minute IV produces minimal analgesic and variable amnestic effects.³ In selected patients, midazolam or an opioid may be added to propofol for continuous IV sedation. A sense of well-being may accompany recovery from conscious sedation with propofol. A conventional patient-controlled analgesia delivery system set to deliver 0.7 mg/kg doses of propofol with a 3-minute lockout period has been used as an alternative to continuous IV sedation techniques. Propofol has emerged as the agent of choice for sedation for brief gastrointestinal endoscopy procedures. So reliable are the pharmacologic properties of propofol that extensive design and testing have gone into creation of a computer-assisted personalized sedation for upper endoscopy and colonoscopy, called *SEDASYS*. A comparative, multicenter randomized study concluded that this system could provide endoscopist/nurse teams a safe and effective means to administer propofol to effect minimal to moderate sedation during routine colonoscopy and esophagogastroduodenoscopy without the need for a trained anesthesia provider.²⁹ The *SEDASYS* system received approval from the FDA in 2014 but was withdrawn by the manufacturer in mid-2016 after limited uptake of the device in clinical practice.

Propofol has been administered as a sedative during mechanical ventilation in the ICU in a variety of patient populations including postoperative patients (cardiac surgery, neurosurgery) and patients with head injury.² Propofol also provides control of stress responses and has anticonvulsant and amnestic properties. After cardiac surgery, propofol sedation appears to modulate postoperative hemodynamic responses by decreasing the incidence and severity of tachycardia and hypertension.³⁰ Increasing metabolic acidosis, lipemic plasma, bradycardia, and progressive myocardial failure has been described, particularly in children who were sedated with propofol during management of acute respiratory failure in the ICU.³¹

Maintenance of Anesthesia

The typical dose of propofol for maintenance of anesthesia is 100 to 300 µg/kg/minute IV, often in combination with a short-acting opioid.³ General anesthesia that includes propofol is typically associated with minimal postoperative nausea and vomiting, and awakening is prompt, with minimal residual sedative effects.

Nonhypnotic Therapeutic Applications

In addition to its clinical application as an IV induction drug, propofol has been shown to have beneficial effects that were not anticipated when the drug was initially introduced in 1989.³²

Antiemetic Effects

The incidence of postoperative nausea and vomiting is decreased when propofol is administered, regardless of the anesthetic technique.³² Subhypnotic doses of propofol (10-15 mg IV) may be used in the postanesthesia care unit to treat nausea and vomiting, particularly if it is not of vagal origin. In the postoperative period, the advantage of propofol is its rapid onset of action and the absence of serious side effects. Propofol is generally efficacious in treating postoperative nausea and vomiting at plasma concentrations that do not produce significant sedation. Simulations indicate that antiemetic plasma concentrations of propofol are achieved by a single IV dose of 10 mg followed by 10 µg/kg/minute.³³ Propofol in subhypnotic doses is effective against chemotherapy-induced nausea and vomiting. When administered to induce and maintain anesthesia, it is more effective than ondansetron in preventing postoperative nausea and vomiting.³⁴

Propofol has a profile of CNS depression that differs from other anesthetic drugs. In contrast to thiopental, for example, propofol uniformly depresses CNS structures, including subcortical centers. Most drugs of known antiemetic efficacy exert this effect via subcortical structures, and it is possible that propofol modulates subcortical pathways to inhibit nausea and vomiting or produces a direct depressant effect on the vomiting center. Nevertheless, the mechanisms mediating the antiemetic effects of propofol remain unknown. An antiemetic effect of propofol based on inhibition of dopaminergic activity is unlikely given that subhypnotic doses of propofol fail to increase plasma prolactin concentrations. A rapid and distinct increase in plasma prolactin concentrations is characteristic of drugs that block the dopaminergic system.³⁵ Subhypnotic doses of propofol that are effective as an antiemetic do not inhibit gastric emptying and propofol is not considered a prokinetic drug.³⁶

Antipruritic Effects

Propofol, 10 mg IV, is effective in the treatment of pruritus associated with neuraxial opioids or cholestasis.³⁷ The mechanism of the antipruritic effect may be related to the drug's ability to depress spinal cord activity. In this regard, there is evidence that intrathecal opioids produce pruritus by excitation of neurons within the spinal cord.

Anticonvulsant Activity

Propofol possesses antiepileptic properties, presumably reflecting GABA-mediated presynaptic and postsynaptic inhibition of chloride ion channels. In this regard, propofol in doses of greater than 1 mg/kg IV decreases seizure duration 35% to 45% in patients undergoing electroconvulsive therapy.³⁸

Attenuation of Bronchoconstriction

Compared with thiopental, propofol decreases the prevalence of wheezing after induction of anesthesia and tracheal intubation in healthy and asthmatic patients ([Figure 5.2](#)).³⁹ However, a newer formulation of propofol uses metabisulfite as a preservative. Metabisulfite may cause bronchoconstriction in asthmatic patients. In an animal model, propofol without metabisulfite attenuated vagal nerve stimulation-induced bronchoconstriction, whereas propofol with metabisulfite did not attenuate vagally or methacholine-induced bronchoconstriction and metabisulfite alone caused increases in airway responsiveness.⁴⁰ Following tracheal intubation, in patients with a history of smoking, airway resistance was increased more following the administration of propofol containing metabisulfite than ethylenediaminetetraacetic acid.⁴¹ Therefore, the preservative used for propofol can have effects on its ability to attenuate bronchoconstriction. Nevertheless, propofol-induced bronchoconstriction has been described in patients with allergy histories. The formulation of propofol administered to these patients was Diprivan-containing soybean oil, glycerin, yolk lecithin, and sodium edetate.⁴²

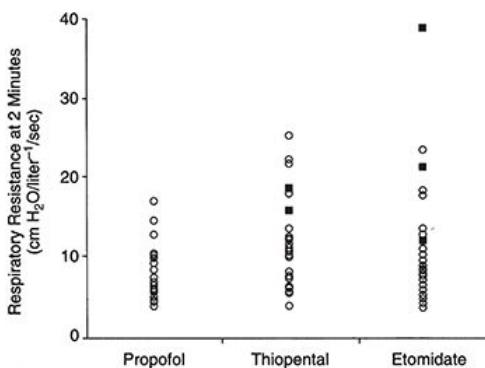

FIGURE 5.2 Respiratory resistance after tracheal intubation is less after induction of anesthesia with propofol than after induction of anesthesia with thiopental or etomidate. The solid squares represent four patients in whom audible wheezing was present. *Reprinted with permission from Eames WO, Rooke GA, Wu RS, et al. Comparison of the effects of etomidate, propofol, and thiopental on respiratory resistance after tracheal intubation. Anesthesiology. 1996;84(6):1307-1311. Interaction With Opioids

In clinical practice, there is an interaction between propofol and opioid analgesics. These interactions occur both at pharmacokinetic and pharmacodynamic levels. For example, the alfentanil and propofol have an effect on each other's plasma concentrations through changes in elimination and distribution clearance⁴³; coadministration of propofol increases remifentanil concentrations through both a decrease in the central V_d and distributional clearance of remifentanil by 40% and elimination clearance by 15%.⁴⁴ Coadministration of propofol and any of the phenylpiperidines (fentanyl and its congeners) show a synergistic pharmacodynamic interaction. In general, the higher the opioid dose used, the lower the propofol dose required to assure adequate anesthesia.⁴⁴ In the presence of short-acting opioids, it is generally wise to use low-dose propofol infusion regimens. In contrast, in the presence of a longer acting opioids like fentanyl, a high propofol dose/low fentanyl dose anesthetic may lead to a stable anesthetic with a more rapid recovery, postoperatively.

Effects on Organ Systems

Central Nervous System

Propofol decreases cerebral metabolic rate for oxygen ($CMRO_2$), cerebral blood flow, and intracranial pressure (ICP).^{45,46} Administration of propofol to produce sedation in patients with intracranial space-occupying lesions does not increase ICP.⁴⁷ However, large-dose propofol may decrease systemic blood pressure sufficiently to also decrease cerebral perfusion pressure. Cerebrovascular autoregulation in response to changes in systemic blood pressure and reactivity of the cerebral blood flow to changes in $Paco_2$ are not affected by propofol. Cerebral blood flow velocity changes in parallel with changes in $Paco_2$ in the presence of propofol and midazolam (Figure 5.3).⁴⁸ Propofol produces cortical electroencephalographic (EEG) changes that are similar to those of thiopental, including the ability of high doses to produce burst suppression.⁴⁹ Cortical somatosensory evoked potentials as used for monitoring spinal cord function are not significantly modified in the presence of propofol alone but the addition of nitrous oxide or a volatile anesthetic results in decreased amplitude.⁵⁰ Propofol does not interfere with the adequacy of electrocorticographic recordings during awake craniotomy performed for the management of refractory epilepsy, provided administration is discontinued at least 15 minutes before recording.⁵¹ At equal levels of sedation, propofol produces the same degree of memory impairment as midazolam, whereas thiopental has less memory effect and fentanyl has none.⁵²

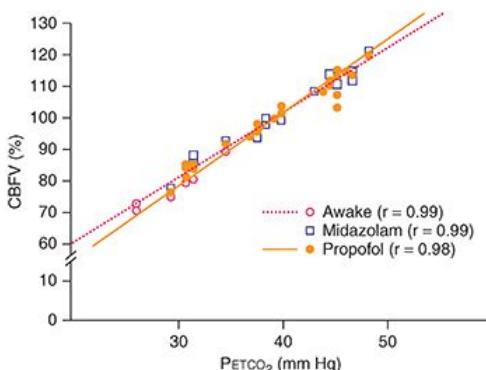

FIGURE 5.3 Changes in the end-tidal PCO_2 (PETCO_2) produce corresponding changes in the cerebral blood flow velocity (CBFV) during infusion of propofol or midazolam. *Reprinted with permission from Streb S, Kaufmann M, Guardiola PM, et al. Cerebral vasomotor responsiveness to carbon dioxide is preserved during propofol and midazolam anesthesia in humans. Anesth Analg. 1994;78(5):884-888. Development of tolerance to drugs that depress the CNS is a common finding, occurring with repeated exposure to opioids, sedative-hypnotic drugs, ketamine, and nitrous oxide. However, tolerance to propofol does not develop in children undergoing repeated exposure to the drug during radiation therapy.⁵³

Cardiovascular System

Propofol produces decreases in systemic blood pressure, which are greater than those evoked by comparable doses of thiopental (Figure 5.4).⁵⁴ These decreases in blood pressure are often accompanied by corresponding changes in cardiac output and systemic vascular resistance. The relaxation of vascular smooth muscle produced by propofol is primarily due to inhibition of sympathetic vasoconstrictor nerve activity.⁵⁵ A negative inotropic effect of propofol may result from a decrease in intracellular calcium availability secondary to inhibition of transsarcolemmal calcium influx. Stimulation produced by direct laryngoscopy and intubation of the trachea reverses the blood pressure effects of propofol. Propofol also effectively blunts the hypertensive response to placement of a laryngeal mask airway. The impact of propofol on desflurane-mediated sympathetic nervous system activation is unclear. In one report, propofol 2 mg/kg IV blunted the increase in epinephrine concentration, which accompanied a sudden increase in the delivered desflurane concentration but did not attenuate the transient cardiovascular response.⁵⁶ Conversely, in another report, induction of anesthesia with propofol, but not etomidate, blunted the sympathetic nervous system activation and systemic hypertension associated with the introduction of rapidly increasing inhaled concentrations of desflurane.⁵⁷ The blood pressure effects of propofol may be exaggerated in hypovolemic patients, elderly patients, and patients with compromised left ventricular function. Adequate hydration before rapid IV administration of propofol is recommended to minimize the blood pressure reduction.

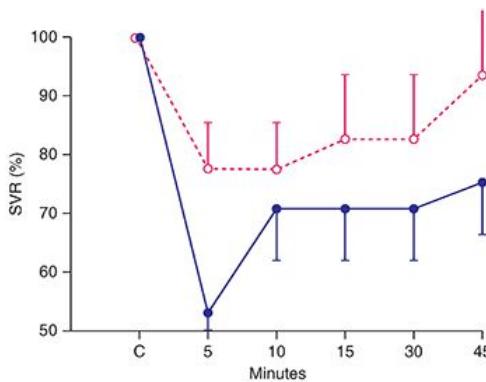

FIGURE 5.4 Comparative changes (expressed in % changes [mean \pm SD]) from control values (C) in systemic vascular resistance (SVR) in the 45 minutes after the administration of thiopental, 5 mg/kg IV (open circles), or propofol, 2.5 mg/kg IV (solid circles). *Reprinted with permission from Rouby JJ, Andreev A, Léger P, et al. Peripheral vascular effects of thiopental and propofol in humans with artificial hearts. Anesthesiology. 1991;75(1):32-42. Copyright © 1991 American Society of Anesthesiologists, Inc.*

Addition of nitrous oxide does not alter the cardiovascular effects of propofol. The pressor response to ephedrine is augmented by propofol ([Figure 5.5](#)).⁵⁸

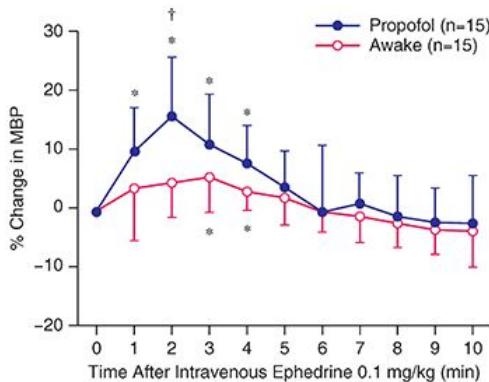

FIGURE 5.5 Mean blood pressure (MBP) increased more following administration of ephedrine (0.1 mg/kg intravenously) to patients during propofol anesthesia than when awake. *Reprinted with permission from Kanaya N, Satoh H, Seki S, et al. Propofol anesthesia enhances the pressor response to intravenous ephedrine. Anesth Analg. 2002;94(5):1207-1211. Copyright © 2002 International Anesthesia Research Society.*

Despite decreases in systemic blood pressure, heart rate typically remains unchanged. Baroreceptor reflex control of heart rate may be depressed by propofol.⁵⁹ However, bradycardia and asystole have been observed after induction of anesthesia with propofol, resulting in the occasional recommendation that anticholinergic drugs be administered when vagal stimulation is likely to occur in association with administration of propofol (see the “[Bradycardia-Related Death](#)” section). Propofol may decrease sympathetic nervous system activity to a greater extent than parasympathetic nervous system activity, resulting in a predominance of parasympathetic activity.¹ Propofol does not alter sinoatrial or atrioventricular node function in normal patients or in patients with Wolff-Parkinson-White syndrome, thus making it an acceptable drug to administer during ablative procedures.^{60,61} Nevertheless, there is a case report of a patient with Wolff-Parkinson-White syndrome in whom delta waves on the electrocardiogram disappeared during infusion of propofol.⁶² Unlike sevoflurane, propofol does not prolong the QTc interval on the electrocardiogram.⁶³

Bradycardia-Related Death

Profound bradycardia and asystole after administration of propofol have been described in healthy adult patients, despite prophylactic anticholinergics.⁶⁴⁻⁶⁷ The risk of bradycardia-related death during propofol anesthesia has been estimated to be 1.4 in 100,000. Propofol anesthesia, compared with other anesthetics, increases the incidence of the oculocardiac reflex in pediatric strabismus surgery, despite prior administration of anticholinergics.⁶⁸ Heart rate responses to IV administration of atropine are attenuated in patients receiving propofol compared with awake patients ([Figure 5.6](#)).⁶⁹ This decreased responsiveness to atropine cannot be effectively overcome by larger doses of atropine suggesting that propofol may induce suppression of sympathetic nervous system activity. Treatment of propofol-induced bradycardia may require treatment with a direct β -agonist such as isoproterenol.

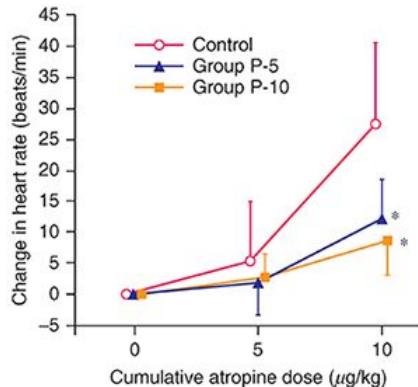

FIGURE 5.6 Heart rate responses to cumulative intravenous (IV) atropine doses in patients receiving no propofol, patients receiving 5 mg/kg/hour IV (group P-5), and patients receiving 10 mg/kg/hour IV (group P-10). Mean \pm standard deviation. * $P < .05$ compared with the control group. Reprinted with permission from Horiguchi T, Nishikawa T. Lungs

Propofol produces dose-dependent depression of ventilation, with apnea occurring in 25% to 35% of patients after induction of anesthesia with propofol.⁷⁰ Opioids administered with the preoperative medication enhances ventilatory depressant. Painful surgical stimulation is likely to counteract the ventilatory depressant effects of propofol. A maintenance infusion of propofol decreases tidal volume and frequency of breathing. The ventilatory response to arterial hypoxemia are also decreased by propofol due to an effect at the central chemoreceptors.⁷¹ Likewise, propofol at sedative doses significantly decreases the slope and causes a downward shift of the ventilatory response curve to hypoxia.⁷² Hypoxic pulmonary vasoconstriction seems to remain intact in patients receiving propofol.

Hepatic and Renal Function

Propofol does not normally affect hepatic or renal function as reflected by measurements of liver transaminase enzymes or creatinine concentrations. Prolonged infusions of propofol have been associated with hepatocellular injury accompanied by lactic acidosis, bradycardias, and rhabdomyolysis as part of the propofol infusion syndrome described in the following text. In rare instances, presumed propofol-induced hepatocellular injury following uneventful anesthesia and surgery has been described.⁷³ Prolonged infusions of propofol may also result in excretion of green urine, reflecting the presence of phenols in the urine. This discoloration does not alter renal function. Urinary uric acid excretion is increased after administration of propofol and may manifest as cloudy urine when the uric acid crystallizes in the urine under conditions of low pH and temperature.²⁴ This cloudy urine is not considered to be detrimental or indicative of adverse renal effects of propofol.

Intraocular Pressure

Laparoscopic surgery is associated with increased intraocular pressure, and some consider laparoscopic surgery with the head-down position a risk in the presence of preexisting ocular hypertension. In this regard, propofol is associated with significant decreases in intraocular pressure that occur immediately after induction of anesthesia and are sustained during tracheal intubation.¹ Total IV anesthesia with propofol for laparoscopic surgery was associated with lower intraocular pressures than in patients undergoing similar surgery with isoflurane anesthesia (Figure 5.7).⁷⁴

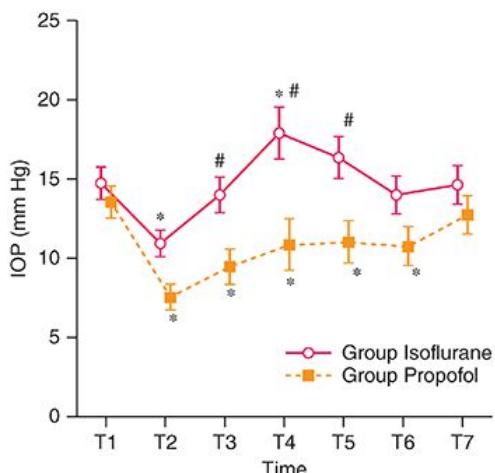

FIGURE 5.7 Changes in intraocular pressure (IOP) in patients receiving isoflurane or propofol. Measurements were made before induction of anesthesia (T1), after induction of anesthesia (T2), after pneumoperitoneum (T3), after head-down position (T4), after return to neutral supine position (T5), after evacuation of pneumoperitoneum (T6), and in the postanesthesia care unit (T7). Abbreviations: *, significant difference compared with T1; #, significant difference between the isoflurane and propofol groups. Reprinted with permission from Mowafi HA, Al-Ghamdi A, Rushood A. Intraocular pressure changes during laparoscopy in patients anesthetized with propofol total intravenous anesthesia versus isoflurane inhaled anesthesia. Anesth Analg. 2003;97(2):471-474. Copyright © 2003 International Anesthesia Research Society.

Coagulation

Propofol does not alter tests of coagulation or platelet function. This is reassuring because the emulsion in which propofol is dispensed resembles intralipid, which has been associated with alterations in blood coagulation. However, propofol inhibits platelet aggregation that is induced by proinflammatory lipid mediators including thromboxane A₂ and platelet-activating factor.⁷⁵

Other Side Effects

Side effects of propofol may reflect the parent drug or actions attributed to the oil-in-water emulsion formulation. For example, some of the side effects of propofol (bradycardia, risk of infection, pain on injection, hypertriglyceridemia with prolonged administration, potential for pulmonary embolism) are believed to be due in large part to the lipid emulsion formulation.^{8,9}

Allergic Reactions

Allergenic components of propofol include the phenyl nucleus and diisopropyl side chain.⁷⁶ Patients who develop evidence of anaphylaxis on first exposure to propofol may have been previously sensitized to the diisopropyl radical, which is present in many dermatologic preparations. Likewise, the phenol nucleus is common to many drugs. Indeed, anaphylaxis to propofol during the first exposure to this drug has been observed, especially in patients with a history of other drug allergies, often to neuromuscular blocking drugs.⁷⁷ Propofol-induced bronchoconstriction has been described in patients with allergy histories.⁴² The formulation of propofol administered to these patients was Diprivan-containing soybean oil, glycerin, yolk lecithin, and sodium edetate.

Lactic Acidosis

Lactic acidosis (“propofol infusion syndrome”) has been described in pediatric and adult patients receiving prolonged high-dose infusions of propofol (>75 µg/kg/minute) for longer than 24 hours.^{78,79} Severe, refractory, and fatal bradycardia in children in the ICU has been observed with long-term propofol

sedation.^{80,81} Even short-term infusions of propofol (Diprivan) for surgical anesthesia have been associated with development of metabolic acidosis.^{82,83} Unexpected tachycardia occurring during propofol anesthesia should prompt laboratory evaluation for metabolic (lactic) acidosis. Measurement of arterial blood gases and serum lactate concentrations is recommended. Documentation of an increased ion gap is useful, followed by prompt discontinuation of propofol administration.⁸⁴ If the results of laboratory studies are delayed, propofol should be discontinued while awaiting results. Metabolic acidosis in its early stages is reversible with discontinuation of propofol administration, although cardiogenic shock requiring assistance with extracorporeal membrane oxygenation has been described in a patient receiving a prolonged propofol infusion (Diprivan) for a craniotomy.⁸⁵

The mechanism for sporadic propofol-induced metabolic acidosis is unclear but may reflect poisoning (cytotoxic hypoxia) of the electron transport chain and impaired oxidation of long chain fatty acids by propofol or a propofol metabolite in uniquely susceptible patients.⁸⁶ Indeed, this propofol infusion syndrome mimics the mitochondrial myopathies, in which there are specific defects in the mitochondrial respiratory chain associated with specific mitochondrial DNA abnormalities, resulting in abnormal lipid metabolism in cardiac and skeletal muscles. These individuals, who are probably genetically susceptible, remain asymptomatic until a triggering event (sepsis, malnutrition) intervenes. The differential diagnosis when propofol-induced lactic acidosis is suspected includes hyperchloremic metabolic acidosis associated with large volume infusions of 0.9% saline and metabolic acidosis associated with excessive generation of organic acids, such as lactate and ketones (diabetic acidosis, release of a tourniquet). Measurement of the anion gap and individual measurements of anions and organic acids will differentiate hyperchloremic metabolic acidosis from lactic acidosis.

Proconvulsant Activity

The majority of reported propofol-induced “seizures” during induction of anesthesia or emergence from anesthesia reflect spontaneous excitatory movements of subcortical origin.³² These responses are not thought to be due to cortical epileptic activity. Prolonged myoclonus associated with meningismus has been associated with propofol administration.⁸⁷ The incidence of excitatory movements and associated electrocardiogram changes are low after the administration of propofol.⁸⁸ Propofol resembles thiopental in that it does not produce seizure activity on the EEG when administered to patients with epilepsy, including those undergoing cortical resection.⁴⁹ There appears to be no reason to avoid propofol for sedation, induction, and maintenance of anesthesia in patients with known seizures.¹²

Abuse Potential

Intense dreaming activity, amorous behavior, and hallucinations have been reported during recovery from low-dose infusions of propofol.³² Addiction to virtually all opioids and hypnotics, including propofol, has been described.^{89,90} The death of music pop star Michael Jackson in 2009 from an overdose of propofol he was receiving as a sleep aid has brought the dangers of propofol misuse to public attention.⁹¹

Bacterial Growth

Propofol strongly supports the growth of *Escherichia coli* and *Pseudomonas aeruginosa*, whereas the solvent (Intralipid) appears to be bactericidal for these same organisms and bacteriostatic for *Candida albicans*.⁹² Clusters of postoperative surgical infections manifesting as temperature elevations have been attributed to extrinsic contamination of propofol.^{93,94} For this reason, it is recommended that (1) an aseptic technique be used in handling propofol as reflected by disinfecting the ampule neck surface or vial rubber stopper with 70% isopropyl alcohol, (2) the contents of the ampule containing propofol should be withdrawn into a sterile syringe immediately after opening and administered promptly, and (3) the contents of an opened ampule must be discarded if they are not used within 6 hours. In the ICU, the tubing and any unused portion of propofol must be discarded after 12 hours. Despite these concerns, there is evidence that when propofol is aseptically drawn into an uncapped syringe, it will remain sterile at room temperature for several days.⁹⁵ Given the cost

of propofol, some have questioned the logic of discarding unused drug at the end of an anesthetic or 6 hours, whichever occurs sooner.³

Antioxidant Properties

Propofol has potent antioxidant properties that resemble those of the endogenous antioxidant vitamin E.^{96,97} Like vitamin E, propofol contains a phenolic hydroxyl group that scavenges free radicals and inhibits lipid peroxidation. A neuroprotective effect of propofol may be at least partially related to the antioxidant potential of propofol's phenol ring structure. For example, propofol reacts with lipid peroxy radicals and thus inhibits lipid peroxidation by forming relatively stable propofol phenoxy radicals. In addition, propofol also scavenges peroxy nitrite, which is one of the most potent reactive metabolites for the initiation of lipid peroxidation. Because peroxy nitrite is a potent bactericidal agent, it is likely that the peroxy nitrite-scavenging activity of propofol contributes to this anesthetic's known ability to suppress phagocytosis.⁹⁸ Conversely, propofol might be beneficial in disease states, such as acute lung injury, in which peroxy nitrite formation is thought to play an important role.⁹⁹

Reintroduction of molecular oxygen into previously ischemic tissues (removal of an aortic cross-clamp) can further damage partially injured cells (reperfusion injury). Oxygen leads to the formation of free oxygen radicals, which react with polyunsaturated fatty acids of cell membranes resulting in disruption of cell membranes. Myocardial cell injury can cause postischemic dysfunction, myocardial stunning, and reperfusion cardiac dysrhythmias. Propofol strongly attenuates lipid peroxidation during coronary artery bypass graft surgery.¹⁰⁰

Pain on Injection

Pain on injection is the most commonly reported adverse event associated with propofol administration to awake patients. This unpleasant side effect of propofol occurs in less than 10% of patients when the drug is injected into a large vein rather than a dorsum vein on the hand. Preceding the propofol with (using the same injection site as for propofol) 1% lidocaine or by prior administration of a potent short-acting opioid decreases the incidence of discomfort experienced by the patient. The incidence of thrombosis or phlebitis is usually less than 1%. Changing the composition of the carrier fat emulsion for propofol to long and medium chain triglycerides decreases the incidence of pain on injection.¹⁰¹

Accidental intra-arterial injection of propofol has been described as producing severe pain but no vascular compromise.¹⁰² In an animal model, propofol-exposed arteries showed no changes in the vascular smooth muscle, and the endothelium was not damaged.¹⁰³

Airway Protection

Inhaled and injected anesthetic drugs alter pharyngeal function with the associated risk of impaired upper airway protection and pulmonary aspiration. Subhypnotic concentrations of propofol, isoflurane, and sevoflurane decrease pharyngeal contraction force.¹⁰⁴

Miscellaneous Effects

Propofol does not trigger malignant hyperthermia and has been administered to patients with hereditary coproporphyrin without incident.¹⁰⁵⁻¹⁰⁷ Secretion of cortisol is not influenced by propofol, even when administered for prolonged periods in the ICU. Temporary abolition of tremors in patients with Parkinson disease may occur after the administration of propofol.¹⁰⁸ For this reason, propofol may not be ideally suited for patients undergoing stereotactic neurosurgery during which the symptom is required to identify the correct anatomic location.

Etomidate

Etomidate is a carboxylated imidazole-containing compound that is chemically unrelated to any other drug used for the IV induction of anesthesia.¹⁰⁹ The imidazole nucleus renders etomidate, like midazolam, water-soluble at an acidic pH and lipid-soluble at physiologic pH.

Commercial Preparation

The original formulation of etomidate included 35% propylene glycol (pH 6.9) contributing to a high incidence of pain during IV injection and occasional venous irritation. This has been changed to a fat emulsion, which has virtually abolished pain on injection and venous irritation, whereas the incidence of myoclonus remains unchanged. An oral formulation of etomidate for transmucosal delivery has been shown to produce dose-dependent sedation.¹¹⁰ Administration through the oral mucosa results in systemic absorption while bypassing hepatic metabolism. As a result, higher blood concentrations are achieved more rapidly compared with drug that is administered by mouth.

Mechanism of Action

Etomidate is unique among injected and inhaled anesthetics in being administered as a single isomer.¹⁰⁹ The anesthetic effect of etomidate resides predominantly in the R(+) isomer, which is approximately 5 times as potent as the S(−) isomer. In contrast to barbiturates, etomidate appears to be relatively selective as a modulator of GABA_A receptors. Stereoselectivity of etomidate supports the concept that GABA_A receptors are the site of action of etomidate. Etomidate exerts its effects on GABA_A receptors by binding directly to a specific site or sites on the protein and enhancing the affinity of the inhibitory neurotransmitter (GABA) for these receptors.¹⁰⁹ Antagonism of steroid-induced psychosis by etomidate is consistent with enhancement of GABA receptor function by this anesthetic drug.¹¹¹ Etomidate is not known to modulate other ligand-gated ion channels in the brain at clinically relevant concentrations.

Pharmacokinetics

The V_d of etomidate is large, suggesting considerable tissue uptake (see **Table 5.1**). Distribution of etomidate throughout body water is favored by its moderate lipid solubility and existence as a weak base (pK 4.2, pH 8.2, 99% unionized at physiologic pH). Etomidate penetrates the brain rapidly, reaching peak levels within 1 minute after IV injection. About 76% of etomidate is bound to albumin independently of the plasma concentration of the drug. Decreases in plasma albumin concentrations result in dramatic increases in the unbound pharmacologically active fraction of etomidate in the plasma. Prompt awakening after a single dose of etomidate principally reflects the redistribution of the drug from brain to inactive tissue sites. Rapid metabolism is also likely to contribute to prompt recovery.

Metabolism

Etomidate is rapidly metabolized by hydrolysis of the ethyl ester side chain to its carboxylic acid ester, resulting in a water-soluble, pharmacologically inactive compound. Hepatic microsomal enzymes and plasma esterases are responsible for this hydrolysis. Hydrolysis is nearly complete, as evidenced by recovery of less than 3% of an administered dose of etomidate as unchanged drug in urine. About 85% of a single IV dose of etomidate can be accounted for as the carboxylic acid ester metabolite in urine, whereas another 10% to 13% is present as this metabolite in the bile. Overall, the clearance of etomidate is somewhat slower than that for propofol (18-25 mL/kg/minute vs 20-30 mL/kg/minute, respectively). The V_d for etomidate is about half that of propofol (2.5-4.5 L/kg vs 2-10 L/kg, respectively).¹¹²⁻¹¹⁴ Slower clearance will delay elimination, while a small V_d will result in more rapid elimination. In the case of etomidate, the effect of volume dominates, and etomidate has a shorter terminal elimination half-life (3-5 hours) than propofol (4-7 hours). Likewise, the context-sensitive half-time (the time for the plasma level of the drug to drop 50% after cessation of infusion) of etomidate is less likely to be increased by continuous infusion as compared with propofol.

Cardiopulmonary Bypass

Institution of hypothermic cardiopulmonary bypass causes an initial decrease of about 34% in the plasma etomidate concentration that then returns to within 11% of the pre-bypass value only to be followed by a further decrease with rewarming.²⁶ The return of the plasma concentration toward pre-bypass levels is attributed to decreased metabolism, and the subsequent decrease on rewarming is attributed to increased

metabolism. In addition, hepatic blood flow changes during cardiopulmonary bypass may alter metabolism, as etomidate is a high-hepatic extraction drug.

Clinical Uses

Etomidate may be viewed as an alternative to propofol or barbiturates for the IV induction of anesthesia, especially in the presence of an unstable cardiovascular system. After a standard induction dose of 0.2 to 0.4 mg/kg IV, the onset of unconsciousness occurs within one arm-to-brain circulation time. Involuntary myoclonic movements are common during the induction period as a result of alteration in the balance of inhibitory and excitatory influences on the thalamocortical tract. The frequency of this myoclonic-like activity can be attenuated by prior administration of an opioid. Awakening after a single IV dose of etomidate is more rapid than after barbiturates and similar to that of propofol. This has been tested in numerous settings, including induction of anesthesia for electroconvulsive therapy³⁶ and for cardioversion,¹¹⁵ where awakening occurs within 5 to 15 minutes after doses of etomidate ranging from 0.1 to 0.3 mg/kg and propofol ranging from 0.75 to 1.5 mg/kg,¹¹⁵ and there is little or no evidence of a hangover or cumulative drug effect. Full recovery of psychomotor function after administration of etomidate is somewhat slower than following use of propofol. The duration of action is prolonged by increasing the dose of etomidate or administering the drug as a continuous infusion. As with barbiturates and propofol, analgesia is not produced by etomidate. For this reason, administration of an opioid before induction of anesthesia with etomidate may be useful to blunt the hemodynamic responses evoked by direct laryngoscopy and tracheal intubation. Etomidate, 0.15 to 0.3 mg/kg IV, has minimal effects on the duration of electrically induced seizures and thus may serve as an alternative to drugs that decrease the duration of seizures (propofol, thiopental) in patients undergoing electroconvulsive therapy.³⁸

The principal limiting factor in the clinical use of etomidate for induction of anesthesia is the ability of this drug to transiently depress adrenocortical function (see the “[Adrenocortical Suppression](#)” section). It is widely viewed that postoperative nausea and vomiting is increased in patients receiving etomidate for induction of anesthesia.¹¹⁶ Nevertheless, comparison of etomidate with propofol did not document an increased incidence of nausea and vomiting in the first 24 hours after surgery in patients receiving etomidate.¹¹⁷

Side Effects

Central Nervous System

Etomidate is a potent direct cerebral vasoconstrictor that decreases cerebral blood flow and CMRO₂ 35% to 45%.¹¹⁸ As a result, previously increased ICP is lowered by etomidate. These effects of etomidate are similar to those changes produced by comparable doses of propofol. Suppression of adrenocortical function limits the clinical usefulness for long-term treatment of intracranial hypertension (see the “[Adrenocortical Suppression](#)” section).

Etomidate produces a pattern on the EEG that is similar to thiopental and propofol. However, the frequency of excitatory spikes on the EEG is greater with etomidate than with propofol, thiopental, and methohexital, suggesting caution in administration of etomidate to patients with a history of seizures.⁸⁸ Like methohexital, etomidate may activate seizure foci, manifesting as fast activity on the EEG.¹¹⁹ For this reason, etomidate should also be used with caution in patients with focal epilepsy. Conversely, this characteristic has been observed to facilitate localization of seizure foci in patients undergoing cortical resection of epileptogenic tissue. Etomidate also possesses anticonvulsant properties and has been used to terminate status epilepticus. Etomidate has been observed to augment the amplitude of somatosensory evoked potentials, making monitoring of these responses more reliable.¹²⁰

Cardiovascular System

Cardiovascular stability is characteristic of induction of anesthesia with 0.3 mg/kg IV of etomidate. After this dose of etomidate, there are minimal changes in heart rate, stroke volume, or cardiac output, whereas mean arterial blood pressure may decrease up to 15% because of decreases in systemic vascular resistance. The

decrease in systemic blood pressure in parallel with changes in systemic vascular resistance suggests that administration of etomidate to acutely hypovolemic patients could result in sudden hypotension. When an induction dose of etomidate is 0.45 mg/kg IV, significant decreases in systemic blood pressure and cardiac output may occur.¹²¹ During induction of patients undergoing elective cardiac surgery, propofol caused a significantly greater decline in mean arterial pressure (MAP) than etomidate, while changes in other hemodynamic parameters were not significantly changed.¹²²

Effects of etomidate on myocardial contractility are important to consider, as this drug has been proposed for induction of anesthesia in patients with little or no cardiac reserve. It is difficult to document anesthetic-induced negative inotropic effects *in vivo* because of concurrent changes in preload, afterload, sympathetic nervous system activity, and baroreceptor reflex activity. Therefore, direct effects of anesthetics on intrinsic myocardial contractility may be more accurately assessed *in vitro*. Etomidate causes dose-dependent decreases in developed tension in isolated cardiac muscle obtained from patients undergoing coronary artery bypass graft operations or cardiac transplantation (Figure 5.8).¹²³ This depression was reversible with β -adrenergic stimulation. Nevertheless, concentrations required to produce these negative inotropic effects are in excess of those achieved with clinical use. Thus, etomidate may differ from most other IV anesthetics in that depressive effects on myocardial contractility are minimal at concentrations needed for the production of anesthesia. Hepatic and renal functions tests are not altered by etomidate. Intraocular pressure is decreased by etomidate to a similar degree as by propofol. Etomidate does not result in detrimental effects when accidentally injected into an artery.

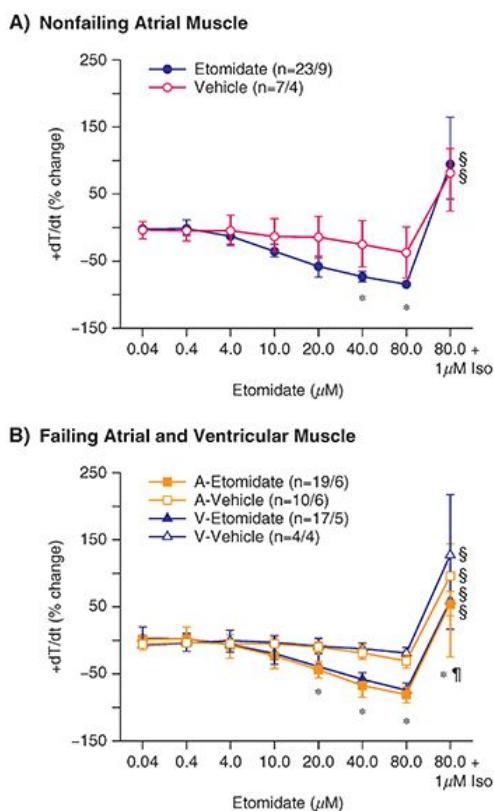

FIGURE 5.8 Effects of etomidate on maximal rate of contraction ($+dT/dt$) in nonfailing atrial muscle (A) and in failing atrial and ventricular muscle (B). Mean \pm standard deviation. * $P < .05$ versus vehicle.

Ventilation

The depressant effects of etomidate on ventilation seem to be less than those of barbiturates and propofol, although apnea may occasionally accompany a rapid IV injection of the drug.¹²⁴ In the majority of patients, etomidate-induced decreases in tidal volume are offset by compensatory increases in the frequency of breathing. These effects on ventilation are transient, lasting only 3 to 5 minutes. Etomidate may stimulate ventilation independently of the medullary centers that normally respond to carbon dioxide. For this reason, etomidate may be useful when maintenance of spontaneous ventilation is desirable. However, careful analysis of the impact of equipotent doses of etomidate on respiration in comparison to other sedative-hypnotics has not been conducted. A recent Cochrane Database review of 23 trials comparing various anesthetic and sedative agents for cardioversion concluded that there were no discernible differences among agents or combinations of agents using in this common setting.¹²⁵ Depression of ventilation may be exaggerated when etomidate is combined with inhaled anesthetics or opioids during continuous infusion techniques.

Pain on Injection

Pain on injection and venous irritation has been virtually eliminated with use of etomidate in a lipid emulsion vehicle rather than propylene glycol.

Myoclonus

Commonly administered IV anesthetics can cause excitatory effects that may manifest as spontaneous movements, such as myoclonus, dystonia, and tremor. These spontaneous movements, particularly myoclonus, occur in 50% to 80% of patients receiving etomidate in the absence of premedication.⁸⁸ In one report, 87% of patients receiving etomidate developed excitatory effects, of which 69% were myoclonic. Multiple spikes appeared on the EEG of 22% of these patients.⁸⁸ In this same report, the frequency of excitatory effects was 17% after thiopental, 13% after methohexital, and 6% after propofol, and none of the patients treated with other drugs developed myoclonus with spike activity on the EEG.⁸⁸ Inclusion of atropine in the preoperative medication may suppress spike activity on the EEG associated with the administration of etomidate. Prior administration of an opioid (fentanyl, 1-2 µg/kg IV) or a benzodiazepine may decrease the incidence of myoclonus associated with administration of etomidate. Furthermore, the incidence and intensity of myoclonus following the administration of etomidate is dose related and suppressed by pretreatment with small doses of etomidate (0.03-0.075 mg/kg IV) before administration of the induction dose.¹²⁶

The mechanism of etomidate-induced myoclonus appears to be disinhibition of subcortical structures that normally suppress extrapyramidal motor activity. In many patients, excitatory movements are coincident with the early slow phase of the EEG, which corresponds to the beginning of deep anesthesia.⁸⁸ It is possible that myoclonus could occur on awakening if the extrapyramidal system emerged more quickly than the cortex that inhibits it.¹²⁷ Others have not documented seizure-like activity on the EEG in association with etomidate-induced myoclonus.¹²⁶

Adrenocortical Suppression

Etomidate causes adrenocortical suppression by producing a dose-dependent inhibition of the conversion of cholesterol to cortisol (**Figure 5.9**).^{128,129} The specific enzyme inhibited by etomidate appears to be 11-β-hydroxylase as evidenced by the accumulation of 11-deoxycorticosterone.¹³⁰ This enzyme inhibition lasts 4 to 8 hours after an induction dose of etomidate. Conceivably, patients experiencing sepsis or hemorrhage and who might require an intact cortisol response would be at a disadvantage should etomidate be administered.¹³¹ Conversely, suppression of adrenocortical function could be considered desirable from the standpoint of “stress-free” anesthesia. Nevertheless, in at least one report, it was not possible to demonstrate a difference in the plasma concentrations of cortisol, corticosterone, or adrenocorticotropic hormone in patients receiving a single dose of etomidate or thiopental.¹³² In a retrospective study of almost 1,700 trauma patients receiving a single induction dose of etomidate or another induction agent, use of etomidate had no impact on mortality, length of ICU stay, or duration of mechanical ventilation.¹³³ In a retrospective study of more than 3,000 cardiac surgical patients who received etomidate for induction of anesthesia, there was no

evidence to suggest that etomidate exposure was associated with severe hypotension, longer mechanical ventilation hours, longer length of hospital stay, or in-hospital mortality.¹³⁴ In contrast, another large-scale retrospective study demonstrated that anesthetic induction with etomidate, rather than propofol, was associated with increased 30-day mortality and cardiovascular morbidity after noncardiac surgery.¹³⁵ The clinical benefit of minimizing cardiac suppression should be carefully weighed against the potential for worsened long-term outcomes when using propofol in high-risk patients.

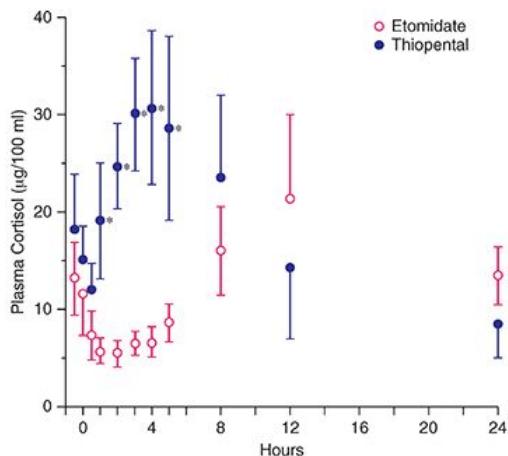

FIGURE 5.9 Etomidate, but not thiopental, is associated with decreases in the plasma concentrations of cortisol. Mean \pm standard deviation. * $P < .05$ compared with thiopental. Copyright © 1984 American Society of Anesthesiologists, Inc.

Allergic Reactions

The incidence of allergic reactions following administration of etomidate is very low.¹³⁶ When reactions have occurred, it is difficult to separate the role of etomidate from other concomitantly administered drugs (neuromuscular blocking drugs) that are more likely to evoke histamine release than etomidate.

Benzodiazepines

Benzodiazepines are drugs that exert, in slightly varying degrees, five principal pharmacologic effects: anxiolysis, sedation, anticonvulsant actions, spinal cord-mediated skeletal muscle relaxation, and anterograde amnesia (acquisition or encoding of new information).¹³⁷ The amnestic potency of benzodiazepines is greater than their sedative effects resulting in a longer duration of amnesia than sedation. Stored information (retrograde amnesia) is not altered by benzodiazepines.¹³⁸ Benzodiazepines do not produce adequate skeletal muscle relaxation for surgical procedures nor does their use influence the required dose of neuromuscular blocking drugs. The frequency of anxiety and insomnia in clinical practice combined with the efficacy of benzodiazepines has led to widespread use of these drugs. For example, it is estimated that 4% of the population uses “sleeping pills” sometime during a given year, and 0.4% of the population uses hypnotics for more than a year.¹³⁹ Although benzodiazepines are effective for the treatment of acute insomnia, their use for management of chronic insomnia is decreasing as their impact on cognitive function and mortality have emerged.¹⁴⁰ Compared with barbiturates, benzodiazepines have fewer tendencies to produce tolerance, less potential for abuse, a greater margin of safety, and elicit fewer and less serious drug interactions. Unlike barbiturates, benzodiazepines do not induce hepatic microsomal enzymes. Benzodiazepines are intrinsically far less addicting than opioids, cocaine, amphetamines, or barbiturates.

Midazolam is the most commonly used benzodiazepine in the perioperative period. Furthermore, the context-sensitive half-times for diazepam and lorazepam are prolonged; therefore, only midazolam is likely to be used for prolonged administration when prompt recovery is desired. However, the longer context-

sensitive half-time of lorazepam makes this drug an attractive choice to facilitate sedation of patients in critical care environments. Unlike other drugs administered IV to produce CNS effects, benzodiazepines, as a class of drugs, are unique in the availability of a specific pharmacologic antagonist, *flumazenil*. Structurally, benzodiazepines are similar and share many active metabolites. The duration of action of benzodiazepines is not linked to receptor events but rather is determined by the rate of metabolism and elimination. Importantly, benzodiazepines do not produce enzyme induction.

Mechanism of Action

Benzodiazepines appear to produce all their pharmacologic effects by facilitating the actions of GABA.¹⁴¹ Benzodiazepines do not activate the GABA_A receptors but rather enhance the affinity of the receptors for GABA (Figure 5.10).¹⁴² As a result of increased affinity for GABA, there is a greater probability of chloride channel openings, resulting in increased chloride conductance and hyperpolarization of the postsynaptic cell membrane. The postsynaptic neurons are thus rendered more resistant to excitation. This resistance to excitation is presumed to be the mechanism by which benzodiazepines produce anxiolysis, sedation, anterograde amnesia, alcohol potentiation, and anticonvulsant and skeletal muscle relaxant effects.

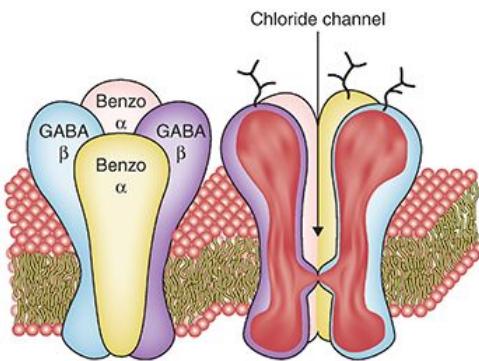

FIGURE 5.10 Model of the γ -aminobutyric acid (GABA) receptor forming a chloride channel. Benzodiazepines (benzo) attach selectively to α subunits and are presumed to facilitate the action of the inhibitory neurotransmitter GABA on α subunits. Reprinted with permission from Möhler H, Richards JG. *The benzodiazepine receptor: a pharmacologic control element of brain function*. Eur J Anaesthesiol Suppl. 1988;2:15-24. Copyright © 1988 European Society of Anaesthesiology.

Benzodiazepines interact with a site located between the α and γ subunits of the GABA_A receptor. The γ subunit is required for benzodiazepine binding. The α_1 - and α_5 -containing GABA_A receptors are important for sedation, whereas anxiolytic activity is due to interaction with α_2 and α_5 subunit-containing receptors.^{143,144} The α_1 -containing GABA_A receptors are the most abundant receptor subtypes accounting for approximately 60% of GABA_A receptors in the brain. The α_2 subunits have more restricted expression, principally in the hippocampus and amygdala. The α_5 -containing GABA_A receptors are principally extrasynaptic and are responsible for modulation of the resting membrane potential. This anatomic distribution of receptors is consistent with the minimal effects of these drugs outside the CNS (minimal circulatory effects). In the future, it may be possible to design benzodiazepines that selectively activate specific GABA_A receptor types to produce anxiolysis without sedation.

The GABA_A receptor is a large macromolecule that contains physically separate binding sites (principally α , β , and γ subunits) not only for GABA and the benzodiazepines but also barbiturates, etomidate, propofol, steroids, and alcohol. Acting on a single receptor at different binding sites, the benzodiazepines, barbiturates, and alcohol can produce synergistic effects to increase GABA_A receptor-mediated inhibition in the CNS. This property explains the pharmacologic synergy of these substances and, likewise, the risks of combined overdose, which can produce life-threatening CNS depression. This synergy is also the basis for pharmacologic cross-tolerance between these different classes of drugs and is consistent

with the clinical use of benzodiazepines as the first-choice drugs for detoxication from alcohol. Conversely, benzodiazepines have a built-in ceiling effect that prevents them from exceeding the physiologic maximum of GABA inhibition. The low toxicity of the benzodiazepines and their corresponding clinical safety is attributed to this limitation of their effect on GABAergic neurotransmission.

Differences in the onset and duration of action among commonly administered benzodiazepines reflect differences in potency (receptor binding affinity), lipid solubility (ability to cross the blood–brain barrier and redistribute to peripheral tissues), and pharmacokinetics (uptake, distribution, metabolism, and elimination). All benzodiazepines are highly lipid soluble and are highly bound to plasma proteins, especially albumin. Hypoalbuminemia owing to hepatic cirrhosis or chronic renal failure may increase the unbound fraction of benzodiazepines, resulting in enhanced clinical effects produced by these drugs. Following oral administration, benzodiazepines are highly absorbed from the gastrointestinal tract, and after IV injection, they rapidly enter the CNS and other highly perfused organs.

Nucleoside Transporter Systems

Benzodiazepines decrease adenosine degradation by inhibiting the nucleoside transporter, which is the principal mechanism whereby the effect of adenosine is terminated through reuptake into cells.¹⁴⁵ Adenosine is an important regulator of cardiac function (reduces cardiac oxygen demand by slowing heart rate and increases oxygen delivery by causing coronary vasodilation), and its physiologic effects convey cardioprotection during myocardial ischemia.

Electroencephalogram

The effects of benzodiazepines on the EEG resemble those of barbiturates in that α activity is decreased and low-voltage rapid β activity is increased. This shift from α to β activity occurs more in the frontal and rolandic areas with benzodiazepines, which, unlike the barbiturates, do not cause posterior spread. In common with barbiturates, however, tolerance to the effects of benzodiazepines on the EEG does not occur. Midazolam, in contrast to barbiturates and propofol, is unable to produce an isoelectric EEG.

Side Effects

Fatigue and drowsiness are the most common side effects in patients treated chronically with benzodiazepines. Sedation that could impair performance usually subsides within 2 weeks in patients chronically treated with benzodiazepines. Patients should be instructed to ingest benzodiazepines before meals and in the absence of antacids because meals and antacids may decrease absorption from the gastrointestinal tract. Chronic administration of benzodiazepines does not adversely affect systemic blood pressure, heart rate, or cardiac rhythm. Although effects on ventilation seem to be absent, it may be prudent to avoid these drugs in patients with chronic lung disease characterized by hypoventilation and/or decreased arterial oxygenation as they may interact with other medications to have adverse effects. Decreased motor coordination and impairment of cognitive function may occur, especially when benzodiazepines are used in combination with other CNS depressant drugs. Acute administration of benzodiazepines may produce transient anterograde amnesia, especially if there is concomitant ingestion of alcohol. For example, there have been reports of profound amnesia in travelers who have ingested triazolam combined with alcohol to facilitate sleep on airline flights.¹⁴⁶

Drug Interactions

Benzodiazepines exert synergistic sedative effects with other CNS depressants including alcohol, inhaled and injected anesthetics, opioids, and α_2 agonists. Anesthetic requirements for inhaled and injected anesthetics are decreased by benzodiazepines. Although benzodiazepines, especially midazolam, potentiate the ventilatory depressant effects of opioids, the analgesic actions of opioids are reduced by benzodiazepines.^{147,148} Indeed, antagonism of benzodiazepine effects with flumazenil results in enhanced analgesic effects of opioids. In patients receiving long-term opioid therapy for chronic pain, all-cause mortality is significantly higher in those receiving opioids and benzodiazepines concurrently.¹⁴⁹

Hypothalamic-Pituitary-Adrenal Axis

Benzodiazepine-induced suppression of the hypothalamic-pituitary-adrenal axis is supported by evidence of suppression of cortisol levels in treated patients.¹⁵⁰ In animals, alprazolam produces dose-dependent inhibition of adrenocorticotropic hormone and cortisol secretion.¹⁵¹ This suppression is enhanced compared with other benzodiazepines and may contribute to the unique efficacy of alprazolam in the treatment of major depression.

Dependence

Even therapeutic doses of benzodiazepines may produce dependence as evidenced by the onset of physical or psychologic symptoms after the dosage is decreased or the drug is discontinued. Symptoms of dependence may occur after more than 6 months of use of commonly prescribed low-potency benzodiazepines. It is misleading to consider dependence as evidence of addiction in the absence of inappropriate drug-seeking behaviors. Withdrawal symptoms (irritability, insomnia, tremulousness) have a time of onset that reflects the elimination half-time of the drug being discontinued. Typically, symptoms of withdrawal appear within 1 to 2 days for short-acting benzodiazepines and within 2 to 5 days for longer acting drugs.

Aging

Aging and liver disease affect glucuronidation less than oxidative metabolic pathways. Lorazepam, oxazepam, and temazepam are metabolized only by glucuronidation and have no active metabolites. For this reason, these benzodiazepines may be preferentially selected in elderly patients over benzodiazepines, such as diazepam, and that is metabolized by hepatic microsomal enzymes to form active metabolites. Elderly patients may also be intrinsically sensitive to benzodiazepines, suggesting that the enhanced response to these drugs that occurs with aging has pharmacodynamic as well as pharmacokinetic components. Long-term benzodiazepine administration may accelerate cognitive decline in elderly patients. Benzodiazepine withdrawal symptoms in the elderly include confusion. Postoperative confusion is more common in elderly long-term benzodiazepine users (daily use for >1 year) than in short-term users or nonusers of benzodiazepines.¹⁵²

Platelet Aggregation

Benzodiazepines may inhibit platelet-activating factor–induced aggregation resulting in drug-induced inhibition of platelet aggregation. Midazolam-induced inhibition of platelet aggregation may reflect conformational changes in platelet membranes.¹⁵³ Although benzodiazepines significantly inhibit platelet aggregation in vitro, they do not appear to affect the risk of hemorrhagic complications in patients with severe, chemotherapy-induced thrombocytopenia¹⁵⁴; the clinical significance of benzodiazepine-induced inhibition of platelet aggregation in the surgical arena is unclear.

Midazolam

Midazolam is a water-soluble benzodiazepine with an imidazole ring in its structure that accounts for stability in aqueous solutions and rapid metabolism.¹⁵⁵ This benzodiazepine has replaced diazepam for use in preoperative medication and conscious sedation. As with other benzodiazepines, the amnestic effects of midazolam are more potent than its sedative effects. Thus, patients may be awake following administration of midazolam but remain amnestic for events and conversations (postoperative instructions) for several hours.

Commercial Preparation

The pK of midazolam is 6.15, which permits the preparation of salts that are water soluble. The parenteral solution of midazolam used clinically is buffered to an acidic pH of 3.5. This is important because midazolam is characterized by a pH-dependent ring-opening phenomenon in which the ring remains open at pH values of less than 4, thus maintaining water solubility of the drug ([Figure 5.11](#)). The ring closes at pH values of greater than 4, as when the drug is exposed to physiologic pH, thus converting midazolam to a highly lipid-soluble drug (see [Figure 5.11](#)). The water solubility of midazolam obviates the need for a solubilizing preparation, such as propylene glycol required for other benzodiazepines that can produce venous irritation or

interfere with absorption after intramuscular (IM) injection. Indeed, midazolam causes minimal to no discomfort during or after IV or IM injection. Midazolam is compatible with lactated Ringer solution and can be mixed with the acidic salts of other drugs, including opioids and anticholinergics.

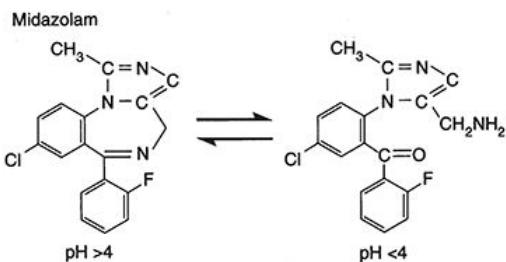

FIGURE 5.11 Reversible ring opening of midazolam above and below a pH of 4. The ring closes at a pH greater than 4, converting midazolam from a water-soluble to a lipid-soluble drug.

Pharmacokinetics

Midazolam undergoes rapid absorption from the gastrointestinal tract and prompt passage across the blood-brain barrier. Despite this prompt passage into the brain, midazolam is considered to have a relatively slow effect-site equilibration time (0.9–5.6 minutes) compared with other drugs such as propofol and thiopental. In this regard, IV doses of midazolam should be sufficiently spaced to permit the peak clinical effect to be appreciated before a repeat dose is considered. Only about 50% of an orally administered dose of midazolam reaches the systemic circulation, reflecting a substantial first-pass hepatic effect. As for most benzodiazepines, midazolam is extensively bound to plasma proteins; this binding is independent of the plasma concentration of midazolam ([Table 5.2](#)).^{155,156} The short duration of action of a single dose of midazolam is due to its lipid solubility, leading to rapid redistribution from the brain to inactive tissue sites as well as rapid hepatic clearance.

TABLE 5.2

Comparative pharmacology of benzodiazepines

	Equivalent dose (mg)	Volume of distribution (L/kg)	Protein binding (%)	Clearance (mL/kg/minute)	Elimination half-time (hour)
Midazolam	0.15-0.3	1.0-1.5	96-98	6-8	1-4
Diazepam	0.3-0.5	1.0-1.5	96-98	0.2-0.5	1-37
Lorazepam	0.05	0.8-1.3	96-98	0.7-1.0	10-20

The elimination half-time of midazolam is 1 to 4 hours, which is much shorter than that of diazepam (see [Table 5.2](#)).¹⁵⁵ The elimination half-time may be doubled in elderly patients, reflecting age-related decreases in hepatic blood flow and possibly enzyme activity. The V_d of midazolam and diazepam are similar, probably reflecting their similar lipid solubility and high degree of protein binding. Elderly and morbidly obese patients have an increased V_d of midazolam resulting from enhanced distribution of the drug into peripheral adipose tissues. The clearance of midazolam is more rapid than that of diazepam, as reflected by the context-sensitive half-time. As a result of these differences, the CNS effects of midazolam would be expected to be shorter than those of diazepam. Indeed, tests of mental function return to normal within 4 hours after the administration of midazolam in healthy young patients.

The institution of cardiopulmonary bypass is associated with a decrease in the plasma concentration of midazolam and an increase on termination of cardiopulmonary bypass.²⁶ These changes are attributed to redistribution of priming fluid into body tissues. In addition, benzodiazepines are extensively bound to protein, and changes in protein concentrations and pH that accompany institution and termination of cardiopulmonary bypass may have significant effects on the unbound and pharmacologically active fractions of these drugs. The elimination half-time of midazolam is prolonged after cardiopulmonary bypass.

Metabolism

Midazolam is rapidly metabolized by hepatic and small intestine cytochrome P450 (CYP3A4) enzymes to active and inactive metabolites (**Figure 5.12**).¹⁵⁵ The principal metabolite of midazolam, 1-hydroxymidazolam, has approximately half the activity of the parent compound.¹⁵⁷ This active metabolite is rapidly conjugated to 1-hydroxymidazolam glucuronide and is subsequently cleared by the kidneys. This glucuronide metabolite has substantial pharmacologic activity when present in high concentrations, as may occur in critically ill patients with renal insufficiency who are receiving continuous IV infusions of midazolam over prolonged periods of time. In these patients, the glucuronide metabolite may have synergistic sedative effects with the parent compound.¹⁵⁸ The other pharmacologically active metabolite of midazolam, 4-hydroxymidazolam, is not present in detectable concentrations in the plasma following IV administration of midazolam.

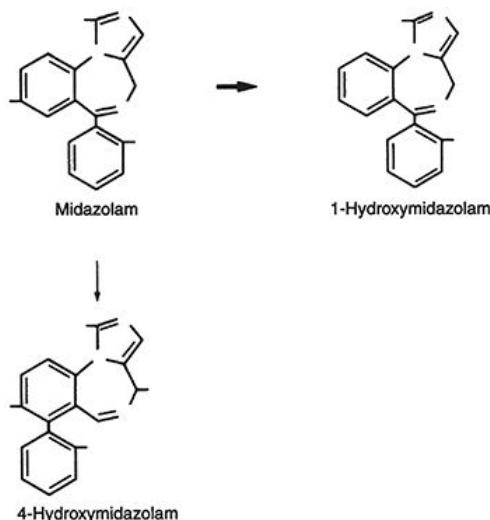

FIGURE 5.12 The principal metabolite of midazolam is 1-hydroxymidazolam. A lesser amount of midazolam is metabolized to 4-hydroxymidazolam. Reprinted with permission from Reves JG, Fragen RJ, Vinik HR, et al. *Midazolam: pharmacology and uses*. Anesthesiology. 1985;62(3):310-324. Copyright © 1985 American Society of Anesthesiologists, Inc.

Metabolism of midazolam is slowed in the presence of drugs (cimetidine, erythromycin, calcium channel blockers, antifungal drugs) that inhibit cytochrome P450 enzymes resulting in unexpected CNS depression.¹⁵⁹ Cytochrome P450 3A enzymes also influence the metabolism of fentanyl. In this regard, the hepatic clearance of midazolam is inhibited by fentanyl as administered during general anesthesia.¹⁶⁰ Overall, the hepatic clearance rate of midazolam is 5 times greater than that of lorazepam and 10 times greater than that of diazepam.

Renal Clearance

The elimination half-time, V_d , and clearance of midazolam are not altered by renal failure.¹⁶¹ This is consistent with the extensive hepatic metabolism of midazolam.

Effects on Organ Systems

Central Nervous System

Midazolam, like other benzodiazepines, produces decreases in CMRO₂ and cerebral blood flow analogous to barbiturates and propofol. Midazolam causes dose-related changes in regional cerebral blood flow in brain regions associated with the normal functioning of arousal, attention, and memory.¹⁶² Cerebral vasomotor responsiveness to carbon dioxide is preserved during midazolam anesthesia.⁴⁸ Patients with decreased intracranial compliance show little or no change in ICP when given midazolam doses of 0.15 to 0.27 mg/kg

IV. Thus, midazolam is an acceptable alternative to barbiturates for induction of anesthesia in patients with intracranial pathology. There is some evidence, however, that patients with severe head trauma but ICP of less than 18 mm Hg may experience an undesirable increase in ICP when midazolam (0.15 mg/kg IV) is administered rapidly (**Figure 5.13**).¹⁶³ Similar to thiopental, induction of anesthesia with midazolam does not prevent increases in ICP associated with direct laryngoscopy for tracheal intubation.¹⁶⁴ Although midazolam may improve neurologic outcome after incomplete ischemia, benzodiazepines have not been shown to possess neuroprotective activity in humans. Midazolam is a potent anticonvulsant effective in the treatment of status epilepticus. Prolonged sedation of infants in critical care units (4–11 days) with midazolam and fentanyl has been associated with encephalopathy on withdrawal of the benzodiazepine.¹⁶⁵ Paradoxical excitement occurs in less than 1% of all patients receiving midazolam and is effectively treated with a specific benzodiazepine antagonist, flumazenil.¹⁶⁶

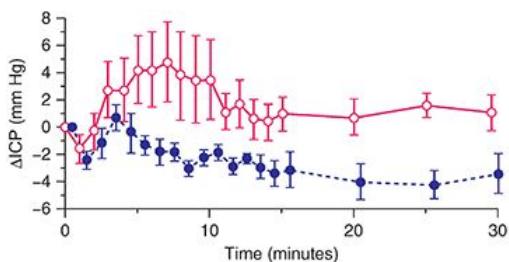

FIGURE 5.13 Administration of midazolam, 0.15 mg/kg IV, to patients with severe head injury (Glasgow Coma Scale score ≤ 6) was associated with an increase in intracranial pressure (ICP) when the control ICP was less than 18 mm Hg (open circles) but not when the control ICP was ≥ 18 mm Hg or greater (closed circles). Reprinted from Papazian L, Albanese J, Thirion X, et al. Effect of bolus doses of midazolam on intracranial pressure and cerebral perfusion pressure in patients with severe head injury. Br J Anaesth. 1993;71(2):267-271. Copyright © 1993 Elsevier. With permission.

Ventilation

Midazolam produces dose-dependent decreases in ventilation with 0.15 mg/kg IV producing effects similar to diazepam, 0.3 mg/kg IV.¹⁶⁷ Patients with chronic obstructive pulmonary disease experience even greater midazolam-induced depression of ventilation.¹⁶⁸ Transient apnea may occur after rapid injection of large doses of midazolam (>0.15 mg/kg IV), especially in the presence of preoperative medication that includes an opioid.¹⁶⁹ In healthy volunteers, midazolam alone produced no ventilatory depressant effects, whereas the combination of midazolam, 0.05 mg/kg IV, and fentanyl, 2 μ g/kg IV, resulted in arterial hypoxemia and/or hypoventilation.¹⁷⁰ Midazolam, 0.05 or 0.075 mg/kg IV, was shown to depress resting ventilation in healthy volunteers, whereas spinal anesthesia (mean sensory level T6) stimulated resting ventilation, and the combination had a modest synergistic effect for depressing resting ventilation.¹⁷¹ Benzodiazepines also depress the swallowing reflex and decrease upper airway activity.

Cardiovascular System

Historically, large IV doses of midazolam were tested for use as an anesthetic induction agent. The use of midazolam never gained widespread use; loss of consciousness, even with high doses, is slow and unreliable, and hemodynamic response to endotracheal intubation is not reliably blunted. Midazolam, 0.2 mg/kg IV, for induction of anesthesia produces a greater decrease in systemic blood pressure and increase in heart rate than does diazepam, 0.5 mg/kg IV.¹⁷² Conversely, these midazolam-induced hemodynamic changes are similar to the changes produced by thiopental, 3 to 4 mg/kg IV.¹⁷³ Cardiac output is not altered by midazolam, suggesting that blood pressure changes are due to decreases in systemic vascular resistance. In this regard, benzodiazepines may be beneficial in improving cardiac output in the presence of congestive heart failure. In the presence of hypovolemia, administration of midazolam results in enhanced blood pressure–lowering effects similar to those produced by other IV induction drugs.¹⁷⁴ Midazolam does not prevent blood pressure

and heart rate responses evoked by intubation of the trachea. In fact, this mechanical stimulus may offset the blood pressure–lowering effects of large doses of midazolam administered IV. The effects of midazolam on systemic blood pressure are directly related to the plasma concentration of the benzodiazepine. However, a plateau plasma concentration appears to exist (ceiling effect) above which little further change in systemic blood pressure occurs.

Clinical Uses

Preoperative Medication

Midazolam is the most commonly used oral preoperative medication for children. Oral midazolam syrup (2 mg/mL) is effective for producing sedation and anxiolysis at a dose of 0.25 mg/kg with minimal effects on ventilation and oxygen saturation even when administered at doses as large as 1 mg/kg (maximum, 20 mg).¹⁷⁵ Midazolam, 0.5 mg/kg administered orally 30 minutes before induction of anesthesia, provides reliable sedation and anxiolysis in children without producing delayed awakening (**Figure 5.14**).¹⁷⁶ Use of oral midazolam to produce mild to moderate sedation in children before surgery remains common¹⁷⁷; recent comparative studies suggest that oral dexmedetomidine produces similar sedation while reducing emergence delirium.¹⁷⁸ Although it is recommended that oral midazolam be administered at least 20 minutes before surgery, there is evidence that significant anterograde amnesia is present when 0.5 mg/kg orally is administered 10 minutes before surgery.¹⁷⁹ Midazolam crosses the placenta, but the fetal-to-maternal ratio is significantly less than that for other benzodiazepines.

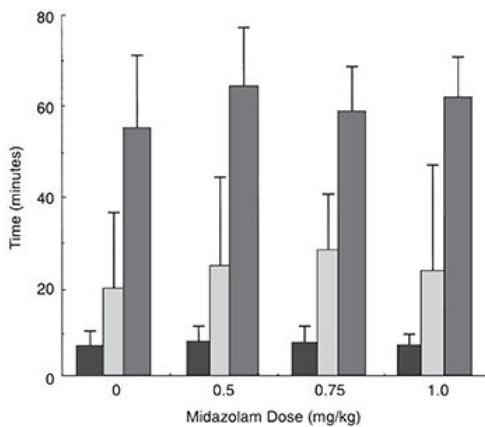

FIGURE 5.14 Increasing doses of oral midazolam premedication administered 30 minutes before the induction of anesthesia did not produce different effects on the interval from the end of surgery until transported to the postanesthesia care unit (solid bars), interval from arrival in the postanesthesia care unit until spontaneous eye opening (light gray bars), and time in the postanesthesia care unit (dark gray bars). *Reprinted by permission from Springer: McMillan CO, Spahr-Schopfer IA, Sikich N, et al. Premedication of children with oral midazolam. Can J Anaesth. 1992;39(6):545-550. Copyright © 1992 Canadian Anesthesiologists.*

Intravenous Sedation

Midazolam in doses of 1.0 to 2.5 mg IV (onset within 30-60 seconds, time to peak effect 3-5 minutes, duration of sedation 15-80 minutes) is effective for sedation during regional anesthesia as well as for brief therapeutic procedures. The effect-site equilibrium time for midazolam must be considered in recognizing the likely time of peak clinical effect and the need for supplemental doses of midazolam.

The most significant side effect of midazolam when used for sedation is depression of ventilation caused by a decrease in the hypoxic drive, particularly in concert with other anesthetic drugs. Midazolam-induced depression of ventilation is exaggerated (synergistic effects) in the presence of opioids and other CNS depressant drugs.¹⁴⁸ Patients with chronic obstructive pulmonary disease may also manifest exaggerated

depression of ventilation following administration of benzodiazepines to produce sedation. It is important to appreciate that increasing age greatly increases pharmacodynamic variability and is associated with generally increased sensitivity to the hypnotic effects of midazolam.¹⁸⁰

Induction of Anesthesia

Although seldom used for this purpose currently, anesthesia can be induced by administration of midazolam, 0.1 to 0.2 mg/kg IV, over 30 to 60 seconds. Nevertheless, thiopental usually produces induction of anesthesia 50% to 100% faster than midazolam (Figure 5.15).¹⁸¹ Onset of unconsciousness (synergistic interaction) is facilitated when a small dose of opioid (fentanyl, 50-100 µg IV or its equivalent) precedes the injection of midazolam by 1 to 3 minutes. The dose of midazolam required for the IV induction of anesthesia is also less when preoperative medication includes a CNS depressant drug. In healthy patients receiving small doses of benzodiazepines, the cardiovascular depression associated with these drugs is minimal. When significant cardiovascular responses occur, it is most likely a reflection of benzodiazepine-induced peripheral vasodilation. As with depression of ventilation, cardiovascular changes produced by benzodiazepines may be exaggerated in the presence of other CNS depressant drugs such as propofol and thiopental.

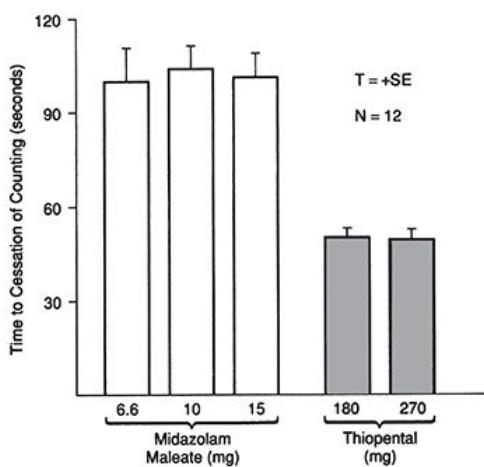

FIGURE 5.15 Induction of anesthesia as depicted by time to cessation of counting occurs in about 110 seconds after the intravenous administration of midazolam compared with about 50 seconds after injection of thiopental. Reprinted with permission from Sarnquist FH, Mathers WD, Brock-Utne J, et al. A bioassay of water-soluble benzodiazepine against sodium thiopental. *Anesthesiology*. 1980;52(2):149-153. Copyright © 1980 American Society of Anesthesiologists, Inc.

Maintenance of Anesthesia

Midazolam may be administered to supplement opioids, propofol, and/or inhaled anesthetics during maintenance of anesthesia. The context-sensitive half-time for midazolam increases modestly with an increasing duration of administration of a continuous infusion of this benzodiazepine.¹⁹ Anesthetic requirements for volatile anesthetics are decreased in a dose-dependent manner by midazolam. Awakening after general anesthesia that includes induction of anesthesia with midazolam is 1.0 to 2.5 times longer than that observed when thiopental is used for the IV induction of anesthesia.¹⁸² Gradual awakening in patients who receive midazolam is rarely associated with nausea, vomiting, or emergence excitement.

Postoperative Sedation

Long-term IV administration of midazolam (loading dose 0.5-4 mg IV and maintenance dose 1-7 mg/hour IV) to produce sedation in intubated patients results in relative saturation of peripheral tissues with midazolam and clearance from the systemic circulation becomes less dependent on redistribution into peripheral tissues and more dependent on hepatic metabolism.¹⁸³ In addition, pharmacologically active

metabolites may accumulate with prolonged IV administration of the parent drug. Under these conditions, plasma concentrations of midazolam decrease more slowly (emergence delayed) after discontinuation of the IV infusion compared with single IV injections. Emergence time is also a function of the plasma concentrations of midazolam at the time the IV infusion is discontinued. Patients maintained at higher plasma concentrations of midazolam take longer to awaken than patients maintained at lower plasma concentrations for comparable periods of time. The concomitant administration of analgesic doses of opioids greatly decreases the needed dose of midazolam and results in a more rapid recovery from sedation following discontinuation of the IV infusion of midazolam.¹⁸³ Emergence time from midazolam infusion is increased in elderly patients, obese patients, and in the presence of severe liver disease.

Paradoxical Vocal Cord Motion

Paradoxical vocal cord motion is a cause of nonorganic upper airway obstruction and stridor that may manifest postoperatively. Midazolam 0.5 to 1 mg IV may be an effective treatment for paradoxical vocal cord motion.¹⁸⁴

Diazepam

Diazepam is a highly lipid-soluble benzodiazepine with a more prolonged duration of action compared with midazolam. Because of the beneficial aspects of midazolam pharmacology, parenteral diazepam is seldom used as part of current anesthetic regimens.

Commercial Preparation

Diazepam is dissolved in organic solvents (propylene glycol, sodium benzoate) because it is insoluble in water. The solution is viscid, with a pH of 6.6 to 6.9. Dilution with water or saline causes cloudiness but does not alter the potency of the drug. Injection by either the IM or IV route may be painful. Diazepam is also available in a unique soybean formulation for IV injection. This formulation is associated with a lower incidence of pain on injection and thrombophlebitis.

Diazepam is rapidly absorbed from the gastrointestinal tract after oral administration with bioavailability nearing 100%, reaching peak concentrations in about 1 hour in adults but as quickly as 15 to 30 minutes in children. There is rapid uptake of diazepam into the brain, followed by redistribution to inactive tissue sites, especially fat, as this benzodiazepine is highly lipid soluble. The V_d of diazepam is large, reflecting extensive tissue uptake of this lipid-soluble drug (see [Table 5.2](#)). Women, with a greater body fat content, are likely to have a larger V_d for diazepam than men. Diazepam rapidly crosses the placenta, achieving fetal concentrations equal to and sometimes greater than those present in the maternal circulation.¹⁸⁵

Protein Binding

The protein binding of benzodiazepines parallels their lipid solubility. As such, highly lipid-soluble diazepam is extensively bound, presumably to albumin (see [Table 5.2](#)). Cirrhosis of the liver or renal insufficiency, with associated decreases in plasma concentrations of albumin, may manifest as decreased protein binding of diazepam and an increased incidence of drug-related side effects.¹⁸⁶ The high degree of protein binding limits the efficacy of hemodialysis in the treatment of diazepam overdose.

Metabolism

Diazepam is principally metabolized by hepatic microsomal enzymes using an oxidative pathway of *N*-demethylation. The two principal metabolites of diazepam are desmethyldiazepam and oxazepam, with a lesser amount metabolized to temazepam ([Figure 5.16](#)). Desmethyldiazepam is metabolized more slowly than oxazepam and is only slightly less potent than diazepam. Therefore, it is likely that this metabolite contributes to the return of drowsiness that manifests 6 to 8 hours after administration of diazepam as well as to sustained effects usually attributed to the parent drug. Alternatively, enterohepatic recirculation may contribute to recurrence of sedation.¹⁸⁷ The plasma concentration of diazepam at this time is clinically insignificant and probably reflects its rapid removal as a conjugate of glucuronic acid. Ultimately,

desmethyl diazepam is excreted in urine in the form of oxidized and glucuronide conjugated metabolites. Unchanged, diazepam is not appreciably excreted in urine.

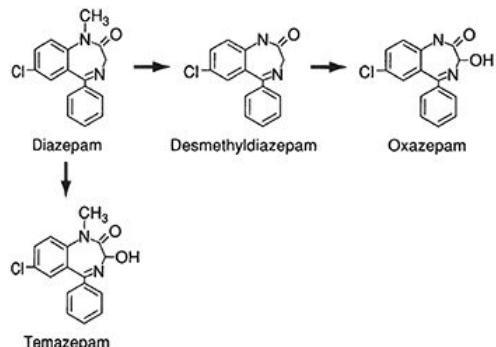

FIGURE 5.16 The principal metabolites of diazepam are desmethyldiazepam and oxazepam. A lesser amount of diazepam is metabolized to temazepam.

Elimination Half-Time

The elimination half-time of diazepam is ranges from 21 to 37 hours in healthy volunteers (see [Table 5.2](#)). Cirrhosis of the liver is accompanied by up to fivefold increases in the elimination half-time of diazepam.¹⁸⁸ Likewise, the elimination half-time of diazepam increases progressively with increasing age, which contributes to the increased sensitivity of these patients to the drug's sedative effects.¹⁸⁸ Prolongation of the elimination half-time of diazepam in the presence of cirrhosis of the liver is due to decreased protein binding of the drug, leading to an increased V_d . In addition, hepatic clearance of diazepam is likely to be decreased, reflecting decreased hepatic blood flow characteristic of cirrhosis of the liver. Compared with lorazepam, diazepam has a longer elimination half-time but shorter duration of action because it dissociates more rapidly than lorazepam from GABA_A receptors, permitting more rapid redistribution to inactive tissue sites.

Desmethyl diazepam, the principal metabolite of diazepam, has an elimination half-time of 48 to 96 hours. As such, the elimination half-time of the metabolite may exceed that of the parent drug. Plasma concentrations of diazepam often decline more rapidly than plasma concentrations of desmethyl diazepam. This pharmacologically active metabolite can accumulate in plasma and tissues during chronic use of diazepam. Prolonged somnolence associated with high doses of diazepam is likely to be caused by sequestration of the parent drug and its active metabolite, desmethyl diazepam, in tissues, presumably fat, for subsequent release back into the circulation. A week or more is often required for elimination of these compounds from plasma after discontinuation of chronic diazepam therapy.

Effects on Organ Systems

Diazepam, like other benzodiazepines, produces significant effects on ventilation and minimal effects on the systemic circulation. Hepatic and renal functions are not altered appreciably. Diazepam does not increase the incidence of nausea and vomiting. There is no change in the circulating plasma concentrations of stress-responding hormones (catecholamines, arginine vasopressin, cortisol).

Ventilation

Diazepam produces minimal depressant effects on ventilation, with detectable increases in Paco_2 not occurring until 0.2 mg/kg IV is administered. This slight increase in Paco_2 is due primarily to a decrease in tidal volume. Nevertheless, rarely, small doses of diazepam (<10 mg IV) have produced apnea.¹⁸⁹ Combination of diazepam with other CNS depressants (opioids, alcohol) or administration of this drug to patients with chronic obstructive airway disease may result in exaggerated or prolonged depression of ventilation. The slope of the line depicting the ventilatory response to carbon dioxide is decreased nearly 50% within 3 minutes after the administration of diazepam, 0.4 mg/kg IV (Figure 5.17).¹⁹⁰ This depression of the

slope persists for about 25 minutes and parallels the level of consciousness. Despite the decrease in slope, the carbon dioxide response curve is not shifted to the right as observed with depression of ventilation produced by opioids. These depressant effects on ventilation seem to be a CNS effect because the mechanics of respiratory muscles are unchanged.

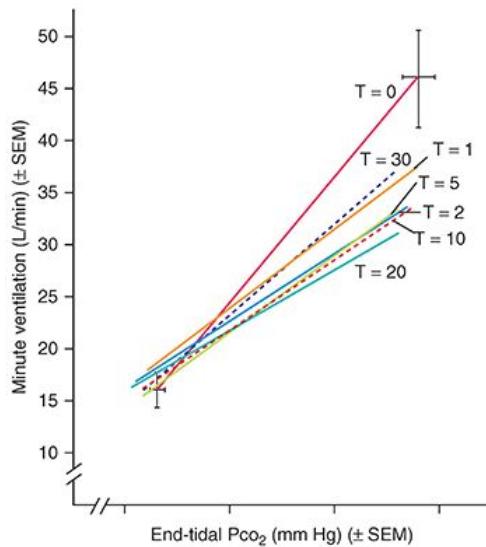

FIGURE 5.17 The slope of the line depicting the ventilatory response to carbon dioxide is decreased ($T = \text{minutes}$) following administration of diazepam, 0.4 mg/kg intravenously. Abbreviation: SEM, standard error of the mean. Reprinted with permission from Gross JB, Smith L, Smith TC. Time course of ventilatory response to carbon dioxide after intravenous diazepam. Anesthesiology. 1982;57(1):18-21. Copyright © 1982 American Society of Anesthesiologists, Inc.

Cardiovascular System

Diazepam administered in doses of 0.5 to 1 mg/kg IV for induction of anesthesia typically produces minimal decreases in systemic blood pressure, cardiac output, and systemic vascular resistance that are similar in magnitude to those observed during natural sleep (10%-20% decreases) (Table 5.3).¹⁹¹ Because of its relative hemodynamic stability, high-dose diazepam was once used for cardiac surgery. There is a transient depression of baroreceptor-mediated heart rate responses that is less than the depression evoked by volatile anesthetics but that could, in hypovolemic patients, interfere with optimal compensatory changes.¹⁹² In patients with increased left ventricular end-diastolic pressure, a small dose of diazepam significantly decreases this pressure. Diazepam appears to have no direct action on the sympathetic nervous system, and it does not cause orthostatic hypotension.

TABLE 5.3

Cardiovascular effects of diazepam (0.5 mg/kg intravenously) and diazepam-nitrous oxide^a

	Awake	Diazepam	Diazepam-nitrous oxide
Systolic blood pressure (mm Hg)	144	125 ^a	121 ^a
Diastolic blood pressure (mm Hg)	81	74	75

Skeletal Muscle

Skeletal muscle relaxant effects reflect actions of diazepam on spinal internuncial neurons and not actions at the neuromuscular junction.¹⁹³ Presumably, diazepam diminishes the tonic facilitatory influence on spinal γ neurons, and thus, skeletal muscle tone is decreased. Tolerance occurs to the skeletal muscle relaxant effects of benzodiazepines.

Overdose

A CNS intoxication can be expected at diazepam plasma concentrations of greater than 1,000 ng/mL. Despite massive overdoses of diazepam, serious sequelae are unlikely to occur if cardiac and pulmonary functions are supported and other drugs such as alcohol are not present.

Clinical Uses

Diazepam remains a popular oral drug for preoperative medication of adults and has been recommended for treatment of local anesthetic-induced seizures. Both diazepam and lorazepam are commonly used benzodiazepines for management of delirium tremens.¹⁹⁴ Production of skeletal muscle relaxation by diazepam is often used in the management of lumbar disc disease and may be of value in the rare patient who develops tetany. Midazolam has largely replaced diazepam for IV sedation and the preoperative medication of children.

Anticonvulsant Activity

The prior administration of diazepam, 0.25 mg/kg IV, to animals protects against the development of seizures due to local anesthetic toxicity. Evidence for this protection is an increased convulsant dose of lidocaine in benzodiazepine-pretreated animals (**Figure 5.18**).¹⁹⁵ Diazepam, 0.1 mg/kg IV, is effective in abolishing seizure activity produced by lidocaine, delirium tremens, and status epilepticus.

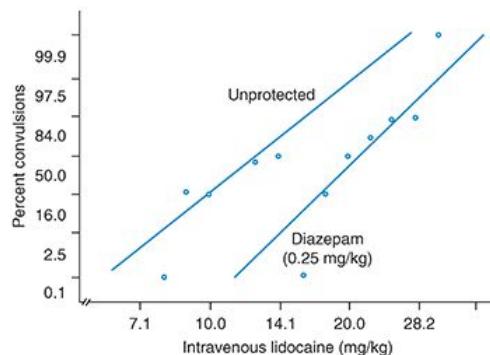

FIGURE 5.18 Prior administration of diazepam, 0.25 mg/kg intravenously, increases the intravenous dose of lidocaine required to produce seizures compared with untreated (unprotected) animals. *Reprinted with permission from De Jong RH, Heavner JE. Diazepam prevents and aborts lidocaine convulsions in monkeys. Anesthesiology. 1974;41(3):226-230. Copyright © 1974 American Society of Anesthesiologists, Inc.*

The efficacy of diazepam as an anticonvulsant may reflect its ability to facilitate the actions of the inhibitory neurotransmitter GABA. In contrast to barbiturates, which inhibit seizures by nonselective depression of the CNS, diazepam selectively inhibits activity in the limbic system, particularly the

hippocampus. If diazepam is administered to terminate seizures, a longer acting antiepileptic drug such as fosphenytoin is also administered.

Lorazepam

Lorazepam resembles oxazepam, differing only in the presence of an extra chloride atom on the ortho position of the 5-phenyl moiety. Lorazepam is a more potent sedative and amnesic than midazolam and diazepam, with a duration of action intermediate between the other two agents. Its effects on ventilation, the cardiovascular system, and skeletal muscles resemble those of other benzodiazepines.

Pharmacokinetics

Lorazepam is conjugated with glucuronic acid in the liver to form pharmacologically inactive metabolites that are excreted by the kidneys. This contrasts with formation of pharmacologically active metabolites after the administration of midazolam and diazepam. The elimination half-time is 10 to 20 hours, with urinary excretion of lorazepam glucuronide accounting for greater than 80% of the injected dose (see [Table 5.2](#)). Compared with midazolam, lorazepam has a much slower metabolic clearance. This may be explained by the slower hepatic glucuronidation of lorazepam compared with more rapid oxidative hydroxylation of midazolam. Because formation of glucuronide metabolites of lorazepam is not entirely dependent on hepatic microsomal enzymes, the metabolism of lorazepam is less likely than that of diazepam to be influenced by alterations in hepatic function, increasing age, or drugs that inhibit P450 enzymes such as cimetidine. The elimination half-time of lorazepam is not prolonged in elderly patients or in those treated with cimetidine. Lorazepam has a slower onset of action than midazolam or diazepam because of its lower lipid solubility and slower entrance into the CNS.

Clinical Uses

Lorazepam undergoes reliable absorption after oral and IM injection, which contrasts with diazepam. After oral administration, maximal plasma concentrations of lorazepam occur in 2 to 4 hours and persist at therapeutic levels for up to 24 to 48 hours. The recommended oral dose of lorazepam for preoperative medication is 50 µg/kg, not to exceed 4 mg.¹⁹⁶ With this dose, maximal anterograde amnesia lasting up to 6 hours occurs, and sedation is not excessive. Larger oral doses produce additional sedation without increasing amnesia. The prolonged duration of action of lorazepam limits its usefulness for preoperative medication when rapid awakening at the end of surgery is desirable.

After a single IV dose (1-4 mg), the onset of effect occurs within 1 to 2 minutes, with a time-to-peak effect of 20 to 30 minutes, and a duration of sedative effects ranging from 6 to 10 hours.¹⁹⁷ Infusions of lorazepam to produce postoperative sedation result in significant delays in emergence from sedation compared with midazolam.¹⁸³ Obesity prolongs the sedative effects of lorazepam reflecting the larger V_d and longer elimination half-time.

A slow onset limits the usefulness of lorazepam for (1) IV induction of anesthesia, (2) IV sedation during regional anesthesia, or (3) use as an anticonvulsant. Like diazepam, lorazepam is effective in limiting the incidence of emergence reactions after administration of ketamine. Although it is insoluble in water and thus requires use of solvents such as polyethylene glycol or propylene glycol, lorazepam is alleged to be less painful on injection and to produce less venous thrombosis than diazepam.

Temazepam

Temazepam is an orally active benzodiazepine administered exclusively for the treatment of insomnia. Oral absorption is complete, but peak plasma concentrations do not reliably occur until about 2.5 hours after its administration. Metabolism in the liver results in weakly active to inactive metabolites that are conjugated with glucuronic acid. The elimination half-time is about 15 hours. Temazepam, 15 to 30 mg orally, does not alter the proportion of rapid eye movement sleep to total sleep in adults. Despite the relatively long elimination half-time, temazepam, as used to treat insomnia, is unlikely to be accompanied by residual drowsiness the following morning. Tolerance or signs of withdrawal do not occur, even after nightly administration for 30 consecutive days.

Remimazolam

Remimazolam is a new ultrashort acting benzodiazepine derivative. It is a carboxylic acid ester that, like remifentanil, is rapidly metabolized by nonspecific tissue esterases to an inactive carboxylic acid.¹⁹⁸ Remimazolam is a high-affinity and selective ligand for the benzodiazepine site of the GABA_A receptor. The drug is currently under development for FDA approval for the indication of anesthetic/sedative in gastrointestinal or pulmonary procedures. Recent studies show that full alertness after a short diagnostic procedure (bronchoscopy) was more rapid after remimazolam than after midazolam (6.0 vs 12 minutes).¹⁹⁹

Flumazenil

Flumazenil, a 1,4-imidazobenzodiazepine derivative, is a specific and exclusive benzodiazepine antagonist with a high affinity for benzodiazepine receptors, where it exerts minimal agonist activity.^{200 201} As a competitive antagonist, flumazenil prevents or reverses, in a dose-dependent manner, all the agonist effects of benzodiazepines. Flumazenil also effectively antagonizes the benzodiazepine component of ventilatory depression that is present during combined administration of a benzodiazepine and opioid.¹⁴⁸ Metabolism of flumazenil is by hepatic microsomal enzymes to inactive metabolites.

Dose and Administration

The dose of flumazenil should be titrated individually to obtain the desired level of consciousness. The recommended initial dose is 0.2 mg IV (8-15 µg/kg IV), which typically reverses the CNS effects of benzodiazepine agonists within about 2 minutes. If required, further doses of 0.1 mg IV (to a total of 1 mg IV) may be administered at 60-second intervals. Generally, total doses of 0.3 to 0.6 mg IV have been adequate to decrease the degree of sedation to the required extent in patients sedated or anesthetized with benzodiazepines, whereas total doses of 0.5 to 1.0 mg IV are usually sufficient to completely abolish the effect of a therapeutic dose of a benzodiazepine. In patients who are unconscious due to an overdose with an unknown drug or drugs, failure to respond to IV doses of flumazenil of more than 5 mg probably indicates the involvement of intoxicants other than benzodiazepines or the presence of functional organic disorders. The duration of action of flumazenil is 30 to 60 minutes, and supplemental doses of the antagonist may be needed to maintain the desired level of consciousness. An alternative to repeated doses of flumazenil to maintain wakefulness is a continuous low-dose infusion of flumazenil, 0.1 to 0.4 mg per hour.²⁰⁰ The administration of flumazenil to patients being treated with antiepileptic drugs for control of seizure activity is not recommended as it could precipitate acute withdrawal seizures.²⁰²

Side Effects

Flumazenil-induced antagonism of excess benzodiazepine agonist effects is not followed by acute anxiety, hypertension, tachycardia, or neuroendocrine evidence of a stress response in postoperative patients.^{203 204} Reversal of benzodiazepine agonist effects with flumazenil is not associated with alterations in left ventricular systolic function or coronary hemodynamics in patients with coronary artery disease.²⁰⁵ The weak intrinsic agonist activity of flumazenil most likely attenuates evidence of abrupt reversal of agonist effects. Flumazenil does not alter anesthetic requirements (minimum alveolar concentration [MAC]) for volatile anesthetics, suggesting that these drugs do not exert any of their depressant effects on the CNS at GABA_A receptors.²⁰⁶ Flumazenil, administered at about 10 times the clinically recommended dose, has no agonist effects on resting ventilation or psychomotor performance in normal individuals.²⁰⁷

Short-Acting Nonbenzodiazepine Benzodiazepines

Benzodiazepine refers to a specific chemical structure consisting of a benzene ring and a diazepine ring, hence the name benzodiazepine. Unfortunately, the name has also come to refer to a pharmacologic class of drugs with a shared clinical activity and a shared molecular binding site on the GABA_A receptor at the interface between the α and γ subunits, the benzodiazepine site. Eventually, drugs were found that bound to the same receptor, and exhibited the same pharmacology, but did not consist of a benzene ring bound to a diazepine ring. These drugs were given the cumbersome but vaguely amusing name: nonbenzodiazepine

benzodiazepine. The agents that have been approved are zaleplon (Sonata), zolpidem (Ambien), and more recently eszopiclone (Lunesta).

Zaleplon, zolpidem, and eszopiclone exert activity at the GABA receptor complex.²⁰⁸ These drugs seem to have more selectivity for certain subunits of GABA receptors, resulting in a clinical profile for treatment of sleeping disorders that is more efficacious with fewer side effects than occur with conventional benzodiazepines. Their use has steadily risen during the past decade, with 3% of Americans now reporting use of one or more of these agents during the prior month.²⁰⁹ Due to variations in binding to GABA receptor subunits, these drugs show differences in their effect on sleep stages. Zaleplon (10 mg orally) has a rapid elimination, so there are few residual side effects after taking a single dose at bedtime. It may be particularly useful for patients with delayed onset of sleep. By comparison, zolpidem (10 mg orally) has a delayed elimination, prolonging drug effect. This may result in residual sedation and side effects but may be used for sustained treatment of insomnia with less waking during the night. All of these agents are slightly effective for insomnia, but their overall effects are of questionable clinical importance.²¹⁰

Barbiturates

The introduction of thiopental in 1934 revolutionized the practice of anesthesia. This rapid-acting barbiturate made it possible to induce general anesthesia in seconds, avoiding a slow, often unpleasant, more dangerous induction with diethyl ether. Thiopental and other barbiturate sedative-hypnotics were imported from manufacturers overseas, but these companies have now ceased exporting barbiturates to the United States in order to protest their use as a part of the lethal injection “cocktail” for capital punishment.²¹¹ We still include a discussion of barbiturate pharmacology in this chapter, and this is done for several reasons: First, it is conceivable that shipments of these drugs may resume. Second, some anesthesiologists who practice outside of the United States use these drugs. Most importantly, the pharmacokinetics and pharmacodynamics of barbiturates are the prototypes and comparators for almost all of our clinically used IV anesthetics. To understand the literature on drugs like propofol, etomidate, and midazolam, it is critical to know the properties of barbiturates to which they were often compared, as these were the gold standard during their development.

Barbiturates' Use in Anesthesia

The clinically used barbiturates are derived from barbituric acid. The substitutions on this molecule determine the physicochemical properties, pharmacokinetics, and the relative potency to produce various effects. Oxybarbiturates (pentobarbital, secobarbital) have oxygen at the second position. Replacement of the oxygen with a sulfur atom results in the corresponding thiobarbiturates (thiopental, thiamylal), which are much more lipid soluble and have greater hypnotic potency. A phenyl group at the fifth position (phenobarbital) increases the anticonvulsant, but not hypnotic, potency. On the other hand, a methyl group on the nitrogen (as with methohexitol) increases hypnotic potency but lowers the seizure threshold and causes myoclonus during induction.

Mechanism of Action

Barbiturates are one of the earliest examples of CNS depressants that act in part by potentiating GABA_A channel activity. At clinically used concentrations, they also act on glutamate, adenosine, and neuronal nicotinic acetylcholine receptors. Studies in knock-in mice have shown that GABA_A receptors containing β₃ subunits are responsible for the immobilizing activity of pentobarbital and partly responsible for the hypnotic activity.²¹² The interaction of barbiturates (as well as propofol and etomidate acting at different sites) functions allosterically to increase the affinity of GABA for its binding site, thereby increasing the duration of the GABA_A-activated opening of chloride channels (see **Figure 5.10**). Barbiturates can also mimic the action of GABA by directly activating GABA_A receptors at higher doses.

Pharmacokinetics

Thiopental causes rapid onset and rapid awakening after a single IV dose due to rapid uptake then rapid redistribution out of the brain into inactive tissues (**Figure 5.19**).²¹³ As previously discussed, this is the basis for the short action of most other highly lipophilic drugs. Ultimately, elimination from the body depends almost entirely on metabolism because less than 1% of thiopental is recovered unchanged in urine.²¹⁴ The time required for the plasma concentration of thiopental to decrease 50% after discontinuation of a prolonged infusion (context-sensitive half-time) is lengthy. The drug is sequestered in fat and skeletal muscle and then it reenters the circulation and prevents the plasma concentration from dropping rapidly.¹⁹

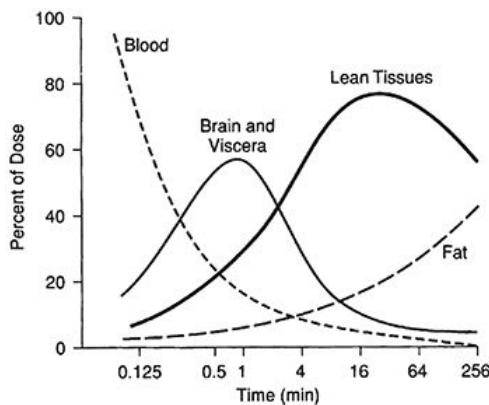

FIGURE 5.19 After a rapid intravenous injection, the percentage of thiopental remaining in the blood rapidly decreases as drug moves from the blood to tissues. Time to achievement of peak levels is a direct function of tissue capacity for barbiturate relative to blood flow. Initially, most thiopental is taken up by the vessel-rich group tissues because of their high blood flow. Subsequently, drug is redistributed to skeletal muscles and, to a lesser extent, to fat. The rate of metabolism equals the early rate of removal by fat, and the sum of these two events is similar to uptake of drug by skeletal muscles. *Reprinted with permission from Saidman LJ. Uptake, distribution, and elimination of barbiturates. In: Eger EI, ed. Anesthetic Uptake and Action. Baltimore, MD: Williams & Wilkins; 1974.*

Thiobarbiturates are metabolized in hepatocytes and, to a small extent, in extrahepatic sites such as the kidneys and possibly the CNS. Metabolites (particularly hydroxythiopental and the 5-carboxylic acid) are usually inactive and are always more water soluble than the parent compound, which facilitates renal excretion. Ultimately, metabolism of thiopental is almost complete (99%). Hepatic clearance of thiopental is characterized by a low hepatic extraction ratio and capacity-dependent elimination. This means factors affecting hepatic enzyme activity should change clearance. However, the reserve capacity of the liver to oxidize barbiturates is huge, so hepatic dysfunction must be extreme before a prolonged duration of action occurs.

In pediatric patients, the elimination half-time of thiopental is shorter than in adults.²¹⁵ This is due to more rapid hepatic clearance of thiopental by pediatric patients. Therefore, recovery after large or repeated doses of thiopental may be more rapid for infants and children than for adults. Protein binding and V_d of thiopental are not different in pediatric and adult patients. Elimination half-time is prolonged during pregnancy because of the increased protein binding of thiopental.

Pharmacodynamics and Clinical Applications

Premedication

Oral and injectable barbiturates have been replaced by benzodiazepines for preanesthetic medication. Drowsiness may last for only a short time after a sedative-hypnotic dose of a barbiturate is administered orally, but residual CNS effects characterized as “hangover” may persist. The rapid onset of action of barbiturates renders these drugs useful for treatment of grand mal seizures, but, again, benzodiazepines are probably superior, providing a more specific site of action in the CNS. Rectal administration of barbiturates, especially methohexitol, 20 to 30 mg/kg, has been used to induce anesthesia in uncooperative or young

patients.²¹⁶ Loss of consciousness after rectal administration of methohexitol correlates with a plasma concentration greater than 2 µg/mL.²¹⁷

Induction of Anesthesia

The relative potency of barbiturates used for IV induction of anesthesia assumes that thiopental is 1, thiamylal is 1.1, and methohexitol is 2.5. At a blood pH of 7.4, methohexitol is 76% nonionized compared with 61% for thiopental, which is consistent with the greater potency of methohexitol. These drugs produce minimal to no direct effects on skeletal, cardiac, or smooth muscles. Induction dose requirements for thiopental vary with patient age, weight, and most importantly cardiac output. The dose of thiopental required to induce anesthesia decreases with age, reflecting a slower passage of barbiturate from the central compartment to peripheral compartments (Figure 5.20).^{218,219} The dose of thiopental needed to produce anesthesia in early pregnancy (7–13 weeks of gestation) is decreased about 18% compared with that for nonpregnant females (Figure 5.21).²²⁰ Thiopental requirements, for unknown reasons, seem to be increased in children for more than 1 year after thermal injury.²²¹ Despite a contrary clinical impression, thiopental dose requirements (with EEG suppression as the end point) are not different between nonalcoholics and alcoholics with abstinence of 9 to 17 days and 30 days (Figure 5.22).²²²

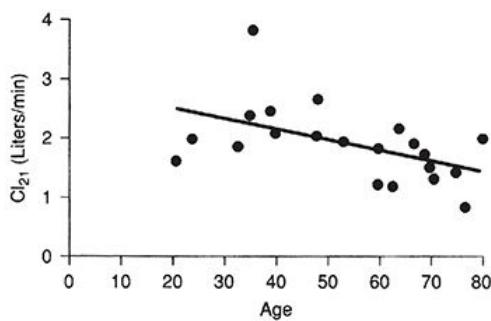

FIGURE 5.20 The rate of intercompartmental clearance of thiopental from the central compartment to the peripheral compartment slows with increasing age. Methohexitol is the only barbiturate with pharmacodynamic effects sufficiently different from thiopental and thiamylal to offer an alternative for IV induction. One advantage of methohexitol is its effect to lower the seizure threshold. Methohexitol, but not thiopental, is effective in inducing seizure activity in patients with psychomotor epilepsy undergoing temporal lobe resection of seizure-producing areas.^{223,224} The decreased anticonvulsant effect of methohexitol is useful during electroconvulsive therapy because the therapeutic effect is related to the duration of the seizure. The principal disadvantage of methohexitol is the incidence of excitatory phenomena, such as involuntary skeletal muscle movements (myoclonus) and other signs of excitatory activity including hiccoughs. These phenomena are dose dependent and may be decreased by pretreatment with opioids.

Even before the removal of barbiturates from the US market, propofol had replaced them for induction of anesthesia in most cases. The time to awaken from a single induction dose of propofol was not that different, but it produced less nausea, and generally, patients met recovery milestones (voiding, walking) more rapidly, especially in those where rapid awakening is considered desirable.

Treatment of Increased Intracranial Pressure and Ischemic Injury

Barbiturates can be administered to decrease refractory ICP that remains increased despite other measures. Barbiturates decrease ICP by decreasing cerebral blood volume through drug-induced cerebral vascular vasoconstriction and an associated decrease in cerebral blood flow. The decrease in cerebral blood flow and increase in the perfusion-to-metabolism ratio made thiopental a useful drug for induction of anesthesia in patients with increased ICP ([Figure 5.23](#)).²²⁵ The drug can be titrated to a level that produces EEG burst suppression, and an isoelectric EEG occurs with maximal (~55%) barbiturate-induced depression of CMRO₂. However, this therapy produces significant hypotension, and improved outcome after head trauma has not been demonstrated in patients treated with barbiturates, despite the ability of these drugs to decrease and control ICP.²²⁶

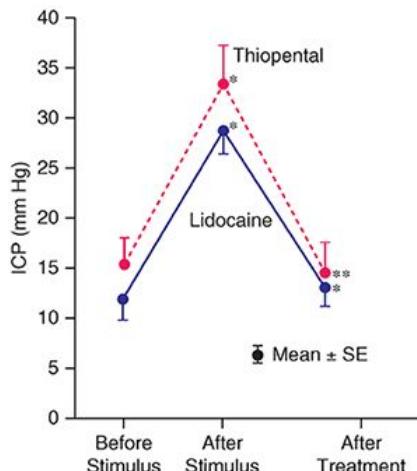

FIGURE 5.23 The administration of thiopental, 3 mg/kg intravenously (IV), is as effective as lidocaine, 1.5 mg/kg IV, in decreasing intracranial pressure (ICP) after surgical stimulation in patients with brain tumors. * $P < .025$ versus preceding value; ** $P < .02$ versus preceding value. Reprinted with permission from Bedford RF, Persing JA, Pobereskin L, et al. Lidocaine or thiopental for rapid control of intracranial hypertension? Anesth Analg. 1980;59(6):435-437. Copyright © 1980 International Anesthesia Research Society.

Barbiturate therapy has also been used to improve brain survival after global cerebral ischemia due to cardiac arrest, but the efficacy for this indication remains unproven.²²⁷ There are data suggesting that neuropsychiatric complications after cardiopulmonary bypass (presumably due to embolism) clear more rapidly in patients treated prospectively with thiopental to maintain an isoelectric EEG.²²⁸ There is insufficient evidence, however, to support routine use of this therapy.

In contrast to global cerebral ischemia, animal studies consistently show improved outcome with barbiturate therapy of incomplete (focal) cerebral ischemia that permits drug-induced metabolic suppression.²²⁹ In this regard, barbiturate-induced decreases in CMRO₂ exceed decreases in cerebral blood flow, which may provide protection to poorly perfused areas of the brain. The routine use of barbiturates during cardiac surgery or after stroke is not recommended because moderate degrees of hypothermia (33°C–34°C) appear to provide superior neuroprotection without prolonging the recovery phase.

Side Effects

Side effects, especially on the cardiovascular system, inevitably accompany the clinical use of barbiturates. In normovolemic subjects, thiopental, 5 mg/kg IV, produces a transient 10- to 20-mm Hg decrease in blood pressure that is offset by a compensatory 15 to 20 beats per minute increase in heart rate (Figure 5.24).²³⁰ The mild and transient decrease in systemic blood pressure that accompanies induction of anesthesia with barbiturates is principally due to peripheral vasodilation, reflecting depression of the medullary vasomotor center and decreased sympathetic nervous system outflow from the CNS. This dose of thiopental produces minimal to no evidence of direct myocardial depression.

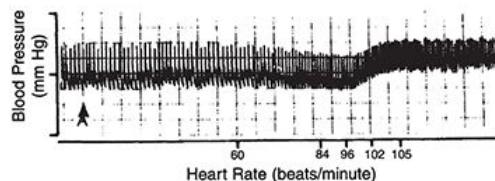

FIGURE 5.24 In normovolemic patients, the rapid administration of thiopental, 5 mg/kg IV (A), is followed by a modest decrease in blood pressure, which is subsequently offset by a compensatory increase in heart rate. Reprinted with permission from Filner BF, Karliner JS. Alterations of normal left ventricular

performance by general anesthesia. Anesthesiology. 1976;45(6):610-621. Copyright © 1976 American Society of Anesthesiologists, Inc.

Ventilation

Barbiturates also produce dose-dependent depression of medullary and pontine ventilatory centers. Thiopental decreases the sensitivity of the medullary ventilatory center to stimulation of carbon dioxide, and apnea is especially likely in the presence of other depressant drugs. Resumption of spontaneous ventilation after a single IV induction dose of barbiturate is characterized by a slow frequency of breathing and decreased tidal volume. Laryngeal reflexes and the cough reflex are not depressed until large doses of barbiturates have been administered.

Somatosensory Evoked Responses

Thiopental produces dose-dependent changes in median nerve somatosensory evoked responses and brainstem auditory evoked responses. However, some response is always obtainable,²³¹ so thiopental is an acceptable drug to administer when the ability to monitor somatosensory evoked potentials is desirable.

Other Effects

Enzyme Induction

Barbiturates, especially phenobarbital, stimulate an increase in liver microsomal protein content (enzyme induction) after 2 to 7 days of sustained drug administration. Altered drug responses and drug interactions may reflect barbiturate-induced enzyme induction, resulting in accelerated metabolism of (1) other drugs, such as oral anticoagulants, phenytoin, and tricyclic antidepressants, or (2) endogenous substances, including corticosteroids, bile salts, and vitamin K. The production of heme is accelerated, and this may exacerbate acute intermittent porphyria in susceptible patients.

Intra-arterial Injection

Inadvertent intra-arterial injection of thiopental usually results in immediate, intense vasoconstriction and excruciating pain that radiates along the distribution of the artery. Vasoconstriction may obscure distal arterial pulses and blanching of the extremity is followed by cyanosis. Gangrene and permanent nerve damage may occur. Treatment of accidental intra-arterial injection of a barbiturate includes immediate attempts to dilute the drug, prevention of arterial spasm by injecting vasodilators such as lidocaine or papaverine, and general measures to sustain adequate blood flow.

Allergic Reactions

Allergic reactions in association with IV administration of barbiturates for induction of anesthesia most likely represent anaphylaxis (antigen–antibody interaction). Nevertheless, thiopental can also produce signs of an allergic reaction in the absence of prior exposure, suggesting an anaphylactoid response.²³² Although true anaphylaxis can occur, some of these reactions appear to be anaphylactoid responses due to direct release of histamine from tissue mast cells.^{232–234} The incidence of allergic reactions to thiopental is estimated to be 1 per 30,000 patients.²³⁵ The majority of reported cases are in patients with a history of chronic atopy who often have received thiopental previously without adverse responses.

Non- γ -Aminobutyric Acid Sedatives and Hypnotics

Ketamine

Ketamine is a phencyclidine derivative that produces “dissociative anesthesia,” which is characterized by evidence on the EEG of dissociation between the thalamocortical and limbic systems.^{236,237} Dissociative anesthesia resembles a cataleptic state in which the eyes remain open with a slow nystagmic gaze. The patient is noncommunicative, although wakefulness may appear to be present. Varying degrees of hypertonus and purposeful skeletal muscle movements often occur independently of surgical stimulation. The patient is

amnesia, and analgesia is intense. Ketamine has advantages over propofol and etomidate in not requiring a lipid emulsion vehicle for dissolution and in producing profound analgesia at subanesthetic doses. However, the frequency of emergence delirium limits the clinical usefulness of ketamine as a sole agent. Ketamine is a drug with significant abuse potential, emphasizing the need to take appropriate precautions against unauthorized nonmedical use.

Structure–Activity Relationships

Ketamine is a water-soluble molecule that structurally resembles phencyclidine. The presence of an asymmetric carbon atom results in the existence of two optical isomers of ketamine.²³⁶ The left-handed optical isomer of ketamine is designated S(+) ketamine (esketamine), and the right-handed optical isomer is designated R(–) ketamine. In the United States, the racemic form of ketamine has been the most frequently used preparation, although esketamine is clinically available for treatment of therapy-resistant depression (Spravato). In Europe, esketamine is widely used as anesthetic and in the treatment of acute and chronic pain. When studied separately, esketamine produces (1) more intense analgesia, (2) more rapid metabolism and thus recovery, (3) less salivation, and (4) a lower incidence of emergence reactions than R(–) ketamine.^{238,239} For example, the analgesic potency of esketamine is approximately twice that of racemic ketamine and 4 times greater than R(–) ketamine. Ketamine isomer induces less fatigue and cognitive impairment than equianalgesic small-dose racemic ketamine.²⁴⁰ Both isomers of ketamine appear to inhibit uptake of catecholamines back into postganglionic sympathetic nerve endings (cocaine-like effect). The fact that individual optical isomers of ketamine differ in their pharmacologic properties suggests that this drug interacts with specific receptors to induce these behaviors. The preservative used for ketamine is benzethonium chloride, but also preservative-free ketamine is available.

Mechanism of Action

The mechanism of action of ketamine-induced analgesia and dissociative anesthesia is unknown. Ketamine is known to interact with multiple CNS receptors, but clear association between receptor interaction and specific behavior has not been established. Ketamine binds noncompetitively to the phencyclidine recognition site on N-methyl-D-aspartate (NMDA) receptors. In addition, ketamine exerts effects at other sites including opioid receptors, monoaminergic receptors, muscarinic receptors, and voltage-sensitive sodium and L-type calcium channels and neuronal nicotinic acetylcholine receptors.^{241–243} Unlike propofol and etomidate, ketamine has only weak actions at GABA_A receptors. Inflammatory mediators produced locally by compression of nerve roots can activate neutrophils that then adhere to blood vessels and impair blood flow. Ketamine suppresses neutrophil production of inflammatory mediators and improves blood flow.²⁴⁴ Direct inhibition of cytokines in blood by ketamine may contribute to the analgesic effects of this drug. In neuropathic pain, ketamine's antiinflammatory and analgesic effects appear to be mediated by the innate repair receptor (CD131-erythropoietin receptor complex).²⁴⁵ This receptor plays a pivotal role in subduing tissue damage and inflammation. Activation of the receptor system by ketamine effectively relieves neuropathic pain from peripheral nerve injury, which is not observed in mice lacking the CD131 receptor.²⁴⁵ Ketamine-induced relief of acute pain is not affected by the innate repair receptor because acute pain relief was maintained in mice without the CD131 receptor.

N-Methyl-D-Aspartate Receptor Antagonism

The NMDA receptors (members of the glutamate receptors family) are ligand-gated ion channels that are unique in that channel activation requires binding of the excitatory neurotransmitter, glutamate with glycine as an obligatory coagonist ([Figure 5.25](#)).²³⁶ Ketamine inhibits activation of NMDA receptors by glutamate and decreases presynaptic release of glutamate. The interaction with phencyclidine binding sites appears to be stereoselective, with the S(+) isomer of ketamine having the greatest affinity.

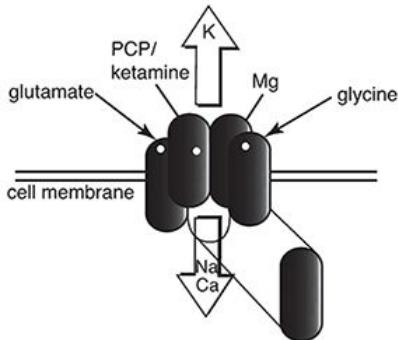

FIGURE 5.25 Schematic diagram of the *N*-methyl-D-aspartate (NMDA) glutamate receptor channel complex. The receptor consists of five subunits surrounding a central ion channel that is permeable to calcium, potassium, and sodium. Binding sites for the agonist glutamate and the obligatory coagonist glycine are indicated. The NMDA receptors are ligand-gated ion channels that are activated by the excitatory neurotransmitter glutamate. Glutamate is the most abundant neurotransmitter in the central nervous system. One of the subunits has been removed to show the interior of the ion channel and binding sites for magnesium and ketamine, which produce noncompetitive NMDA receptor blockade. *Reprinted with permission from Kohrs R, Durieux ME. Ketamine: teaching an old drug new tricks. Anesth Analg.* 1998;87(5):1186-1193. Copyright © 1998 International Anesthesia Research Society.

Opioid Receptors

Ketamine has been reported to directly interact with μ -, δ -, and α -opioid receptors.²⁴⁶ In contrast, other studies have suggested ketamine may be an antagonist at μ receptors and an agonist at α receptors. Ketamine also weakly interacts with δ receptors.

Monoaminergic Receptors

The antinociceptive action of ketamine may involve activation of descending inhibitory monoaminergic pain pathways.

Muscarinic Receptors

Ketamine anesthesia is partially antagonized by anticholinesterase drugs. The fact that ketamine produces anticholinergic symptoms (emergence delirium, bronchodilation, sympathomimetic action) suggests that an antagonist effect of ketamine at muscarinic receptors is more likely than an agonist effect.

Sodium Channels

Consistent with its mild local anesthetic-like properties, ketamine interacts with voltage-gated sodium channels, sharing a binding site with local anesthetics.²⁴²

Neuronal Nicotinic Acetylcholine Receptors

Ketamine interacts with both heteromeric and homomeric α_7 nicotinic acetylcholine receptors.²⁴³ In α_7 -type nicotinic receptors, a single subunit has been identified as a binding site in the extracellular loop between transmembrane segments 2 and 3.²⁴⁷ Nicotinic inhibition by ketamine does not appear to affect sedation or immobility but may play a role in its analgesic effects.²⁴⁸

Pharmacokinetics

The pharmacokinetics of ketamine are similar to thiopental in rapid onset of action, relatively short duration of action, and high lipid solubility (see [Table 5.1](#)). Ketamine has a pK of 7.5 at physiologic pH. Peak plasma concentrations of ketamine occur within 1 minute after IV administration and within 5 minutes after IM injection. Ketamine is not significantly bound to plasma proteins and leaves the blood rapidly to be

distributed into tissues. Initially, ketamine is distributed to highly perfused tissues such as the brain, where the peak concentration may be 4 or 5 times that present in plasma. The extreme lipid solubility of ketamine (5–10 times that of thiopental) ensures its rapid transfer across the blood–brain barrier. Furthermore, ketamine-induced increases in cerebral blood flow could facilitate delivery of drug and thus enhance rapid achievement of high brain concentrations. Subsequently, ketamine is redistributed from the brain and other highly perfused tissues to less well-perfused tissues, the release of which results in late psychodynamic effects after emergence. Ketamine has a high hepatic clearance rate (1 L per minute) and a large V_d (3 L/kg), resulting in an elimination half-time of 2 to 3 hours. The high hepatic extraction ratio suggests that alterations in hepatic blood flow could influence ketamine’s clearance rate.

Metabolism

Ketamine is metabolized extensively by hepatic microsomal enzymes. An important pathway of metabolism is demethylation of ketamine by cytochrome P450 enzymes to form norketamine and subsequently hydroxynorketamine (**Figure 5.26**).²⁴⁹ In animals, norketamine is one-fifth to one-third as potent as ketamine. This active metabolite may contribute to prolonged effects of ketamine (analgesia), especially with repeated doses or a continuous IV infusion. After IV administration, less than 4% of a dose of ketamine can be recovered from urine as unchanged drug. Fecal excretion accounts for less than 5% of an injected dose of ketamine. Chronic administration of ketamine stimulates the activity of enzymes responsible for its metabolism. Accelerated metabolism of ketamine as a result of enzyme induction could explain, in part, the observation of tolerance to the analgesic effects of ketamine that occurs in patients receiving repeated doses of this drug. Indeed, tolerance may occur in burn patients receiving more than two short-interval exposures to ketamine.²⁵⁰ Development of tolerance is also consistent with reports of ketamine dependence.²⁴⁹

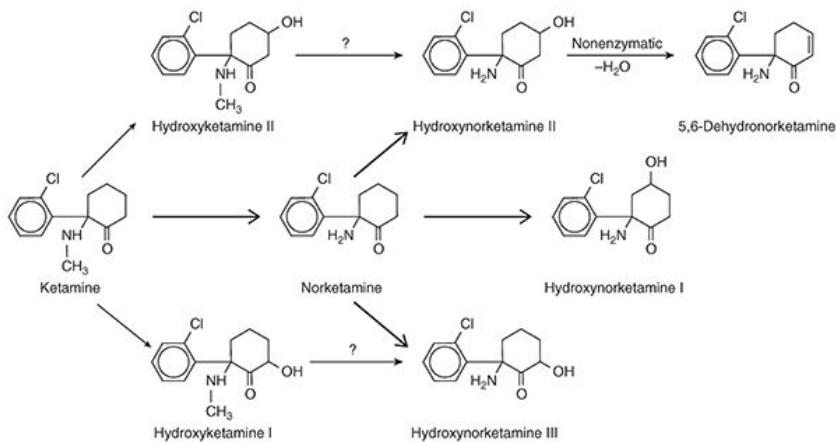

FIGURE 5.26 Metabolism of ketamine. Reprinted with permission from White PF, Way WL, Trevor AJ. *Ketamine – its pharmacology and therapeutic uses*. Anesthesiology. 1982;56(2):119-136. Copyright © 1982 American Society of Anesthesiologists, Inc.

Clinical Uses

Ketamine is a unique drug evoking intense analgesia at subanesthetic doses and producing prompt induction of anesthesia when administered IV at higher doses. Inclusion of an antiallalogue in the preoperative medication is often recommended to decrease the likelihood of coughing and laryngospasm due to ketamine-induced salivary secretions. Glycopyrrolate may be preferable, as atropine or scopolamine can easily cross the blood–brain barrier and could theoretically increase the incidence of emergence delirium (see “[Emergence Delirium \[Psychedelic Effects\]](#)” section).

Analgesia

Intense analgesia can be achieved with subanesthetic doses of ketamine, 0.2 to 0.5 mg/kg IV.²⁵¹ Plasma concentrations of ketamine that produce analgesia are lower after oral than IM administration, presumably reflecting a higher norketamine concentration due to hepatic first-pass metabolism that occurs after oral administration. Analgesia is thought to be greater for somatic than for visceral pain. The analgesic effects of ketamine are likely due to its activity in the thalamic and limbic systems, which are responsible for the interpretation of painful signals. Additionally, ketamine activates descending inhibition.²⁵² Small doses of ketamine are also useful adjuvants to opioid analgesia.²⁵³

Spinal cord sensitization is responsible for pain associated with touching or moving an injured body part that would normally not be painful (allodynia). Central to the development of spinal cord sensitization is activation of NMDA receptors, which are located in the spinal cord dorsal horn. The NMDA receptors are excitatory amino acid receptors that are important in pain processing and the modulation of pain.²⁵⁴ Excitatory amino acids, particularly glutamate, acting at NMDA receptors play an important role in spinal nociceptive pathways. Inhibition of spinal NMDA receptors by drugs, such as ketamine, magnesium, and dextromethorphan, is useful in the management of postoperative pain including decreases in analgesic consumption. Analgesia can be produced during labor without associated depression of the neonate.^{255 256} Neonatal neurobehavioral scores of infants born by vaginal delivery with ketamine analgesia are lower than those for infants born with epidural anesthesia but higher than the scores in infants delivered with thiopental–nitrous oxide anesthesia.²⁵⁷ Postoperative sedation and analgesia after pediatric cardiac surgery can be produced by continuous infusions of ketamine, 1 to 2 mg/kg/hour. Ketamine is useful as an analgesic adjuvant in patients with preexisting chronic pain syndromes who require surgery.

Ketamine metabolites may play a role in the production of analgesia. In three rodent pain models (nerve-injury neuropathic pain, tibia fracture complex regional pain syndrome pain, and plantar incision postoperative pain), it was shown that hydroxynorketamine produces long-lasting pain relief (outlasting the effects of ketamine) without causing motor incoordination.²⁵⁸ Moreover, hydroxynorketamine has a lower potential for abuse or addiction and is associated with profound antidepressant effects.

Neuraxial Analgesia

The efficacy of extradural ketamine is controversial. Although ketamine has been reported to interact with opioid receptors, the affinity for spinal opioid receptors may be 10,000-fold weaker than that of morphine.²⁵⁹ It seems likely that extradural effects of ketamine (30 mg) are due to both spinal and systemic effects and possibly interaction with local anesthetic binding sites on voltage-gated sodium ion channels. Overall, the epidural effects of ketamine are relatively small, but in combination with other epidural analgesics (opioids, local anesthetics), an additive or synergistic effect may occur.²⁶⁰ Intrathecal administration of ketamine (5-50 mg in 3 mL of saline) produces variable and brief analgesia, unless the ketamine is also combined with epinephrine to slow systemic absorption. The neuraxial use of ketamine to produce analgesia appears to be of limited value and is not an approved indication.²⁴¹

Induction of Anesthesia

Induction of anesthesia is produced by administration of ketamine, 1 to 2 mg/kg IV or 4 to 8 mg/kg IM. Injection of ketamine IV does not produce pain or venous irritation. The need for large IV doses reflects a significant first-pass hepatic effect for ketamine. Consciousness is lost in 30 to 60 seconds after IV administration and in 2 to 4 minutes after IM injection. Unconsciousness is associated with maintenance of normal or only slightly depressed pharyngeal and laryngeal reflexes. Return of consciousness usually occurs in 10 to 20 minutes after an injected induction dose of ketamine but return to full orientation may require an additional 60 to 90 minutes. Emergence times are even longer after repeated IV injections or a continuous infusion of ketamine. Amnesia persists for about 60 to 90 minutes after recovery of consciousness, but ketamine does not produce retrograde amnesia. Because of its rapid onset of action, ketamine has been used as an IM induction drug in children and difficult-to-manage mentally challenged patients regardless of age. Due to its intense analgesic activity, ketamine has been used extensively for burn dressing changes, debridement, and skin grafting procedures. The excellent analgesia and ability to maintain spontaneous

ventilation in an airway that might otherwise be altered by burn scar contractures are important advantages of ketamine in these patients. Tolerance may develop, however, in burn patients receiving repeated, short-interval anesthesia with ketamine.^{[250](#)}

Induction of anesthesia in acutely hypovolemic patients is often accomplished with ketamine, taking advantage of the drug's cardiovascular-stimulating effects. In this regard, it is important to recognize that ketamine, like all injected anesthetics, may become a myocardial depressant if endogenous catecholamine stores are depleted and sympathetic nervous system compensatory responses are impaired.^{[261](#)}

The administration of ketamine to patients with coronary artery disease is complicated by increased myocardial oxygen requirements that may accompany this drug's sympathomimetic effects on the heart. Furthermore, the absence of cardioprotective effects (preconditioning) associated with racemic ketamine is a consideration when this drug is administered to patients with known coronary artery disease (see the "[Drug Interactions](#)" section on preconditioning). Nevertheless, induction of anesthesia with administration of diazepam, 0.5 mg/kg IV, and ketamine, 0.5 mg/kg IV, followed by a continuous infusion of ketamine, 15 to 30 µg/kg/minute IV, has been used for anesthesia in patients with coronary artery disease historically.^{[249](#)} The combination of subanesthetic doses of ketamine with propofol for production of total IV anesthesia has been reported to produce more stable hemodynamics than propofol and fentanyl while avoiding the undesirable emergence reactions that may accompany administration of higher doses of ketamine.^{[262](#)}

The beneficial effects of ketamine on airway resistance due to drug-induced bronchodilation make this a potentially useful drug for rapid IV induction of anesthesia in patients with asthma.^{[263](#)}

Ketamine should be used cautiously or avoided in patients with systemic or pulmonary hypertension or increased ICP, although this recommendation may deserve reevaluation based on more recent data (see the "[Central Nervous System](#)" and "[Cardiovascular System](#)" sections). Nystagmus associated with administration of ketamine may be undesirable in operations or examinations of the eye performed under anesthesia.

Ketamine has been administered safely to patients with malignant hyperthermia and does not trigger the syndrome in susceptible swine.^{[264](#)} Extensive experience with ketamine for pediatric cardiac catheterization has shown the drug to be useful, but its possible cardiac-stimulating effects must be considered in the interpretation of catheterization data.

Reversal of Opioid Tolerance

Subanesthetic doses of ketamine are effective in preventing and reversing morphine-induced tolerance.^{[265](#)} Although the mechanism of opioid-induced tolerance is unknown, it is believed to involve interaction between NMDA receptors, the nitric oxide pathway, and µ-opioid receptors. Administration of subanesthetic doses of ketamine (0.3 mg/kg/hour) reduces the likelihood of opioid tolerance and improves analgesia.

Improvement of Psychiatric Disorders

The NMDA receptors for glutamate are thought to be involved in the pathophysiology of mental depression and the mechanism of action of antidepressants. Ketamine in small doses improved the postoperative depressive state in patients with mental depression.^{[266](#)} Intermittent treatment with low-dose ketamine also results in long-term suppression of obsessions and compulsions in patients with obsessive-compulsive disorder.^{[267](#)} Recently, the FDA-approved intranasal esketamine in conjunction with an oral antidepressant for treatment of therapy-resistant depression (Spravato).

Restless Leg Syndrome

A single case report describes symptomatic improvement in two patients with restless leg syndrome treated with oral ketamine.^{[268](#)} It is possible that ketamine inhibits neuroinflammation in the spinal cord or higher centers. Within the spinal cord, restless leg syndrome may reflect NMDA receptor activation and production of inflammatory mediators that impair spinal cord blood flow.

Side Effects

Ketamine is unique among injected anesthetics in its ability to stimulate the cardiovascular system and produce emergence delirium.²³⁷ Although generally considered contraindicated in patients with increased ICP, it must be recognized that many of the early studies of ketamine's effects on ICP were conducted on spontaneously breathing subjects.²³⁷

Central Nervous System

Ketamine is traditionally considered to increase cerebral blood flow and CMRO₂, although there is also evidence suggesting that this may not be a valid generalization.²³⁷

Intracranial Pressure

Ketamine is reported to be a potent cerebral vasodilator capable of increasing cerebral blood flow by 60% in the presence of normocapnia.²⁶⁹ As a result, patients with intracranial pathology are commonly considered vulnerable to sustained increases in ICP after administration of ketamine. Nevertheless, in mechanically ventilated animals with increased ICP, there was no further increase in ICP after administration of ketamine, 0.5 to 2.0 mg/kg IV.²⁷⁰ Furthermore, anterior fontanelle pressure, an indirect monitor of ICP, decreases in mechanically ventilated preterm neonates after administration of ketamine, 2 mg/kg IV.²⁷¹ In patients requiring craniotomy for brain tumor or cerebral aneurysm resection, administration of ketamine, 1 mg/kg IV, did not increase middle cerebral artery blood flow velocity, and ICP decreased modestly (**Figure 5.27**).²⁷² In patients with traumatic brain injury, the administration of ketamine, 1.5, 3.0, and 5.0 mg/kg IV, during mechanical ventilation of the lungs resulted in significant decreases in ICP regardless of the dose of ketamine.²⁷³ These results in patients suggest that ketamine can be administered to patients with mildly increased ICP if administered with mild hyperventilation without adversely altering cerebral hemodynamics. Prior administration of thiopental, diazepam, or midazolam has been shown to blunt ketamine-induced increases in cerebral blood flow.

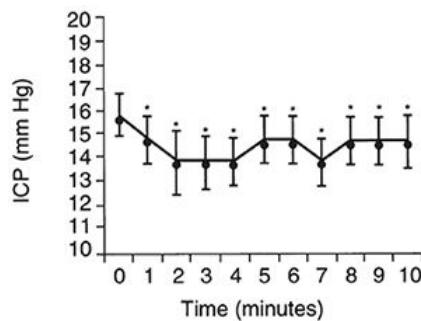

FIGURE 5.27 In patients with a brain tumor or cerebral aneurysm, the administration of ketamine, 1 mg/kg intravenously, during mechanical ventilation of the lungs with nitrous oxide and isoflurane was associated with a modest decrease in intracranial pressure (ICP). This decrease in ICP was accompanied by a corresponding decrease in cerebral artery blood flow velocity. Reprinted with permission from Mayberg TS, Lam AM, Matta BF, et al. Ketamine does not increase cerebral blood flow velocity or intracranial pressure during isoflurane/nitrous oxide anesthesia in patients undergoing craniotomy. Anesth Analg. 1995;81(1):84-89. Copyright © 1995 International Anesthesia Research Society.

Neuroprotective Effects

Activation of NMDA receptors has been implicated in cerebral ischemic damage.²⁴¹ The antagonist effect of ketamine on NMDA receptors suggests a possible neuroprotective role for this drug although this remains an unproved hypothesis. Indeed, S(+) ketamine offers no greater neuroprotection than remifentanil.²⁷⁴

Electroencephalogram

Ketamine's effects on the EEG are characterized by abolition of alpha rhythm and dominance of θ activity. Onset of δ activity coincides with loss of consciousness. At high doses, ketamine produces a burst suppression pattern. Ketamine-induced excitatory activity occurs in both the thalamus and limbic systems without evidence of subsequent spread of seizure activity to cortical areas.²⁷⁵ As such, ketamine would be unlikely to precipitate generalized convulsions in patients with seizure disorders. Indeed, ketamine does not alter the seizure threshold in epileptic patients.²⁷⁶ Although myoclonic- and seizure-like activity may occur in normal patients, EEG evidence of cortical epileptic activity is absent and ketamine is considered to possess anticonvulsant activity.²⁷⁷

Somatosensory Evoked Potentials

Ketamine increases the cortical amplitude of somatosensory evoked potentials.²⁷⁸ This ketamine-induced increase in amplitude is attenuated by nitrous oxide. Auditory and visual evoked responses are decreased by ketamine.

Cardiovascular System

Ketamine produces cardiovascular effects that resemble sympathetic nervous system stimulation. Indeed, a direct negative cardiac inotropic effect is usually overshadowed by central sympathetic stimulation.

Hemodynamic Effects

Systemic and pulmonary arterial blood pressure, heart rate, cardiac output, cardiac work, and myocardial oxygen requirements are increased after IV administration of ketamine (**Table 5.4**).²⁷⁹ The increase in systolic blood pressure in adults receiving clinical doses of ketamine is 20 to 40 mm Hg, with a slightly smaller increase in diastolic blood pressure. Typically, systemic blood pressure increases progressively during the first 3 to 5 minutes after IV injection of ketamine and then decreases to predrug levels over the next 10 to 20 minutes. The cardiovascular-stimulating effects on the systemic and pulmonary circulations are blunted or prevented by prior administration of benzodiazepines or concomitant administration of inhaled anesthetics, including nitrous oxide.^{237,280} Likewise, ketamine administered to mildly sedated infants fails to produce hemodynamic changes in either the systemic or pulmonary circulation.²⁸¹

TABLE 5.4

Circulatory effects of ketamine

	Control	Ketamine (2 mg/kg IV)	% Change
Heart rate (beats per minute)	74	98	+33
Mean arterial pressure (mm Hg)	93	119	+28
Stroke volume index (mL/m ²)	43	44	
Systemic vascular resistance (units)	16.2	15.9	
Right atrial pressure (mm Hg)	7.0	8.9	
Left ventricular end-diastolic pressure (mm Hg)	13.0	13.1	
Pulmonary artery pressure (mm Hg)	17.0	24.5	+44
Minute work index (kg/minute/m ²)	5.4	8.9	+40
Tension-time index (mm Hg per second)	2,700	4,600	+68

Critically ill patients occasionally respond to ketamine with unexpected decreases in systemic blood pressure and cardiac output, which reflect depletion of endogenous catecholamine stores and exhaustion of sympathetic nervous system compensatory mechanisms, leading to an unmasking of ketamine's direct myocardial depressant effects.^{261,282} Conversely, ketamine has been shown to decrease the need for inotropic support in septic patients, perhaps reflecting an inhibition of catecholamine reuptake.^{283,284}

In shocked animals, ketamine is associated with an increased survival rate compared with animals anesthetized with halothane.²⁸⁵ Blood pressure may be better maintained in hemorrhaged animals

anesthetized with ketamine. However, ketamine administration is associated with greater increases in arterial lactate concentrations than occur in animals with lower systemic blood pressures anesthetized with a volatile anesthetic.²⁸⁶ This suggests inadequate tissue perfusion despite maintenance of systemic blood pressure by ketamine. Presumably, ketamine-induced vasoconstriction maintains systemic blood pressure at the expense of tissue perfusion.

Cardiac Rhythm

The effect of ketamine on cardiac rhythm is inconclusive. There is evidence that ketamine enhances the dysrhythmogenicity of epinephrine.²⁸⁷ Conversely, ketamine may abolish epinephrine-induced cardiac dysrhythmias.

Mechanisms of Cardiovascular Effects

The mechanisms for ketamine-induced cardiovascular effects are complex. Direct stimulation of the CNS leading to increased sympathetic nervous system outflow seems to be the most important mechanism for cardiovascular stimulation.²⁸⁸ Evidence for this mechanism is the ability of inhaled anesthetics, ganglionic blockade, β -blockade, cervical epidural anesthesia, and spinal cord transection to prevent ketamine-induced increases in systemic blood pressure and heart rate.^{289,290} Furthermore, increases in plasma concentrations of epinephrine and norepinephrine occur as early as 2 minutes after IV administration of ketamine and return to control levels 15 minutes later.²⁹¹ In vitro, ketamine produces direct myocardial depression, emphasizing the importance of an intact sympathetic nervous system for the cardiac-stimulating effects of this drug.²⁹² The role of ketamine-induced inhibition of norepinephrine uptake (reuptake) into postganglionic sympathetic nerve endings and associated increases of plasma catecholamine concentrations on the drug's cardiac-stimulating effects are not known.²⁸⁷

Ventilation and Airway

Ketamine does not produce significant depression of ventilation. The ventilatory response to carbon dioxide is maintained during ketamine anesthesia, and the PaCO_2 is unlikely to increase more than 3 mm Hg.²⁹³

Breathing frequency typically decreases for 2 to 3 minutes after administration of ketamine. Apnea, however, can occur if the drug is administered rapidly IV or an opioid is included in the preoperative medication.

Upper airway skeletal muscle tone is well maintained, and upper airway reflexes remain relatively intact after administration of ketamine.²⁹⁴ Despite continued presence of upper airway reflexes, ketamine anesthesia does not negate the need for protection of the lungs against aspiration by placement of a cuffed tube in the patient's trachea. Salivary and tracheobronchial mucous gland secretions are increased by IM or IV administration of ketamine, leading to the frequent recommendation that an antisialagogue be included in the preoperative medication when use of this drug is anticipated.

Bronchomotor Tone

Ketamine has bronchodilatory activity and is as effective as halothane or enflurane in preventing experimentally induced bronchospasm in dogs.²⁶³ Ketamine has been used in subanesthetic doses to treat bronchospasm in the operating room and ICU. Successful treatment of status asthmaticus with ketamine has been reported.²⁹⁵ In the presence of active bronchospasm, ketamine may be recommended as the IV induction drug of choice. The mechanism by which ketamine produces airway relaxation is unclear, although several mechanisms have been suggested, including increased circulating catecholamine concentrations, inhibition of catecholamine uptake, voltage-sensitive calcium channel block, and inhibition of postsynaptic nicotinic or muscarinic receptors.²⁴¹

Tissue Damage

Repeated use of ketamine in high doses is associated with tissue damage. This relates not only to individuals that abuse ketamine (by snorting high doses of ketamine to induce a state of psychosis) but also to chronic pain patients treated with repeated and sometimes high ketamine doses. Increase in liver enzymes, allergic

hepatitis, cholangiopathy, hemorrhagic cystitis, thickening of the bladder wall, or renal damage may occur.^{[296,297](#)}

Allergic Reactions

Ketamine does not evoke the release of histamine and rarely, if ever, causes allergic reactions.^{[298](#)}

Platelet Aggregation

Ketamine inhibits platelet aggregation possibly by suppressed formation of inositol 1,4,5-triphosphate and subsequent inhibition of cytosolic free calcium concentrations.^{[299](#)} Drug-induced effects on platelet aggregation are a consideration in patients with known bleeding disorders undergoing surgery.

Emergence Delirium (Psychedelic Effects)

Emergence from ketamine anesthesia in the postoperative period may be associated with visual, auditory, proprioceptive, and confusional illusions, which may progress to delirium. Cortical blindness may be transiently present. Dreams and hallucinations can occur up to 24 hours after administration of ketamine. The dreams frequently have a morbid content and are often experienced in vivid color. Dreams and hallucinations usually disappear within a few hours.

Mechanisms

Emergence delirium probably occurs secondary to ketamine-induced depression of the inferior colliculus and medial geniculate nucleus, leading to misinterpretation of auditory and visual stimuli.^{[249](#)} Furthermore, the loss of skin and musculoskeletal sensations results in decreased ability to perceive gravity, thereby producing a sensation of bodily detachment or floating in space. Opioids that act as κ agonists produce similar psychedelic effects suggesting a potential role for ketamine interaction with κ receptors.

Incidence

The observed incidence of emergence delirium after ketamine ranges from 5% to 30% and is partially dose dependent.^{[249](#)} Factors associated with an increased incidence of emergence delirium include (1) age older than 15 years, (2) female gender, (3) doses of ketamine of greater than 2 mg/kg IV, and (4) a history of personality problems or frequent dreaming.^{[249](#)} In healthy volunteers, the incidence of psychedelic effects is related to the plasma concentration of ketamine (**Figure 5.28**).^{[300](#)} It is possible that the incidence of dreaming is similar in children, but this age group is less able to communicate the dream's occurrence. Indeed, there are reports of recurrent hallucinations in children as well as in adults receiving ketamine.^{[301,302](#)} Nevertheless, psychological changes in children after anesthesia with ketamine or inhaled drugs are not different.^{[303](#)} Likewise, no significant long-term personality differences are present in adults receiving ketamine compared with thiopental.^{[304](#)}

Prevention

A variety of drugs used in preoperative medication or as adjuvants during maintenance of anesthesia have been evaluated in attempts to prevent emergence delirium after administration of ketamine. Benzodiazepines have proved the most effective in prevention of this phenomenon, with midazolam being more effective than diazepam.^{305,306} A common approach is to administer the benzodiazepine IV about 5 minutes before induction of anesthesia with ketamine. Inclusion of thiopental or inhaled anesthetics may decrease the incidence of emergence delirium attributed to ketamine. Conversely, the inclusion of atropine in the preoperative medication may increase the incidence of emergence delirium.³⁰⁷ Despite contrary opinions, there is no evidence that permitting patients to awaken from ketamine anesthesia in quiet areas alters the incidence of emergence delirium.³⁰⁸

Drug Interactions

The importance of an intact and normally functioning CNS in determining the cardiovascular effects of ketamine is emphasized by hemodynamic depression rather than stimulation that occurs when ketamine is administered in the presence of inhaled anesthetics. For example, depression by inhaled anesthetics of sympathetic nervous system outflow from the CNS prevents the typical increases in systemic blood pressure and heart rate that occur when ketamine is administered alone.²⁸⁹ Ketamine administered in the presence of volatile anesthetics may result in hypotension.³⁰⁹ Presumably, volatile anesthetics depress sympathetic nervous system outflow from the CNS, thus unmasking the direct cardiac depressant effects of ketamine. Diazepam, 0.3 to 0.5 mg/kg IV, or an equivalent dose of midazolam is also effective in preventing the cardiac-stimulating effects of ketamine. In the presence of verapamil, the blood pressure-elevating effects of ketamine may be attenuated, whereas drug-induced increases in heart rate are enhanced.³¹⁰ β -Blockade reduces ketamine-induced increase in heart rate and blood pressure.

Ketamine-induced enhancement of nondepolarizing neuromuscular blocking drugs may reflect interference by ketamine with calcium ion binding or its transport.³¹¹ Alternatively, ketamine may increase sensitivity of postjunctional membranes to neuromuscular blocking drugs. The duration of apnea after administration of succinylcholine is prolonged, possibly reflecting inhibition of plasma cholinesterase activity by ketamine.

Pharmacologic activation of adenosine triphosphate-regulated potassium channels mimics ischemic preconditioning and decreases infarct size or improves functional recovery of ischemic, reperfused viable (stunned) myocardium. Conversely, pharmacologic blockade of adenosine triphosphate-regulated potassium channels can antagonize the cardioprotective effects of ischemic preconditioning. In an animal model, ketamine blocked the cardioprotective effects of ischemic preconditioning and this effect was due to the R(-) isomer.³¹² Conversely, S(+) ketamine does not block the cardioprotective effects of preconditioning or alter myocardial infarct size (**Figure 5.29**).³¹³ In patients at risk for myocardial infarction during the perioperative period, drugs known to block preconditioning should be used with caution, whereas drugs known to elicit early and late preconditioning (opioids, volatile anesthetics) may be beneficial.

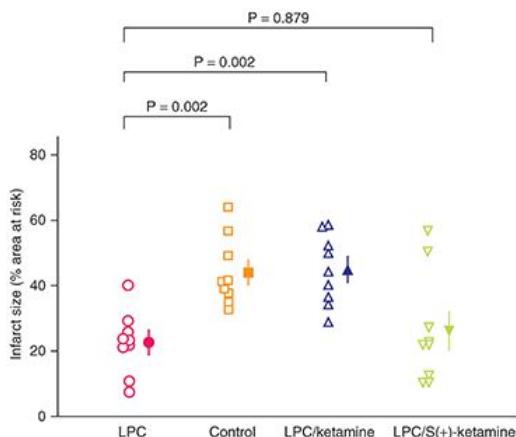

FIGURE 5.29 Infarct size as a percentage of the area at risk in late preconditioning (LPC), control, LPC/ketamine, and LPS/S(+) ketamine. Solid symbols represent mean \pm standard error of the mean. Reprinted with permission from Müllenheim J, Rulands R, Wietschorke T, et al. Late preconditioning is blocked by racemic ketamine, but not by S(+)-ketamine. Anesth Analg. 2001;93(2):265-270. Dextromethorphan

Dextromethorphan (*d*-isomer of levorphanol) is a low-affinity NMDA antagonist that is a common ingredient in over-the-counter cough suppressants. It also has activity at multiple other ligands including neuronal nicotinic receptors. It is equal in potency to codeine as an antitussive but lacks analgesic or physical dependence properties. Unlike codeine, this drug rarely produces sedation or gastrointestinal disturbances. Its euphoric effects lead to a significant abuse potential. Signs and symptoms of intentional excessive intake of dextromethorphan include systemic hypertension, tachycardia, somnolence, agitation, slurred speech, ataxia, diaphoresis, skeletal muscle rigidity, seizures, coma, and decreased core body temperature. Hepatotoxicity may be a consideration when dextromethorphan with acetaminophen is ingested in excessive amounts.

Dexmedetomidine

Dexmedetomidine is a highly selective, specific, and potent α_2 -adrenergic agonist (1,620:1 α_2 to α_1).^{314,315} One of the highest densities of α_2 receptors is present in the pontine locus coeruleus, an important source of sympathetic nervous system innervation of the forebrain and a vital modulator of vigilance. The sedative effects evoked by dexmedetomidine most likely reflect inhibition of this nucleus.³¹⁶

Dexmedetomidine is the dextroisomer and pharmacologically active component of medetomidine, which has been used for many years in veterinary practice for its hypnotic, sedative, and analgesic effects. Compared with clonidine, dexmedetomidine is 7 to 10 times more selective for α_2 receptors and has a shorter duration of action than clonidine. In this regard, dexmedetomidine is considered a full agonist at the α_2 receptor, whereas clonidine is a partial agonist (ratio of α_2 to α_1 activity for clonidine is 220:1).³¹⁵

Atipamezole is a specific and selective α_2 -receptor antagonist that rapidly and effectively reverses the sedative and cardiovascular effects of IV dexmedetomidine.³¹⁷ Atipamezole as an emergency treatment for overdose of α_2 agonists used in zoo and wildlife anesthesia and is not currently available for human use.³¹⁸

The quality of sedation produced by α_2 agonists differs from sedation produced by drugs (midazolam, propofol) that act on GABA.³¹⁹ For example, dexmedetomidine, acting on α_2 receptors, produces sedation by decreasing sympathetic nervous system activity and the level of arousal. The result is a calm patient who can be easily aroused to full consciousness. Amnesia is not assured. Drugs that activate GABA receptors produce a clouding of consciousness and can cause paradoxical agitation as well as tolerance and dependence.

Pharmacokinetics

The elimination half-time of dexmedetomidine is 2 to 3 hours compared with 6 to 10 hours for clonidine. Dexmedetomidine is highly protein bound (>90%) and undergoes extensive hepatic metabolism. The resulting methyl and glucuronide conjugates are excreted by the kidneys. Dexmedetomidine has weak inhibiting effects on cytochrome P450 enzyme systems that might manifest as increased plasma concentrations of opioids as administered during anesthesia.³²⁰

Clinical Uses

As with clonidine, pretreatment with dexmedetomidine attenuates hemodynamic responses to tracheal intubation, decreases plasma catecholamine concentrations during anesthesia, decreases perioperative requirements for inhaled anesthetics and opioids, and increases the likelihood of hypotension.^{321,322} Dexmedetomidine decreases MAC for volatile anesthetics in animals by greater than 90% compared with a plateau effect between 25% to 40% for clonidine (**Figure 5.30**).³²³ In patients, isoflurane MAC was decreased 35% and 48% by dexmedetomidine plasma concentrations of 0.3 and 0.6 ng/mL, respectively.³²⁴ Despite marked dose-dependent analgesia and sedation produced by this drug, there is only mild depression of ventilation. Dexmedetomidine in high doses (loading dose of 1 µg/kg IV followed by 5-10 µg/kg/hour IV) produces total IV anesthesia without associated depression of ventilation.³²⁵ The preservation of breathing provides a potential anesthetic technique for patients with a difficult upper airway. More recent evidence suggests that light to moderate sedation with dexmedetomidine does not offer any protection from central apnea or upper airway collapse when compared with similar levels of sedation provided with propofol.³²⁶ As with clonidine, dexmedetomidine has been reported to be effective in attenuating the cardiotonulatory and postanesthetic delirium effects of ketamine.³²⁷ Addition of 0.5 µg/kg dexmedetomidine to lidocaine being administered to produce IV regional anesthesia improves the quality of anesthesia and postoperative analgesia without causing side effects.³²⁸ Dexmedetomidine markedly increases the range of temperatures not triggering thermoregulatory defenses. For this reason, dexmedetomidine, like clonidine, is likely to promote perioperative hypothermia and also prove to be an effective treatment for nonthermally induced shivering.³²⁹ Severe bradycardia may follow the rapid infusion of dexmedetomidine, and cardiac arrest has been reported in a patient receiving a dexmedetomidine infusion as a supplement to general anesthesia.³³⁰

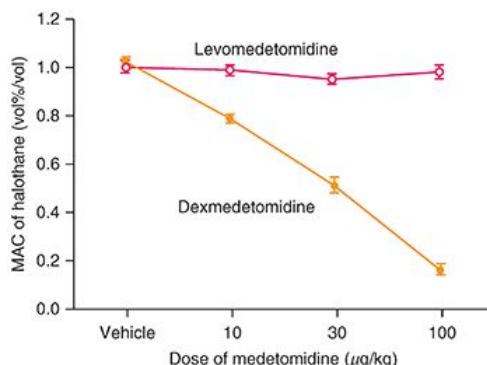

FIGURE 5.30 Dexmedetomidine produces dose-dependent decreases in halothane minimum alveolar concentration (MAC) in rats. Levomedetomidine did not produce any changes in MAC. Data are mean ± standard error of the mean. *Reprinted with permission from Segal IS, Vickery RG, Walton JK, et al. Dexmedetomidine diminishes halothane anesthetic requirements in rats through a postsynaptic alpha-2 adrenergic receptor. Anesthesiology. 1988;69(6):818-823. Postoperative Sedation

Dexmedetomidine (0.2-0.7 µg/kg/hour IV) is useful for sedation of postoperative critical care patients in an ICU environment, particularly when mechanical ventilation via a tracheal tube is necessary. In comparison

with remifentanil, dexmedetomidine infusions do not result in clinically significant depression of ventilation and sedation exhibits some similarity with natural sleep.³³¹ Following tracheal extubation, dexmedetomidine-sedated patients breathe spontaneously and appear calm and relaxed.³³² Both clonidine and dexmedetomidine are useful in the ICU to prevent drug withdrawal symptoms following long-term sedation with benzodiazepines. Because of its sympatholytic and vagomimetic actions, dexmedetomidine may be accompanied by systemic hypotension and bradycardia. The ability to specifically antagonize the sedative effects of dexmedetomidine with atipamezole may be useful.³¹⁷

Effects on the Control of Breathing

Dexmedetomidine is promoted as a sedative with minimal impact on the control of breathing and the upper airway musculature. However, in common with propofol, dexmedetomidine reduces the ventilatory response to hypoxia, while resting ventilation may be minimally affected.³³³ Additionally, dexmedetomidine does not protect the upper airways against obstruction.³³³ These are important observations, as a reduction of ventilatory drive together with a tendency toward upper airway collapse is a potentially life-threatening effect that may further be aggravated by the concomitant use of opioids.

Pain Physiology

Hui Yang • Bihua Bie • Mohamed A. Naguib[†]

Pain is a complex phenomenon and includes both sensory-discriminative and motivational-affective components.¹ The sensory-discriminative component of pain depends on ascending projections of tracts (includes the spinothalamic and trigeminothalamic tracts) into the cerebral cortex. Sensory processing at these higher levels results in the perception of the quality of pain (pricking, burning, aching), the location of the painful stimulus, the intensity of the pain, and the duration of the pain. The motivational-affective responses to painful stimuli include attention and arousal, somatic and autonomic reflexes, endocrine responses, and emotional changes. These account collectively for the unpleasant nature of painful stimuli.

The definition of pain as accepted by the International Association for the Study of Pain (IASP) emphasizes the complex nature of pain as a physical, emotional, and psychological condition. It is recognized that pain does not necessarily correlate with the degree of tissue damage that is present. Failure to appreciate the complex factors that affect the experience of pain and reliance entirely on physical examination findings and laboratory tests may lead to misunderstanding and inadequate treatment of pain. Oversimplified anatomic concepts predispose to simplistic therapeutic interventions, such as neurectomy or rhizotomy that may intensify pain or create new and often more distressing pain.

In reality, the nociceptive system is highly complex and highly adaptable. Sensitivity of most of its components can be reset by a variety of physiologic and pathologic conditions. Innovative medications are being developed that target the causes of pain by actions on pain transduction, transmission, interpretation, and modulation in both the peripheral nervous system (PNS) and the central nervous system (CNS).

Social Impact

Pain is one of the most common reasons for visiting a physician. It is estimated that chronic pain may affect as many as 40% of the adult population.² The prevalence of low back pain ranges from 8% to 37% and is particularly prominent in patients between 45 and 60 years of age. It is estimated that 40 million persons experience musculoskeletal pain conditions.³ Patients with malignant disease often experience increasing pain because their disease progresses. The costs to society related to chronic pain are immense with an estimate that the annual cost attributed to back pain, migraine headache, and arthritis alone is 40 billion dollars (not including surgical procedures to treat pain, lost workdays).¹

Neurobiology of Pain

The experience of pain involves a series of complex neurophysiologic processes that reflect four distinct components: transduction, transmission, modulation, and perception. Modulation of pain is the process of altering pain transmission. It is likely that both inhibitory and excitatory mechanisms modulate pain (nociceptive) impulse transmission in the PNS and CNS. Pain perception is thought to occur at the thalamus, with the cortex being important for discrimination of specific sensory experiences.¹ Pain may occur in the absence of the occurrence of these four steps. For example, pain from trigeminal neuralgia occurs in the absence of transduction of a chemical stimulus at a nociceptor reflecting axonal discharges initiated at the site of a compressed or demyelinated nerve. Modulation of pain impulses may not occur if specific nervous system tracts are injured. For example, phantom limb pain occurs in the absence of nociception or nociceptors (pain receptors).

Peripheral Nerve Physiology of Pain

Nociceptors (Pain Receptors)

Nociceptors are a specialized class of primary afferents that respond to intense, noxious stimuli in skin, muscles, joints, viscera, and vasculature. Nociceptors are distinctive in that they typically respond to the multiple energy forms that produce injury (thermal, mechanical and chemical stimuli) and provide information to the CNS regarding the location and intensity of noxious stimuli. In normal tissues, nociceptors are inactive until they are stimulated by sufficient energy to reach the stimulus (resting) threshold. Thus, nociceptors prevent random signal propagation (screening function) to the CNS for the interpretation of pain.

Specific types of nociceptors react to different types of stimuli. Generally, unmyelinated C-fiber afferents (conduction velocity <2 m/s) have receptive field about 100 mm^2 in human and signal the burning pain from intense heat stimuli applied to the glabrous skin as well as the pain from sustained pressure. Two types of myelinated A-fiber nociceptive afferents (conduction velocity >2 m/s) exist. Type I fibers (including $\text{A}\beta$ and some $\text{A}\delta$ fibers) are typically high-threshold mechanoreceptors and are also usually responsive to heat, mechanical, and chemical stimuli and may therefore be referred to as **polymodal nociceptors**. Type II fibers ($\text{A}\delta$ fibers with lower conduction velocity about 15 m/s) have no demonstrable response to mechanical stimuli and are thought to signal first pain sensation from heat stimuli. Both myelinated and unmyelinated nociceptors signal pain from chemical and cold stimuli.

Sensitization of Nociceptor

Sensitization of nociceptors refers to their increased responsiveness to heat, cold, mechanical, or chemical stimulation that gives rise to primary hyperalgesia to these stimuli.⁴ Sensitization of nociceptors frequently occurs, which was attributable to the increased inflammatory mediators and adaptation of signaling pathways in primary sensory neurons induced by noxious stimuli. In the majority of cases of acute inflammation, the process naturally resolves as tissues heal, peripheral sensitization diminishes, and nociceptors return to their original resting threshold. Chronic pain, however, occurs if the conditions associated with inflammation do not resolve, resulting in sensitization of peripheral and central pain signaling pathway and increased pain sensations to normally painful stimuli (hyperalgesia) and the perception of pain sensations in response to normally nonpainful stimuli (allodynia).

Numerous endogenous chemicals and mediators significantly contribute to the induction of nociception during peripheral inflammation and nerve injury. Most of these mediators are not constitutively stored but synthesized **de novo** at the site of injury. The agents contribute to pain via two principal mechanisms. Some of these agents (eg, bradykinin, protons, prostaglandin E₂, purines, and cytokines) can directly activate nociceptors and/or induce the sensitization of the nociceptor response to painful stimuli, whereas others (eg, serotonin, histamine, arachidonic acid metabolites, and cytokines) may act indirectly to activate the inflammatory cells, which in turn release cytokines to induce the primary hyperalgesia. The chemical mediators released during inflammation can have a synergistic effect in potentiating nociceptor responses (**Figure 6.1**).⁵ For example, bradykinin have the potency to directly activate the peripheral nociceptors, whereas other mediators such as prostaglandins have the potency to sensitize the nociceptors and make them hyperresponsive to peripheral stimulation.⁵

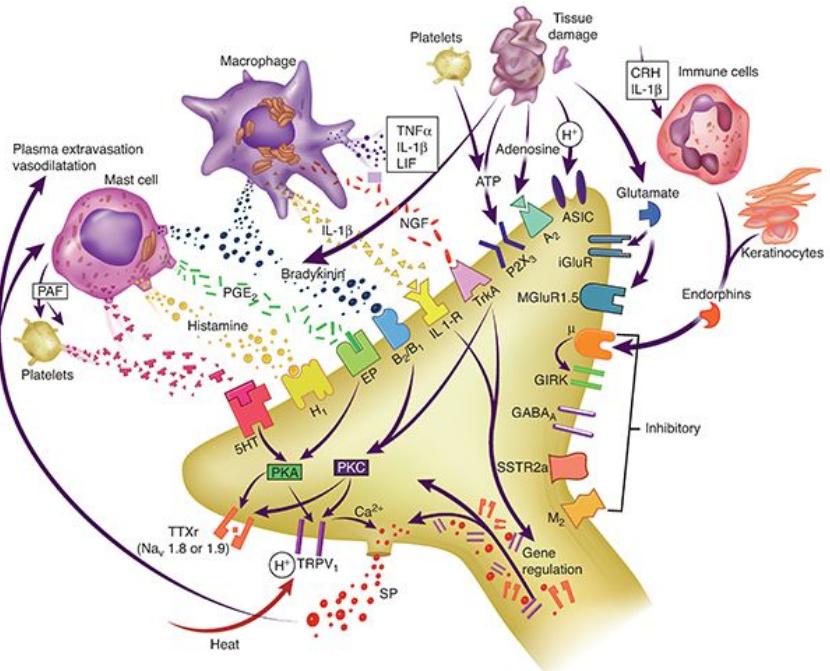

FIGURE 6.1 Cellular mechanisms underlying nociceptor sensitization induced by peripheral inflammation. Activated immune cells (macrophages, mast cells, and other immune cells) and injured cells release numerous chemicals, which may directly or indirectly sensitize the peripheral nerve terminals. Abbreviations: A₂, adenosine A₂ receptor; ASIC, acid-sensing ion channel; ATP, adenosine triphosphate; B₂/B₁, bradykinin receptor B₂/B₁; Ca²⁺, calcium ion; CRH, corticotrophin-releasing hormone; EP, E-prostanoid receptor; GABA_A, gamma-aminobutyric acid receptor type A; GIRK, G-protein-coupled inward rectifying potassium channel; H⁺, hydrogen ion; H₁, histamine H₁ receptor; 5HT, serotonin; iGluR, ionotropic glutamate receptor; IL-1 β , interleukin-1 β ; IL 1-R, interleukin-1 receptor; LIF, leukemia inhibitory factor; M₂, muscarinic receptor; MGlur, metabotropic glutamate receptor; μ , μ -opioid receptor; Na_v, voltage-gated sodium channel; NGF, nerve growth factor; P2X₃, purinergic receptor P2X ligand-gated ion channel 3; PAF, platelet-activating factor; PGE₂, prostaglandin E₂; PKA, protein kinase A; PKC, protein kinase C; SP, substance P; SSTR2a, somatostatin receptor 2a; TNF α , tumor necrosis factor α ; TrkA, tyrosine kinase receptor A; TRPV₁, transient receptor potential vanilloid receptor 1; TTXr, tetrodotoxin-resistant sodium channel. A variety of receptors and ion channels have been identified on dorsal root ganglion neurons and on peripheral terminals of nociceptive afferent fibers. These receptors, including purinergic,⁶ metabotropic glutamatergic, tachykinin,⁷ transient receptor potential vanilloid receptor 1 receptor and neurotrophic receptors, and ion channels (eg, Nav1.8) in primary sensory neurons, may also undergo significant adaptation after exposure to noxious stimuli, which significantly lowers the firing threshold of nociceptor and critically contributes to the induction and maintenance of primary hyperalgesia.⁸

Primary Hyperalgesia and Secondary Hyperalgesia

In general, tissue injury and inflammation may activate a cascade of events leading to enhanced pain in response to noxious stimuli, which is termed as **hyperalgesia**. Hyperalgesia is defined as a leftward shift of the stimulus-response function that relates magnitude of pain to stimulus intensity. Hyperalgesia is a consistent feature of somatic and visceral tissue injury and inflammation. Hyperalgesia at the original site of injury is termed **primary hyperalgesia**, and hyperalgesia in the uninjured skin surrounding the injury is

termed **secondary hyperalgesia**. Primary hyperalgesia is usually manifested as decreased pain threshold, increased response to suprathreshold stimuli, spontaneous pain, and expansion of receptive field. Although primary hyperalgesia is characterized by the presence of enhanced pain from heat *and* mechanical stimuli, secondary hyperalgesia is characterized by enhanced pain response to *only* mechanical stimuli. It is usually accepted that interaction between the proinflammatory mediators and their receptors in nociceptors leads to the induction of primary hyperalgesia, and sensitization of central neurocircuits processing nociceptive information may account for the secondary hyperalgesia after tissue injury.

Central Nervous System Physiology

Pain transmission from peripheral nociceptors to the spinal cord and higher structures of the CNS is a dynamic process involving several pathways, numerous receptors, neurotransmitters, and secondary messengers. The spinal dorsal horn functions as a relay center for nociceptive and other sensory activity. The ascending pathways convey pain-related activity to the brainstem and forebrain in humans. Forebrain somatosensory cortices (SI and SII) account for the perception of sensory-discriminative of peripheral painful stimuli, and some brain regions in the limbic cortex and thalamus account for the perception of motivational-affective components of pain.^{9,10} Descending projections originating from periaqueductal gray (PAG)-RVM (rostral ventromedial medulla) system may either depress or facilitate the integration of painful information in the spinal dorsal horn ([Figure 6.2](#)).

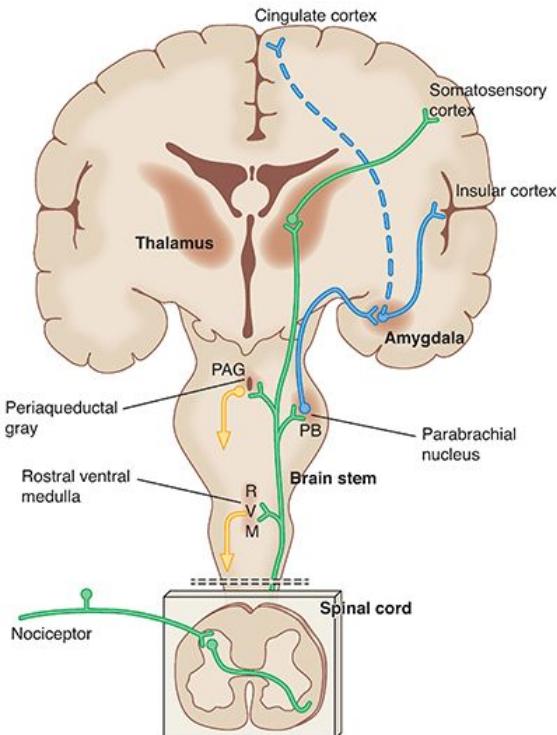

FIGURE 6.2 The projection pathway for the transmission of pain information into the brain. Primary afferent nociceptors convey noxious information to projection neurons within the dorsal horn of the spinal cord. A subset of these projection neurons transmits information to the somatosensory cortex via the thalamus, providing information about the location and intensity of the painful stimulus. Other projection neurons engage the cingulate and insular cortices via connections in the brainstem (parabrachial [PB] nucleus) and amygdala, contributing to the affective component of the pain experience. This ascending information also accesses neurons of the rostral ventromedial medulla (RVM) and midbrain periaqueductal gray (PAG) to engage descending feedback systems that regulate the output from the spinal cord. *Reprinted from Basbaum AI, Bautista DM, Scherrer G, et al. Cellular and molecular mechanisms of pain. Cell. 2009;139(2):267-284. Copyright © 2009 Elsevier. With permission.*

The Dorsal Horn: The Relay Center for Nociception

Afferent fibers from peripheral nociceptors enter the spinal cord in the dorsal root, ascend or descend several segments in the Lissauer tract, and synapse with the dorsal horn neurons for the primary integration of peripheral nociceptive information. The dorsal horn contains four major neuronal components: the central terminals of primary afferent axons; intrinsic neurons, which are terminating locally or extending into other spinal segments; projection neurons that are passing rostrally in the white matter to reach various parts of the brain; and descending axons that pass caudally from several brain regions and play an important role in modulating the integration of nociceptive information.

The central terminals of primary afferents occupy highly ordered spatial locations in the dorsal horn. The dorsal horn consists of six laminae (Figure 6.3). Laminae I (marginal layer) and II (substantia gelatinosa) are often referred to as the **superficial dorsal horn** and serve as main target of afferent C fibers. Lamina I contains both projection neurons and interneurons, and all of the neurons in lamina II are small interneurons. Lamina V is the site of second-order wide dynamic range and nociceptive-specific neurons that receive input from nociceptive and nonnociceptive neurons. The nociceptive-specific neurons respond only to noxious stimuli in their peripheral environment, whereas wide dynamic range neurons respond to innocuous and noxious stimuli of many types. Both types of neurons are believed to be important in the perception of nociceptive information. Myelinated fibers innervating muscles and viscera terminate in laminae I, IV to VII, and the ventral horn, and the unmyelinated fibers from these organs mostly terminate in laminae I, II, and V as well as X.

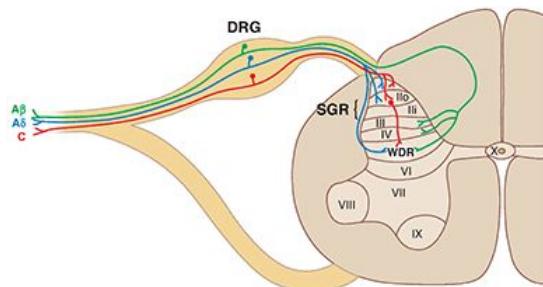

FIGURE 6.3 Schematic representation of the spinal projections of primary afferent fibers. In general, unmyelinated C fibers synapse with the interneurons laminae I (marginal layer) and II (substantia gelatinosa of Rolando [SGR]). Cutaneous A_D fibers usually project to laminae I, II, and V, and A_B fibers primarily terminate in laminae III, IV, V in dorsal horn. Large-diameter myelinated fibers innervating muscles, joint, and viscera may also terminate in laminae I, IV to VII, and the ventral horn. Second-order wide dynamic range (WDR) neurons are located in lamina V and receive input from nociceptive and nonnociceptive neurons. Abbreviation: DRG, dorsal root ganglia.

Interneurons make up the great majority of the neuronal population throughout the dorsal horn. Many dorsal horn interneurons have axons that remain in the same lamina as the cell body, and they also give rise to axons that extend into other laminae. Interneurons in the dorsal horn can be divided into two main functional types: inhibitory cells, which use γ -aminobutyric acid and/or glycine as their principal transmitter, and excitatory glutamatergic cells. Interneurons in dorsal horn are important for integration and modulation of incoming nociceptive information.

Projection neurons with axons that project to the brain are present in relatively large numbers in lamina I and are scattered through the deeper part of the dorsal horn (laminae III-VI) and the ventral horn. Both the lamina I and the laminae III to IV projection neurons that express the neurokinin 1 receptor are heavily innervated by substance P-containing primary afferents. Those in lamina I, together with some of the projection cells in deeper laminae, have axons that cross the midline and ascend to a variety of supraspinal targets including the thalamus, the midbrain periaqueductal gray matter, lateral parabrachial area of the pons, and various parts of the medullary reticular formation.

Two types of descending monoaminergic (serotonergic and norepinephrinergic) axons project from the brain throughout the dorsal horn, mostly terminating in laminae I and II, and are involved in descending pain modulation. Serotonergic axons in the spinal cord originate in the medullary raphe nuclei, whereas those that contain norepinephrine are derived from cells in the locus coeruleus and adjacent areas of the pons.

Gate Theory

The gate control theory of pain was first proposed by Ronald Melzack and Patrick Wall in 1965 to illustrate the neuronal network underlying pain modulation (a neurologic “gate”) in the spinal dorsal horn. According to this theory, painful information is projected to the supraspinal brain regions if the gate is open, although painful stimulus is not felt if the gate is closed by the simultaneous inhibitory impulses ([Figure 6.4](#)). Here is a commonly used example to describe how this neuronal network modulates pain transmission. Usually, rubbing the skin of painful area seems to somehow relieve the pain associated with a bumped elbow. In this case, rubbing the skin activates large-diameter myelinated afferents (A β), which is “faster” than A δ fibers or C fibers conveying painful information. These A β fibers deliver information about pressure and touch to the dorsal horn and overrides some of the pain messages carried by the A δ and C fibers by activating the inhibitory interneurons in the dorsal horn. This hypothesis provided a practical theoretical basis for some approaches such as massage, transcutaneous nerve stimulation, and acupuncture to effectively treat pain in clinical patients.[11-13](#)

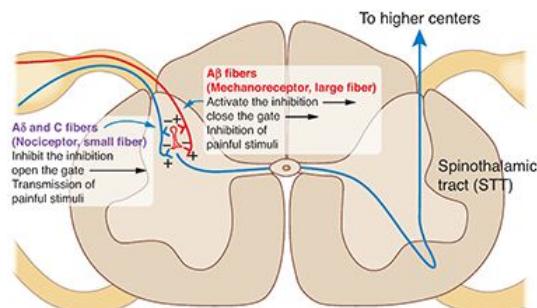

FIGURE 6.4 The illustration of gate theory for pain modulation in spinal dorsal horn. Usually, rubbing the skin of painful area seems to somehow relieve the pain associated with a bumped elbow. Large-diameter myelinated afferents (A β) conveying pressure and touch information have “faster” transduction speed than A δ fibers or C fibers conveying painful information to the dorsal horn. Once appropriate peripheral mechanical stimuli are applied, the excited A β fibers may activate the inhibitory interneurons in the dorsal horn and then somehow override the pain messages carried by the A δ and C fibers.

Central Sensitization of Dorsal Horn Neurons

Peripheral inflammation and nerve injury could alter the synaptic efficacy and induce central sensitization in the dorsal horn neurons, which is considered as a fundamental mechanism underlying the induction and maintenance of chronic pain. This central sensitization takes a number of different and distinct forms.[14](#) The first form of central sensitization is windup of dorsal horn neurons, an activity-dependent progressive increase in the response of neurons over the course of a train of inputs. The second form of central sensitization is a heterosynaptic activity-dependent plasticity that outlasts the initiating stimulus for tens of minutes, in which, following a brief (as short as 10-20 seconds) intense nociceptor-conditioning stimulus, normally subliminal/subthreshold inputs can activate dorsal horn neurons as a result of an increase in synaptic efficacy. Other forms of central sensitization include long-term potentiation, transcription-dependent central sensitization, loss of inhibition, and rearrangement of synaptic contacts. Therefore, central sensitization represents an abnormal state of responsiveness or increased gain of the processing of nociceptive information and pain sensation. Central sensitization is not essentially coupled with the presence, intensity, or duration of individual peripheral stimuli. This is well exemplified by the clinical observations that patients suffering from

neuropathic pain usually exhibit painful response to nonnoxious stimuli, exaggerated or sustained response to a noxious stimulus, and/or painful sensitivity in surrounding normal tissues.¹⁵

Ascending Pathway for Pain Transmission

Ascending pathways from the spinal cord to sites in the brainstem and thalamus are important for the perception and integration of nociceptive information. The major ascending pathways important for pain include the spinothalamic tract (STT, direct projections to the thalamus), spinomedullary and spinobulbar projections (direct projections to homeostatic control regions in the medulla and brainstem), and spinohypothalamic tract (direct projections to the hypothalamus and ventral forebrain). Some indirect projections, such as the dorsal column system and the spinocervicothalamic pathway, also exist to forward nociceptive information to the forebrain through the brainstem. Similar pathways originating from the medulla trigeminal sensory nuclei also exist to process the nociceptive information from the facial structures.

Among these pathways, STT is the most closely associated with pain, temperature, and itch sensation. The STT originates in the spinal dorsal horn neurons in lamina I (receiving input from small-diameter A δ and C primary afferent fibers), laminae IV to V (receiving input primarily from large-diameter A β fibers from skin), and laminae VII to VIII (receiving convergent input from large-diameter skin and muscle, joint inputs). About 85% to 90% of STT cells are found on the contralateral side, with 10% to 15% on the ipsilateral side. The axons of STT cells generally cross in the dorsal and ventral spinal commissures to reach the white matter of the contralateral spinal cord within one or two segments rostral to the cells of origin. The axons of STT terminate in several distinct regions of the thalamus.

Supraspinal Modulation of Nociception

Several brain areas are gradually defined with human brain imaging studies as key supraspinal regions involved in nociceptive perception. The most commonly activated regions during acute and chronic pain include SI, SII, anterior cingulate cortex (ACC), insular cortex (IC), prefrontal cortex, thalamus, and cerebellum (see [Figure 6.2](#)). These brain regions form a cortical and subcortical network, which are critically involved in the formation of emotional aspects of pain and the central modulation of pain perception.

In primate, SI and SII receive noxious and innocuous somatosensory input from somatosensory thalamus.¹⁶ Cingulate cortex receives input from medial thalamic nuclei that contain nociceptive neurons, including nucleus parafascicularis and the ventrocaudal part of nucleus medialis dorsalis as well as from lateral thalamic regions. The IC also receives direct thalamocortical nociceptive input in the primate. The prefrontal cortex receives input from ACC, without direct thalamocortical nociceptive input. In general, somatosensory cortices (eg, SI and SII) are more important for the perception of sensory features (eg, the location and duration of pain), whereas limbic and paralimbic regions (eg, ACC and IC) are more important for the emotional and motivational aspects of pain.¹⁷

Descending Pathway for Pain Modulation

It is well recognized that descending pathways originating from certain supraspinal regions may concurrently promote and suppress nociceptive transmission in the dorsal horn, which were termed as descending inhibition pathway and descending facilitation pathway.¹⁸ Among these brain regions, PAG and consequent rostral ventromedial medulla (RVM) brainstem serve as the critical brain regions underlying descending pain modulation ([Figure 6.5](#)). The PAG neurons receive direct or indirect inputs from several brain structures, including amygdala, nucleus accumbens, hypothalamus, and others, with ascending nociceptive afferents from the dorsal horn. The PAG and the adjacent nucleus cuneiformis are the major source of inputs to the RVM. The RVM also receives an input from serotonin-containing neurons of the dorsal raphe and neurotensinergic neurons of the PAG. The PAG projects only minimally to the spinal cord dorsal horn, and the pain-modulating action of the PAG on the spinal cord is relayed largely, if not exclusively, through the RVM. Electrical stimulation of the RVM at different currents can produce inhibition or facilitation of dorsal horn nociceptive processing, which suggesting that there are parallel inhibitory and facilitatory output pathways from RVM to spinal dorsal horn (see [Figure 6.5](#)).¹⁹ It is also important to note that PAG-RVM system serves as one of the major brain sites underlying opiates-induced analgesia.²⁰ μ -Opioid receptor is

widely expressed in the descending pain modulatory pathway, including the PAG, RVM, and the dorsal horn neurons. Activation of μ -opioid receptor in PAG by exogenous or endogenous opioids decreases the activity of GABAergic neurons in PAG resulting in disinhibition of RVM neurons in descending inhibition pathway and subsequent suppression the neuronal activity in dorsal horn neurons.²¹

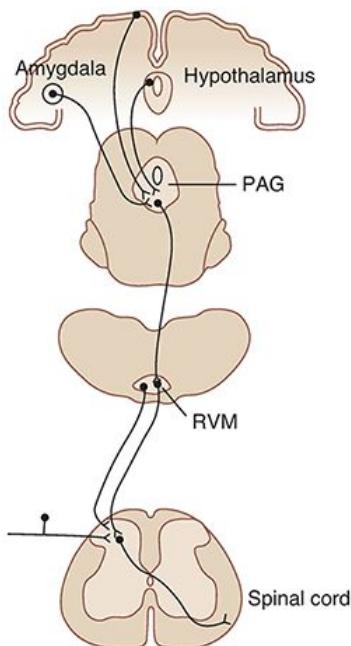

FIGURE 6.5 Properties of proposed medullary pain-modulating neurons. Single-unit extracellular recording was performed by microelectrode in the rostral ventromedial medulla (RVM) while peripheral noxious stimuli (heat) were applied. As shown by the oscilloscope sweeps, the firing of the off cell pauses just prior to the tail flick reflex (indicating pain sensation) in response to noxious heat, although the typical on-cell firing occurs before the tail flick. The diagram illustrates that both on and off cells project to the spinal cord, where they exert bidirectional control over nociceptive dorsal horn neurons. Abbreviation: PAG, periaqueductal gray. Reprinted from McMahon SB, Koltzenburg M. Wall and Melzack's Textbook of Pain. 5th ed. Edinburgh: Churchill Livingstone; 2006. Figure 7.2. Copyright © 2006 Elsevier. With permission.

Spinally projecting noradrenergic neurons of the pontine tegmentum contribute significantly to pain modulation. The locus coeruleus and the A5 and A7 noradrenergic cell groups are the major source of noradrenergic projections to the dorsal horn. Electrical stimulation in each of these regions produces behavioral analgesia and inhibition of dorsal horn neurons mediated by spinal α_2 -adrenergic receptors.

Transition From Acute Pain to Chronic Pain

Acute pain is a short-term pain; when pain receptors no longer detect any tissue damage, the pain sensations would stop. Acute pain does not persist after the initial injury has healed. In contrast, chronic pain is persistent pain beyond the expected period of healing. In this case, pain receptors continue to fire, even in the absence of tissue damage. There may no longer be a physical cause of pain, but the pain response is there. The distinction between acute and chronic pain is not definitely delineated by any clear-cut time interval, although two cutoff points, 3 months and 6 months, are often practically used. Despite recent improvements in techniques for acute pain management, chronic pain still develops in a significant proportion of patients with surgical procedures.

Sensitization of peripheral and central nocisponsive neurons (eg, neurokinin 1 receptor positive dorsal horn neurons) underlies the neurobiologic basis of the transition from acute pain to chronic pain; negative psychological experience during acute pain and noxious stimuli-induced epigenetic modification²² in PNS and CNS are also critically involved in the induction and maintenance of chronic pain. Recent studies suggest

that patients with subacute low back pain who are having negative affective experience (depression and maladaptive cognition) develop greater functional connectivity of the nucleus accumbens with prefrontal cortex; the brain regions processing emotion and rewarding are prone to develop persistent pain.^{23,24}

In the dorsal horn, activated microglia play a substantial role in pain transition from acute to persisted status after peripheral nerve injury or inflammation.²⁵ Peripheral nerve injury induces de novo expression of colony-stimulating factor 1 (CSF1) in injured sensory neurons, which is subsequently transported to the spinal cord and targeted the microglial CSF1 receptor (CSF1R). This CSF1-mediated signaling eventually induces the microglia activation and central sensitization in the dorsal horn and contribute to the transition from acute pain to chronic pain.²⁶ Furthermore, interaction between microglia and nocisponsive dorsal horn neurons, via various chemokines (eg, CX3CL1), cytokines (eg, interleukin-6), and their receptors, epigenetically regulates the expression of various proteins (eg, CXCL12) and enhances the neuronal excitability in dorsal horn in the setting of neuropathic pain.²⁷ Microglia activation appears to be critical in the transition of acute pain to chronic pain. Other molecular and cellular mechanisms (eg, epigenetic modification and neuronal hypersensitivity in peripheral and the dorsal horn neurons) appear to play a role in the transition from acute pain to chronic pain.^{28,29}

Psychobiology of Pain

Pain is defined by the IASP as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Discomfort, fear of pain, and anxiety are the most often psychological symptom observed in the patients suffering from pain, although other aversive emotional qualities, including depression, anger, disgust, and guilt, are not unusual in these patients.

Affective qualities of pain are transmitted and processed in the same pathways as those for the painful sensory transmission. The peripheral nociceptive information is delivered through spinoreticular pathways to diencephalic and telencephalic structures, including the medial thalamus, hypothalamus, amygdala, and limbic cortex. Central sensitization and adaptation of synaptic plasticity occur in these brain regions and contribute to the induction and maintenance of the emotional distress resulting from the pain.¹⁷

It appears that intrinsic interactions occur between the sensory and affective components of pain. Although the affective qualities of painful experience vary across individuals, most patients experiencing acute or chronic pain display substantial emotional, behavioral, or social abnormalities during the onset of pain. Although these affective symptoms may gradually wane and relatively undergo adaptation in some patients, a substantial proportion of patients with chronic pain may display debilitating depression, anxiety, cognitive deficiency, and other negative psychological components of pain. On the other hand, severe emotional distress can trigger new pain or exacerbate the ongoing pain in the patients with previous painful experience.³⁰

Some Specific Types of Pain

Neuropathic Pain

Neuropathic pain, characterized by a reduced nociceptive threshold, persists in the absence of a stimulus and is refractory to traditional analgesics. Injury of peripheral nerves by trauma, surgery, or diseases (eg, diabetes) frequently results in the development of neuropathic pain. Cancer patients are at increased risk of neuropathic pain caused by radiotherapy or a variety of chemotherapeutic agents. Although acute and inflammatory pain are usually considered as an adaptive process of the pain system to provide warning and protection, neuropathic pain actually reflects a maladaptive (pathophysiologic) function of a damaged pain system. In many patients, neuropathic pain persists throughout life and negatively affects physical, emotional, and social quality of life.³¹ There is currently no effective symptomatic treatment for neuropathic pain. Opioids, gabapentin, amitriptyline, and medicinal cannabis preparations have appear to have limited efficacy.³²⁻³⁴ The pathophysiologic process of neuropathic pain has the hallmarks of a neuroinflammatory response following innate immune system activation. Toll-like receptors 2 and 4 on microglia appear to trigger glial activation, initiating proinflammatory and signal transduction pathways^{35,36} that lead to the production of

proinflammatory cytokines. Central cannabinoid receptor type 2 appears to play a protective role, and administration of a cannabinoid receptor type 2 receptor agonist can blunt the neuroinflammatory response and prevent peripheral neuropathy through interference with specific signaling pathways.^{37,38}

The common pathologic features of the neural damage include segmental dysmyelination/demyelination and axonopathy, ranging from metabolic and axoplasmic transport deficits to frank transection of the axon (axotomy). After nerve injury occurs, the proximal stump of axon seals off and forms a terminal swelling or “end bulb,” and numerous fine processes (“sprouts”) start to grow out from the end bulb in 1 or 2 days. These regenerating sprouts normally elongate within their original endoneurial tube and restore the normal sensation in appropriate peripheral targets. However, in case the forward growth is blocked, such as after limb amputation, end bulbs and aborted sprouts form a tangled mass at the nerve end, a “nerve-end neuroma.” Usually, the ectopic firing generated in end bulb and sprouts in neuroma, as well as the cell bodies in dorsal root ganglia, significantly contribute to the nociceptive hypersensitivity and ectopic mechanosensitivity–induced nerve injury.

Visceral Pain

Although somatic pain is easily localized and characterized by distinct sensations, visceral pain is diffuse and poorly localized, typically referred to somatic sites (eg, muscle and skin), and it is usually associated with stronger emotional and autonomic reactions. Also, visceral pain is often produced by stimuli different from those adequate for activation of somatic nociceptors. These features may be attributable to dual nerve innervation and the unique structure of receptive ending.

Among all tissues in the body, the viscera are unique in that each organ receives innervation from two sets of nerves, either vagal and spinal nerves or pelvic parasympathetic nerves, and the visceral afferent innervation is sparse relative to somatic innervation. Spinal visceral afferent fibers have their cell bodies in dorsal root ganglia and terminate in the spinal dorsal horn. The central termination of visceral afferents synapse spinal neurons in laminae I, II, V, and X over several segments and deliver the visceral sensory information through the contralateral STT or ipsilateral dorsal column to supraspinal brain sites. These spinal neurons also receive convergent input from somatic (or another visceral) structures, providing the structural basis for referred pain. Another set of nerve system conveying pain information of organs in the thoracic and abdominal cavities is the vagus nerve, which has cell bodies in the nodose ganglion and central terminals in the nucleus tractus solitarii. The vagus afferent innervation plays an important role in the prominent autonomic and emotional reactions in visceral diseases associated with pain (**Figure 6.6**). The majority of visceral afferent fibers are thinly myelinated A δ fibers or unmyelinated C fibers with unencapsulated free nerve ending, with a small number of A β fibers associated with Pacinian corpuscles in the mesentery activation of visceral nociceptor are generally induced by ischemia, stretching of ligament attachments, spasm of smooth muscles, or distension of a hollow structure such as the gallbladder, common bile duct, or ureter. These stimuli usually occur in many visceral pathologic processes, and the pain they induce may serve a survival function by promoting immobility.

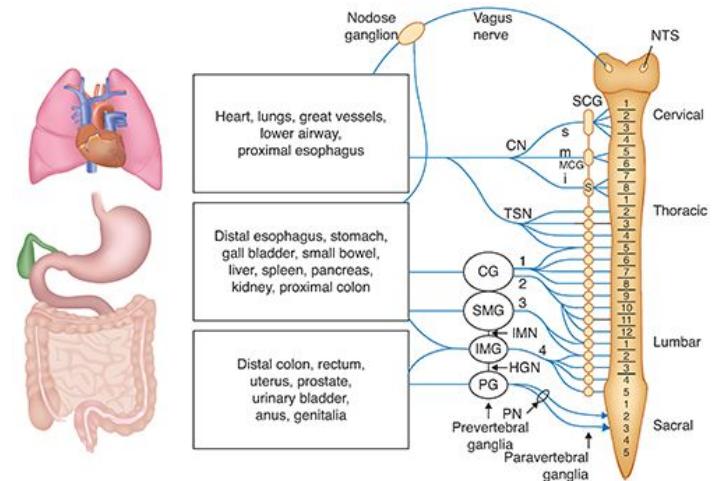

FIGURE 6.6 Visceral innervation. The vagus nerve, with cell bodies in the nodose ganglion and central terminals in the nucleus tractus solitarii (NTS), innervates organs in the thoracic and abdominal cavities. Afferent nerves with terminals in the spinal cord innervate the same thoracic and abdominal organs as well as those in the pelvic floor. Visceral spinal afferents pass through pre- and/or paravertebral ganglia en route to the spinal cord; their cell bodies are located in dorsal root ganglia, which are not illustrated. Abbreviations: CG, celiac ganglion; CN, cardiac nerves (i, inferior; m, middle; s, superior); HGN, hypogastric nerve; IMG, inferior mesenteric ganglia; IMN, intermesenteric nerve; MCG, middle cervical ganglia; PG, pelvic ganglion; PN, pelvic nerve; S, stellate ganglion; SCG, superior cervical ganglion; SMG, superior mesenteric ganglia; TSN, thoracic splanchnic nerves (1, greater; 2, lesser; 3, least; 4, lumbar splanchnic nerves). *Reprinted from McMahon SB, Koltzenburg M. Wall and Melzack's Textbook of Pain. 5th ed. Edinburgh: Churchill Livingstone; 2006. Figure 48.1. Copyright © 2006 Elsevier. With permission.*

Complex Regional Pain Syndromes

The IASP *Classification of Chronic Pain* defines complex regional pain syndrome (CRPS) as “a variety of painful conditions following injury which appears regionally having a distal predominance of abnormal findings, exceeding in both magnitude and duration the expected clinical course of the inciting event often resulting in significant impairment of motor function, and showing variable progression over time.” These chronic pain syndromes comprise different additional clinical features including spontaneous pain, allodynia, hyperalgesia, edema, autonomic abnormalities, active and passive movement disorders, and trophic changes of skin and subcutaneous tissues. Two types of CRPS, type I (reflex sympathetic dystrophy) and type II (causalgia), exist. The current IASP diagnostic clinical criteria for CRPS are as follows: *CRPS I* is (1) a syndrome that develops after an initiating noxious event; (2) spontaneous pain or allodynia/hyperalgesia occurs, is not limited to the territory of a single peripheral nerve, and is disproportionate to the inciting event; (3) there is or has been evidence of edema, skin blood flow abnormality, or abnormal sudomotor activity in the region of the pain since the inciting event; and (4) this diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

CRPS II (1) is a syndrome that develops after nerve injury. Spontaneous pain or allodynia/hyperalgesia occurs and is not necessarily limited to the territory of the injured nerve; (2) there is or has been evidence of edema, skin blood flow abnormality, or abnormal sudomotor activity in the region of the pain since the inciting event; and (3) this diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

CRPS I develops more often than CRPS II, and females are more often affected than males (2:1-4:1). The incidence of CRPS I is 1% to 2% after fractures, 12% after brain lesions, and of 5% after myocardial infarction, and the incidence of CRPS II in peripheral nerve injury varies from 2% to 14% in different series, with a mean around of 4%. The mechanism underlying the pathogenesis of CRPS remains unclear, although it is recognized that CRPS is a neurologic disease including the autonomic, sensory, and motor systems as

well as cortical areas involved in the processing of cognitive and affective information, and the inflammatory component (microglial activation) appears to be particularly important in the acute phase of the disease. So far, very few evidence-based treatment regimens for CRPS are available.

Pain in Neonate and Infant

The outdated thoughts that young children do not feel pain due to the immaturity of the PNS and CNS are no longer valid. Reflex responses to somatic stimuli begin at 15 days (E15, where gestation is 21.5 days) in the rat fetus, and the human fetuses probably obtain painful perception at around 23 to 26 weeks.^{39,40} Postnatal maturity of pain behavior develops quickly after birth. Usually, newborns and young children have significantly lower pain threshold and exaggerated pain responses compared to adults.⁴¹ Some clinical studies reveal the long-term effects of neonatal painful experience, which is affected by several confounding factors such as gestational age at birth, length of intensive care stay, intensity of the stimulus, and parenting style. Usually, the toddlers and adolescents with neonatal painful experience exhibit long-lasting hypersensitivity to painful stimuli. For example, the infants with neonatal circumcision had higher behavioral pain scores and cried longer during vaccination at 4 to 6 months old.⁴² These observations highlight the clinical importance of optimal management of pain in neonate and infant.

Embryologic Origin and Localization of Pain

The position in the spinal cord to which visceral afferent fibers pass for each organ depends on the segment (dermatome) of the body from which the organ developed embryologically. This explains the phenomenon of referred pain to a site distal from the tissue causing the pain (**Figure 6.7**). For example, the heart originates in the neck and upper thorax such that visceral afferents enter the spinal cord at C3 to C5. As a result, the referred pain of myocardial ischemia is to the neck and arm. The gallbladder originates from the ninth thoracic segment, so visceral afferents from the gallbladder enter the spinal cord at T9. Skeletal muscle spasm caused by damage in adjacent tissues may also be a cause of referred pain. For example, pain from the ureter can cause reflex spasm of the lumbar muscles.

Opioid Agonists and Antagonists

Kenneth C. Cummings III • Mohamed A. Naguib[†]

Opioids are a cornerstone of modern perioperative care and pain management. The modern word “**opium**” is derived from the Greek word **opion** (“poppy juice”); the opium poppy (*Papaver somniferum*) is the source of 20 distinct alkaloids. Written mention of the medicinal use of poppy juice dates back to at least 300 BC, although religious use likely goes back much further.¹ Drugs derived from opium are referred to as **opiates**. Morphine, the best known opiate, was isolated in 1803, followed by codeine in 1832 and papaverine in 1848. Morphine can be synthesized, but it is more easily derived from opium. The term **narcotic** is derived from the Greek word for stupor and traditionally has been used to refer to potent morphine-like analgesics with the potential to produce physical dependence. The development of synthetic drugs with morphine-like properties has led to the use of the term **opioid** to refer to all exogenous substances, natural and synthetic, that bind specifically to any of several subpopulations of opioid receptors and produce at least some agonist (morphine-like) effects. Opioids are unique in producing analgesia without loss of touch, proprioception, or consciousness. A convenient classification of opioids includes opioid agonists, opioid agonist-antagonists, and opioid antagonists ([Table 7.1](#)).

TABLE 7.1		
Classification of opioid agonists and antagonists		
Agonists	Agonists-antagonists	Antagonists
Morphine	Pentazocine	Naloxone
Morphine-6-glucuronide	Butorphanol	Naltrexone
Meperidine	Nalbuphine	Nalmefene
Sufentanil	Buprenorphine	
Fentanyl	Nalorphine	
Alfentanil	Bremazocine	
Remifentanil	Dezocine	
Carfentanil	Meptazinol	
Codeine		
Hydromorphone		
Oxymorphone		
Oxycodone		
Hydrocodone		
Propoxyphene		
Methadone		
Tramadol		
Heroin (diacetylmorphine)		

Chemical Structure of Opium Alkaloids

The active components of opium can be divided into two distinct chemical classes: phenanthrenes and benzylisoquinolines. The principal phenanthrene alkaloids present in opium are morphine, codeine, and thebaine ([Figure 7.1](#)). The principal benzylisoquinoline alkaloids present in opium, which lack analgesic activity, are papaverine and noscapine.

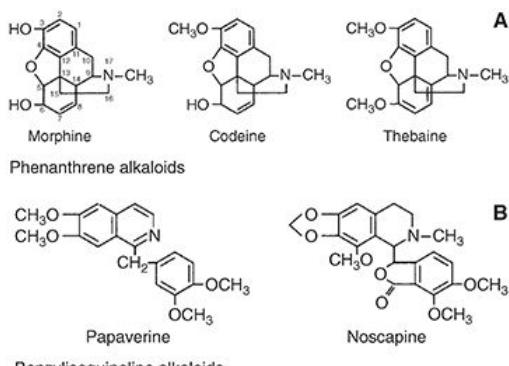

FIGURE 7.1 Chemical structures of opium alkaloids. Phenanthrene (A) and benzylisoquinoline (B) alkaloids.

The three rings of the phenanthrene core are composed of 14 carbon atoms. The fourth piperidine ring includes a tertiary amine nitrogen and is present in most opioid agonists. At pH 7.4, the tertiary amine nitrogen is highly ionized, making the molecule water soluble. These are chiral molecules, with levorotatory isomers being biologically active at opioid receptors.

Semisynthetic Opioids

Simple modification of the morphine molecule yields many derivative compounds with differing properties. For example, substitution of a methyl group for the hydroxyl group on carbon 3 results in methylmorphine (codeine). Substitution of acetyl groups on carbons 3 and 6 results in diacetylmorphine (heroin).

Hydromorphone has a carbonyl group instead of hydroxyl at position 6 and lacks a double bond between carbons 7 and 8. Thebaine has insignificant analgesic activity but serves as the precursor for etorphine (analgesic potency >1,000 times morphine).

Synthetic Opioids

Synthetic opioids contain the phenanthrene nucleus of morphine but are manufactured by synthesis rather than chemical modification of morphine. Morphine derivatives (levorphanol), methadone derivatives, benzomorphan derivatives (pentazocine), and phenylpiperidine derivatives (meperidine, fentanyl) are examples of groups of synthetic opioids. There are similarities in the molecular weights (236–326) and pK_as of phenylpiperidine derivatives and amide local anesthetics.

Fentanyl, sufentanil, alfentanil, and remifentanil ([Figure 7.2](#)) are synthetic opioids that are widely used to supplement general anesthesia or as primary anesthetic drugs in very high doses. There are important clinical differences between these opioids.^{2–4} The major pharmacodynamic differences between these drugs are potency and rate of equilibration between the plasma and the site of drug effect (biophase).

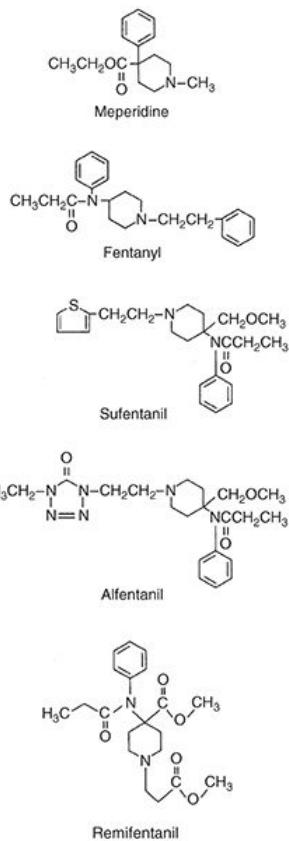

FIGURE 7.2 Synthetic opioid agonists.

Opioid Receptors

Opioid receptors are classified as μ , δ , and κ receptors (Table 7.2).^{5,6} The names of the three subtypes developed from the ligands originally found to bind to them or their tissue of origin (μ —morphine, κ —ketocyclazocine, δ —isolated from mouse *vas deferens*). These opioid receptors belong to a superfamily of seven transmembrane-segment guanine (G) protein-coupled receptors that includes muscarinic, adrenergic, and somatostatin receptors. The opioid receptors have been cloned, and their amino acid sequences defined.^{7,8} A single μ -receptor gene has been identified, and six distinct μ receptors have been identified.

TABLE 7.2

Classification of opioid receptors^a

	μ_1^b	μ_2^b	κ	δ
Effect	Analgesia (supraspinal, spinal)	Analgesia (spinal)	Analgesia (supraspinal, spinal)	Analgesia (supraspinal, spinal)
	Euphoria	Depression of ventilation	Dysphoria, sedation	Depression of ventilation
	Low abuse potential	Physical dependence	Low abuse potential	Physical dependence
	Miosis		Miosis	
		Constipation (marked)		Constipation (minimal)
	Bradycardia			
	Hypothermia

^bThe existence of specific μ_1 and μ_2 receptors is not supported based on cloning studies of μ receptors.

^c μ Receptors seem to be a universal site of action for all endogenous opioid receptors.

In the brain, opioid receptors are primarily found in the periaqueductal gray, locus ceruleus, and the rostral ventral medulla. In the spinal cord, opioid receptors are found both on interneurons and primary afferent neurons in the dorsal horn. Consequently, direct application of opioid agonists to the spinal cord can produce intense analgesia.⁹ Outside the central nervous system (CNS), opioid receptors are found on sensory neurons and immune cells. For example, intraarticular morphine is known to produce analgesia after knee surgery, presumably through action on peripheral nerves.¹⁰ Immune cells recruited to sites of inflammation also secrete opioid peptides to provide local analgesia.¹¹ This may be useful in drug development. For example, lowering the pK_a of an opioid compound should cause its preferential activity at areas of reduced pH such as inflammation.¹²

μ -Opioid receptors are principally responsible for supraspinal and spinal analgesia. Theoretically, activation of a subpopulation of μ receptors (μ_1) is speculated to produce analgesia, whereas μ_2 receptors are responsible for hypoventilation, bradycardia, and physical dependence. Nevertheless, cloning of the μ receptors does not support the existence of separate μ_1 and μ_2 receptor subtypes.⁶ It is possible that such subtypes result from posttranslational modification of a common precursor protein. Additionally, the response of μ -opioid receptors to agonists can be significantly affected by β -arrestins, a family of proteins that regulate the activity of G protein-coupled receptors. For example, β -arrestins have been demonstrated to promote receptor desensitization (or resensitization) as well as to promote clathrin-mediated endocytosis.¹³ In principle, pharmacologic modulation of β -arrestin activity could improve the efficacy and tolerability of opioid agonists.¹⁴

Activation of κ receptors results in inhibition of neurotransmitter release via N-type calcium channels. Respiratory depression characteristic of μ -receptor activation is less prominent with κ -receptor activation, although dysphoria and diuresis may accompany activation of these receptors. A κ receptor-mediated analgesia may be less effective for high-intensity painful stimulation than μ opioid mediated. Opioid agonist-antagonists often act principally on κ receptors. The δ receptors respond to the endogenous ligands known as enkephalins, and these opioid receptors may serve to modulate the activity of the μ receptors.

Functional and physical interactions between these receptor subtypes have been noted.^{15,16} Heteromerization between μ - and δ -opioid receptors leads to distinct receptor pharmacology in that doses of δ -receptor ligands (agonists and antagonists) too low to trigger signaling can potentiate the binding and signaling of μ -receptor agonists. Chronic, but not acute, morphine treatment results in an increase in the μ - δ heteromers in key areas of the CNS that are implicated in pain processing.¹⁷

Previously considered opioid receptors, σ receptors (types 1 and 2) are widespread in the CNS and peripheral tissues. They are now known not to be true opioid receptors but have diverse roles in intracellular signaling, metabolic regulation, mitochondrial metabolism, and other functions.¹⁸

Endogenous Pain-Modulating Mechanisms

The logical reason for the existence of opioid receptors and endogenous opioid agonists is to function as an endogenous pain suppression system. Once pain is consciously perceived, it has served its purpose and it is

reasonable to posit that the ability to dampen this perception would have a survival benefit. Opioid receptors are located in areas of the brain (periaqueductal gray, locus ceruleus, and the rostral ventral medulla) and spinal cord (substantia gelatinosa) that are involved with pain perception, integration of pain impulses, and responses to pain (Figure 7.3).¹⁹ It is speculated that endorphins inhibit the release of excitatory neurotransmitters from terminals of nerves carrying nociceptive impulses. As a result, neurons are hyperpolarized, which suppresses spontaneous discharges and evoked responses. Analgesia induced by electrical stimulation of specific sites in the brain or mechanical stimulation of peripheral areas (acupuncture) most likely reflects release of endorphins.²⁰ Even the analgesic response to a placebo may also involve the release of endorphins. Sustained pain and stress induce the regional release of endogenous opioids interacting with μ -opioid receptors in a number of cortical and subcortical brain regions. The activation of the μ -opioid receptor system is associated with reductions in the sensory and affective ratings of the pain experience, with distinct neuroanatomical involvements.^{21,22}

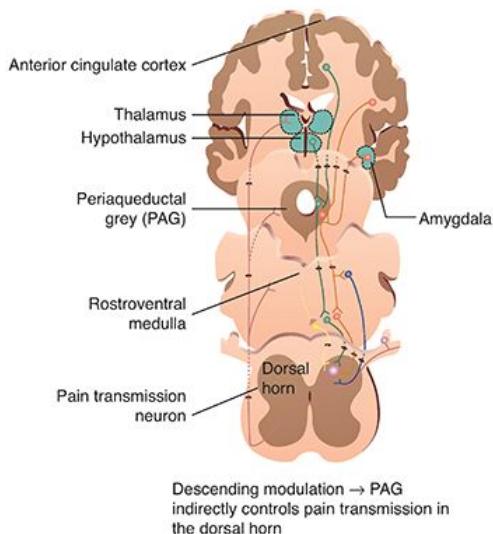

FIGURE 7.3 Opioid-sensitive pain modulation system. Limbic system areas project to the periaqueductal gray (PAG). The PAG in turn controls afferent pain transmission in the rostroventral medulla. This action can be both inhibitory (red) or facilitatory (green). *From Fields H. State-dependent opioid control of pain. Nat Rev Neurosci. 2004;5(7):565-575.*

In addition, one study demonstrated that positive treatment expectancy substantially enhanced (doubled) the analgesic benefit of remifentanil, whereas negative treatment expectancy abolished remifentanil analgesia.²³ These subjective effects were substantiated by significant changes in the neural activity in brain regions involved with the coding of pain intensity. The positive expectancy effects were associated with activity in the endogenous pain modulatory system, and the negative expectancy effects with activity in the hippocampus.²³ On the basis of subjective and objective evidence, we contend that an individual's expectation of a drug's effect critically influences its therapeutic efficacy and that regulatory brain mechanisms differ as a function of expectancy.

Common Opioid Side Effects

An ideal opioid agonist would have a high specificity for receptors, producing desirable responses (analgesia) and little or no specificity for receptors associated with side effects. To date, however, all opioids possess similar side effects that vary only in degree. Therefore, a focus on the effects of morphine provides a suitable starting point.

Cardiovascular System

Morphine, even in large doses, given to supine and normovolemic patients is unlikely to cause direct myocardial depression or hypotension. The same patients changing from a supine to a standing position, however, may manifest orthostatic hypotension and syncope, presumably reflecting morphine-induced impairment of compensatory sympathetic nervous system responses. For example, morphine decreases sympathetic nervous system tone to peripheral veins, resulting in venous pooling and subsequent decreases in venous return, cardiac output, and blood pressure.²⁴

Morphine can also evoke decreases in systemic blood pressure due to drug-induced bradycardia or histamine release. Morphine-induced bradycardia results from increased activity over the vagal nerves, which probably reflects stimulation of the vagal nuclei in the medulla. Morphine may also exert a direct depressant effect on the sinoatrial node and acts to slow conduction of cardiac impulses through the atrioventricular node. These actions, may, in part, explain decreased vulnerability to ventricular fibrillation in the presence of morphine. Administration of opioids (morphine) in the preoperative medication or before the induction of anesthesia (fentanyl) tends to slow heart rate during exposure to volatile anesthetics with or without surgical stimulation.²⁵

Opioid-induced histamine release and associated hypotension are variable in both incidence and severity. The magnitude of morphine-induced histamine release and subsequent decrease in systemic blood pressure can be minimized by (1) limiting the rate of morphine infusion to 5 mg/min intravenously (IV), (2) maintaining the patient in a supine to slightly head-down position, and (3) optimizing intravascular fluid volume. Conversely, administration of morphine, 1 mg/kg IV, over a 10-minute period produces substantial increases in the plasma concentrations of histamine that are paralleled by significant decreases in systemic blood pressure and systemic vascular resistance ([Figure 7.4](#)).²⁶ It is important to recognize, however, that not all patients respond to this rate of morphine infusion with the release of histamine, emphasizing the individual variability associated with the administration of this drug. In contrast to morphine, the infusion of fentanyl 50 µg/kg IV over a 10-minute period does not cause release of histamine in any patient (see [Figure 7.4](#)). Pretreatment of patients with H₁- and H₂-receptor antagonists does not alter release of histamine evoked by morphine but does prevent changes in systemic blood pressure and systemic vascular resistance.²⁷

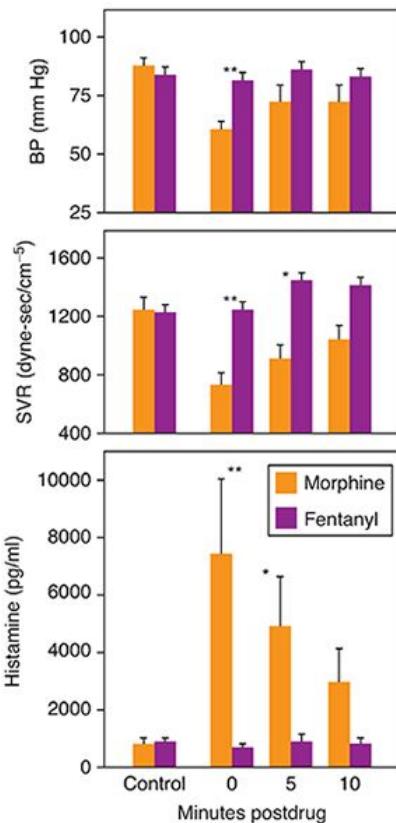

FIGURE 7.4 Morphine-induced decreases in systemic blood pressure (BP) and systemic vascular resistance (SVR) are accompanied by increases in the plasma concentration of histamine. Similar changes do not accompany the intravenous administration of fentanyl (* $P < .05$; ** $P < .005$; mean \pm standard error). *Reprinted with permission from Rosow CE, Moss J, Philbin DM, et al. Histamine release during morphine and fentanyl anesthesia. Anesthesiology. 1982;56(2):93-96. Copyright © 1982 American Society of Anesthesiologists, Inc.*

Morphine does not sensitize the heart to catecholamines or otherwise predispose to cardiac dysrhythmias as long as hypercarbia or arterial hypoxemia does not result from ventilatory depression. Tachycardia and hypertension that occur during anesthesia with morphine are not pharmacologic effects of the opioid but rather are responses to painful surgical stimulation that are not suppressed by morphine. Both the sympathetic nervous system and the renin-angiotensin axis contribute to these cardiovascular responses. Large doses of morphine or other opioid agonists may decrease the likelihood that tachycardia and hypertension will occur in response to painful stimulation, but once this response has occurred, administration of additional opioid is unlikely to be effective.

During anesthesia, however, opioids are commonly administered with inhaled or IV anesthetics to ensure amnesia. The combination of an opioid agonist such as morphine or fentanyl with nitrous oxide results in cardiovascular depression (decreased cardiac output and systemic blood pressure plus increased cardiac filling pressures), which does not occur when either drug is administered alone.²⁸ Likewise, decreases in systemic vascular resistance and systemic blood pressure may accompany the combination of an opioid and a benzodiazepine, whereas these effects do not accompany the administration of either drug alone ([Figure 7.5](#)).²⁹

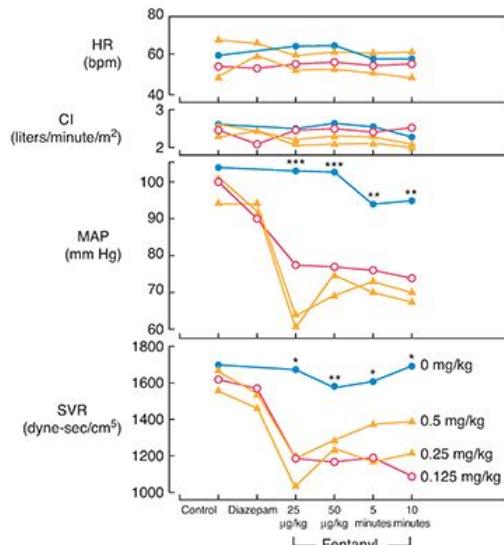

FIGURE 7.5 Administration of fentanyl (50 $\mu\text{g}/\text{kg}$ intravenously [IV] at 400 $\mu\text{g}/\text{minute}$) after injection of diazepam (0.125–0.50 mg/kg IV) is associated with significant decreases in mean arterial pressure (MAP) and systemic vascular resistance (SVR), whereas heart rate (HR) and cardiac index (CI) do not change. Administration of fentanyl in the absence of prior injection of diazepam (0 mg/kg) is devoid of circulatory effects. *Reprinted with permission from Tomicheck RC, Rosow CE, Philbin DM, et al. Diazepam-fentanyl interaction: hemodynamic and hormonal effects in coronary artery surgery. Anesth Analg. 1983;62(10):881–884. Copyright © 1983 International Anesthesia Research Society.*

Opioids have been increasingly recognized to play a role in protecting the myocardium from ischemia. Through several mechanisms, most prominently through σ and α receptors, opioids enhance the resistance of the myocardium to oxidative and ischemic stresses. Mitochondrial adenosine triphosphate-regulated potassium channels appear to be central to this signaling pathway.³⁰ Although once considered opioid receptors, σ receptors are now recognized to play diverse roles in cell signaling, metabolic regulation, and apoptosis and are not considered true opioid receptors.¹⁸

Ventilation

Because analgesic and ventilatory effects of opioids occur by similar mechanisms, it is assumed that equianalgesic doses of all opioids will produce some degree of ventilatory depression and reversal of ventilatory depression with an opioid antagonist always involves some reversal of analgesia. Opioid-induced depression of ventilation is characterized by decreased responsiveness of these ventilation centers to carbon dioxide as reflected by an increase in the resting arterial partial pressure of CO_2 and displacement of the carbon dioxide response curve to the right. Opioid agonists also interfere with pontine and medullary ventilatory centers that regulate the rhythm of breathing, leading to prolonged pauses between breaths and periodic breathing. It is possible that opioid agonists diminish sensitivity to carbon dioxide by decreasing the release of acetylcholine from neurons in the area of the medullary ventilatory center in response to hypercarbia. At the cellular level, there is evidence for β -arrestin mediation of opioid-induced ventilatory depression, which raises the possibility of using “biased ligands” at opioid receptors to mitigate this adverse effect.³¹

Depression of ventilation produced by opioid agonists is rapid and persists for several hours, as demonstrated by decreased ventilatory responses to carbon dioxide. High doses of opioids may result in apnea, but the patient remains conscious and able to initiate a breath if asked to do so. Death from an opioid overdose is almost invariably due to depression of ventilation.

Clinically, depression of ventilation produced by opioids manifests as a decreased frequency of breathing that is often accompanied by a compensatory increase in tidal volume. The incompleteness of this

compensatory increase in tidal volume is evidenced by predictable increases in the Paco_2 . Many factors influence the magnitude and duration of depression of ventilation produced by opioid agonists. For example, advanced age and the occurrence of natural sleep increase the ventilatory depressant effects of opioids. Conversely, pain from surgical stimulation counteracts depression of ventilation produced by opioids. Likewise, the analgesic effect of opioids slows breathing that has been rapid and shallow due to pain.

Opioids produce dose-dependent depression of ciliary activity in the airways. Increases in airway resistance after administration of an opioid are probably due to a direct effect on bronchial smooth muscle and an indirect action due to release of histamine (from some opioids).

Cough Suppression

Opioids depress cough by effects on the medullary cough centers that are distinct from the effects of opioids on ventilation. The greatest cough suppression occurs with opioids that have bulky substitutions at the number 3 carbon position (codeine). One useful property of dextrorotatory isomers (such as dextromethorphan) is that they can suppress cough but do not produce analgesia or depression of ventilation. They are not, however, devoid of abuse potential.³²

Central Nervous System

In the absence of hypoventilation, opioids decrease cerebral blood flow and possibly intracranial pressure (ICP). These drugs must be used with caution in patients with head injury because of their (1) associated effects on wakefulness, (2) production of miosis, and (3) depression of ventilation with associated increases in ICP if the Paco_2 becomes increased. Furthermore, head injury may impair the integrity of the blood-brain barrier, with resultant increased sensitivity to opioids.

The effect of morphine on the electroencephalogram (EEG) resembles changes associated with sleep. For example, there is replacement of rapid α waves by slower δ waves. Recording of the EEG fails to reveal any evidence of seizure activity after administration of large doses of opioids (see “[Fentanyl](#)” section). Opioids do not alter the responses to neuromuscular-blocking drugs. Skeletal muscle rigidity, especially of the thoracic and abdominal muscles, is common when large doses of opioid agonists are administered rapidly and IV.³³ Clonic skeletal muscle activity (myoclonus) occurring during administration of opioids may resemble grand mal seizures, but the EEG does not reflect seizure activity. Skeletal muscle rigidity may be related to actions at opioid receptors and involve interactions with dopaminergic and γ -aminobutyric acid-responsive neurons.

Miosis is due to an excitatory action of opioids on the autonomic nervous system component of the Edinger-Westphal nucleus of the oculomotor nerve. Tolerance to the miotic effect of morphine is not prominent. Miosis can be antagonized by atropine, and profound arterial hypoxemia in the presence of morphine can still result in mydriasis.

Rigidity

Rapid IV administration of large doses of an opioid (particularly fentanyl and its derivatives as used in cardiac surgery) can lead to generalized skeletal muscle rigidity. This can be severe enough to interfere with manual ventilation. Although generally termed “chest wall” rigidity, evidence supports the conclusion that the majority of resistance to ventilation is due to laryngeal musculature contraction. Inhibition of striatal release of γ -aminobutyric acid and increased dopamine production are the likely explanations for opioid-induced increased skeletal muscle tone.³⁴ The reported incidence of difficult ventilation after a moderate dose of sufentanil ranges from 84% to 100%.³⁵ Treatment is muscle relaxation with neuromuscular-blocking drugs or opioid antagonism with naloxone.

Sedation

Postoperative titration of morphine frequently induces sedation that precedes the onset of analgesia.³⁶ The usual recommendation for morphine titration includes a short interval between boluses (5-7 minutes) to allow evaluation of its clinical effect. Sedation occurs in up to 60% of patients during morphine titration and

represents a common reason to discontinue morphine titration for postoperative analgesia. The assumption that sleep occurs when pain is relieved is not necessarily accurate, and morphine-induced sedation should not be considered as an indicator of appropriate analgesia during IV morphine titration.

Biliary Tract

Opioids can cause spasm of biliary smooth muscle, resulting in increases in biliary pressure that may be associated with epigastric distress or biliary colic. This pain may be confused with angina pectoris. Naloxone will relieve pain caused by biliary spasm but not myocardial ischemia. Conversely, nitroglycerin will relieve pain due to either biliary spasm or myocardial ischemia. Equal analgesic doses of fentanyl, morphine, meperidine, and pentazocine increase common bile duct pressure 99%, 53%, 61%, and 15% above predrug levels, respectively.³⁷ During surgery, opioid-induced spasm of the sphincter of Oddi may appear radiologically as a sharp constriction at the distal end of the common bile duct and be misinterpreted as a common bile duct stone. It may be necessary to reverse opioid-induced biliary smooth muscle spasm with naloxone so as to correctly interpret the cholangiogram. Glucagon, 2 mg IV, also reverses opioid-induced biliary smooth muscle spasm and, unlike naloxone, does not antagonize the analgesic effects of the opioid.³⁸ However, biliary muscle spasm does not occur in most patients who receive opioids. Indeed, the incidence of spasm of the sphincter of Oddi is about 3% in patients receiving fentanyl as a supplement to inhaled anesthetics.³⁹

Contraction of the smooth muscles of the pancreatic ducts is probably responsible for increases in plasma amylase and lipase concentrations that may be present after the administration of morphine. Such increases may confuse the diagnosis when acute pancreatitis is a possibility.

Gastrointestinal Tract

Commonly used opioids such as morphine, meperidine, and fentanyl can produce spasm of the gastrointestinal smooth muscles, resulting in a variety of side effects including constipation, biliary colic, and delayed gastric emptying.

Morphine decreases the propulsive peristaltic contractions of the small and large intestines and enhances the tone of the pyloric sphincter, ileocecal valve, and anal sphincter. The delayed passage of intestinal contents through the colon allows increased absorption of water. As a result, constipation often accompanies therapy with opioids and may become a debilitating problem in patients who require chronic opioid therapy, as little tolerance develops to this effect. Of interest, opium was used to treat diarrhea before its use as an analgesic was popularized.

Increased biliary pressure occurs when the gallbladder contracts against a closed or narrowed sphincter of Oddi. Passage of gastric contents into the proximal duodenum is delayed because there is increased tone at the gastroduodenal junction. In this regard, preoperative medication that includes an opioid could slow gastric emptying (potentially increase the risk of aspiration) or delay the absorption of orally administered drugs. All these effects may be reversed or prevented by a peripheral-acting opioid antagonist (see “[Opioid Antagonists](#)” section).

Nausea and Vomiting

Opioid-induced nausea and vomiting are caused by direct stimulation of the chemoreceptor trigger zone in the floor of the fourth ventricle. This may reflect the role of opioid agonists as partial dopamine agonists at dopamine receptors in the chemoreceptor trigger zone. Indeed, apomorphine is a profound emetic and is also the most potent of the opioids at dopamine receptors. Stimulation of dopamine receptors as a mechanism for opioid-induced nausea and vomiting is consistent with the antiemetic efficacy of butyrophenones and phenothiazines. Morphine may also cause nausea and vomiting by increasing gastrointestinal secretions and delaying passage of intestinal contents toward the colon. Nausea and vomiting are relatively uncommon in recumbent patients given morphine, suggesting that a vestibular component may also contribute to opioid-induced nausea and vomiting.

Genitourinary System

Morphine can increase the tone and peristaltic activity of the ureter. In contrast to similar effects on biliary tract smooth muscle, the same opioid-induced effects on the ureter can be reversed by an anticholinergic drug such as atropine. Urinary urgency is produced by opioid-induced augmentation of detrusor muscle tone, but, at the same time, the tone of the urinary sphincter is enhanced, making voiding difficult.

Antidiuresis that accompanies administration of morphine to animals has been attributed to opioid-induced release of arginine vasopressin hormone (antidiuretic hormone). In humans, however, administration of morphine in the absence of painful surgical stimulation does not evoke the release of this hormone.⁴⁰ Furthermore, when morphine is administered in the presence of an adequate intravascular fluid volume, there is no change in urine output.

Cutaneous Changes

Morphine causes cutaneous blood vessels to dilate. The skin of the face, neck, and upper chest frequently becomes flushed and warm. These changes in cutaneous circulation are in part caused by the release of histamine. Histamine release probably accounts for urticaria and erythema commonly seen at the morphine injection site. In addition, morphine-induced histamine release probably accounts for conjunctival erythema and pruritus. Localized cutaneous evidence of histamine release, especially along the vein into which morphine is injected, does not represent an allergic reaction.

Placental Transfer

Opioids are readily transported across the placenta.⁴¹ Therefore, depression of the neonate can occur as a consequence of administration of opioids to the mother during labor. However, their effects on neonates are quite variable: Maternal administration of morphine may produce greater neonatal depression than meperidine.⁴² Although fentanyl crosses the placenta, it does not produce significant neonatal depression unless large doses are used. Chronic maternal use of an opioid can result in the development of physical dependence in the fetus. Subsequent administration of naloxone to the neonate can precipitate a life-threatening neonatal withdrawal syndrome.

Drug Interactions

The ventilatory depressant effects of some opioids may be exaggerated by amphetamines, phenothiazines, monoamine oxidase inhibitors, and tricyclic antidepressants. For example, patients receiving monoamine oxidase inhibitors may experience exaggerated CNS depression and hyperpyrexia after administration of an opioid agonist, especially meperidine.⁴³

Hormonal Changes

Prolonged opioid therapy may influence the hypothalamic-pituitary-adrenal axis and the hypothalamic-pituitary-gonadal axis, leading to endocrine and immune effects.^{44,45} Morphine may cause a progressive decrease in plasma cortisol concentrations. The main effects of opioids on the hypothalamic-pituitary-gonadal axis involve modulation of hormone release including increased prolactin and decreased luteinizing hormone, follicle-stimulating hormone, testosterone, and estrogen concentrations.

Overdose

The principal manifestation of opioid overdose is depression of ventilation manifesting as a slow breathing frequency, which may progress to apnea. Pupils are symmetric and miotic unless severe arterial hypoxemia is present, which results in mydriasis. Skeletal muscles are flaccid, and upper airway obstruction may occur. Pulmonary edema commonly occurs, but the mechanism is not known. Hypotension and seizures develop if arterial hypoxemia persists. The triad of miosis, hypoventilation, and coma should suggest overdose with an opioid. Treatment of opioid overdose is mechanical ventilation of the patient's lungs with oxygen and administration of an opioid antagonist such as naloxone. Administration of an opioid antagonist to treat opioid overdose may precipitate acute withdrawal in dependent patients. With the recent increase in opioid-overdose deaths, the availability of intranasal or intramuscular (IM) naloxone for out-of-hospital treatment is critical. For patients being prescribed high-dose opioids, a prescription for naloxone as a rescue drug is

appropriate. Extremely high doses of naloxone may be necessary for individuals using ultra-potent opioids such as carfentanil.

Provocation of Coughing

Paradoxically, preinduction administration of fentanyl, sufentanil, or alfentanil may be associated with significant reflex coughing.⁴⁶ The exact cause of opioid-induced cough is unclear but is thought to be due to imbalance between sympathetic and vagal innervation of the airways and/or stimulation of juxtapacillary irritant receptors.⁴⁷ Morphine and hydromorphone do not appear to cause this reaction.

Pharmacodynamic Tolerance and Physical Dependence

Pharmacodynamic tolerance and physical dependence with repeated opioid administration are characteristics of all opioid agonists and are among the major limitations of their clinical use. Cross-tolerance develops between all the opioids, although incomplete, as manifested by the reduced doses required with opioid rotation. Tolerance can occur without physical dependence, but the reverse does not seem to occur.

Tolerance is the development of the requirement for increased doses of a drug (in this case, an opioid agonist) to achieve the same effect previously achieved with a lower dose. Such acquired tolerance usually takes 2 to 3 weeks to develop with analgesic doses of morphine, although acute tolerance can develop much more quickly with highly potent opioids.⁴⁸ Tolerance develops to analgesic, euphoric, sedative, depression of ventilation, and emetic effects of opioids but not to their effects on miosis and bowel motility. The potential for physical dependence depends on the agonist effect of opioids. Indeed, physical dependence does not occur with opioid antagonists and is less likely with opioid agonist-antagonists. When opioid agonist actions predominate, there often develops, with repeated use, both psychological and physiologic need for the drug.

Physical dependence on morphine usually requires about 25 days to develop. Some degree of physical dependence, however, occurs after only 48 hours of continuous medication. When physical dependence is established, discontinuation of the opioid agonist produces a withdrawal abstinence syndrome that may vary depending on individual and environmental factors (**Table 7.3**).⁴⁹ Initial symptoms of withdrawal include yawning, diaphoresis, lacrimation, or coryza. Insomnia and restlessness are prominent. Abdominal cramps, nausea, vomiting, and diarrhea reach their peak in 72 hours and then decline over the next 7 to 10 days. During withdrawal, tolerance to morphine is rapidly lost, and the syndrome can be terminated by a modest dose of opioid agonist. The longer the period of abstinence, the smaller the dose of opioid agonist that will be required.

TABLE 7.3

Time course of opioid withdrawal^a

Opioid	Onset	Peak intensity	Duration
Meperidine	2-6 hours	6-12 hours	4-5 days
Fentanyl	2-6 hours	6-12 hours	4-5 days
Morphine	6-18 hours	36-72 hours	7-10 days
Heroin	6-18 hours	36-72 hours	7-10 days
Methadone	24-48 hours	3-21 days	6-7 weeks

^aAdapted from Mitra S, Sinatra RS. Perioperative management of acute pain in the opioid-dependent patient. *Anesthesiology*. 2004;101(1):212-227.

Pharmacodynamic tolerance has been related to neurologic changes that take place after long-term exposure to the opioid.⁴⁹ The classic explanation for tolerance to a receptor agonist involved changes occurring at the level of the receptors and involve receptor desensitization. Opioid receptors on the cell membrane surfaces become gradually desensitized by reduced transcription and subsequent decreases in the absolute numbers of opioid receptors (downregulation). A second mechanism proposed to explain pharmacodynamic tolerance involves upregulation of the cyclic adenosine monophosphate (cAMP) system. Acutely, opioids inhibit functional activity of cAMP pathways by blocking adenylate cyclase, the enzyme that

catalyzes the synthesis of cAMP. Long-term opioid exposure is associated with gradual recovery of cAMP pathways, and tolerance develops. Increased synthesis of cAMP may be responsible for physical dependence and physiologic changes associated with withdrawal. Upregulation of cAMP has been most clearly demonstrated in the locus ceruleus of the brain. Clonidine, a centrally acting α_2 -adrenergic agonist that diminishes transmission in sympathetic pathways in the CNS, is an effective drug in suppressing withdrawal signs in persons who are physically dependent on opioids. Tolerance is not due to enzyme induction because no increase in the rate of metabolism of opioid agonists occurs.

Long-term pharmacodynamic tolerance characterized by opioid insensitivity may persist for months or years in some individuals and most likely represents persistent neural adaptation.⁴⁹ In this regard, *N*-methyl-D-aspartate (NMDA) glutamate receptors are important in the development of opioid tolerance and increased pain sensitivity. Prolonged exposure to opioids activates NMDA receptors via second messenger mechanisms and also downregulates spinal glutamate transporters. The resultant high synaptic concentrations of glutamate and NMDA receptor activation contribute to opioid tolerance and abnormal pain sensitivity (pronociceptive or sensitization process). The observation that treatment with small doses of ketamine (an NMDA receptor antagonist) abolishes the acute opioid tolerance seen with remifentanil supports this hypothesis.⁵⁰

Opioid Agonists

Opioid agonists include but are not limited to morphine, meperidine, fentanyl, sufentanil, alfentanil, and remifentanil (see [Table 7.1](#)).⁵¹ The most notable feature of the clinical use of opioids is the extraordinary variation in dose requirements for pain management.⁵² This interindividual variation emphasizes that usual doses of opioids may produce inadequate or excessive opioid effects. Opioid rotation may be useful when dose escalation is not effective in treating pain.

Morphine

Isolated in 1806 and named for the Greek god of dreams, morphine is the prototype opioid agonist to which all other opioids are compared. In humans, morphine produces analgesia, euphoria, sedation, and a diminished ability to concentrate. Other sensations include nausea, a feeling of body warmth, heaviness of the extremities, dryness of the mouth, and pruritus, especially in the cutaneous areas around the nose. The cause of pain persists, but even low doses of morphine increase the threshold to pain and modify the perception of noxious stimulation such that it is no longer experienced as pain. Continuous, dull pain is relieved by morphine more effectively than is sharp, intermittent pain. Analgesia is most prominent when morphine is administered before the painful stimulus occurs.⁵³

Pharmacokinetics

Morphine is well absorbed after IM administration, with onset of effect in 15 to 30 minutes and a peak effect in 45 to 90 minutes. The clinical duration of action is about 4 hours. Morphine can be administered orally for treatment of chronic pain recognizing that absorption from the gastrointestinal tract may be limited. Morphine is usually administered IV in the perioperative period, thus eliminating the unpredictable influence of drug absorption. The peak effect (equilibration time between the blood and brain) after IV administration of morphine is delayed compared with opioids such as fentanyl and alfentanil, requiring about 15 to 30 minutes ([Table 7.4](#)). Morphine inhaled as an aerosol from a nebulizer may act on afferent nerve pathways in the airways to relieve dyspnea as associated with lung cancer and associated pleural effusion.⁵⁴ However, profound depression of ventilation may follow aerosol administration of morphine.⁵⁵ The onset and duration of the analgesic effects of morphine are similar after IV administration or inhalation via a pulmonary drug delivery system that produces a fine aerosol.⁵⁶

Plasma morphine concentrations after rapid IV injections do not correlate closely with the drug's pharmacologic activity, likely due to the delay in transit of morphine across the blood–brain barrier. Cerebrospinal fluid (CSF) concentrations of morphine peak 15 to 30 minutes after IV injection and decay more slowly than plasma concentrations (**Figure 7.6**).⁵⁷ As a result, the analgesic and ventilatory depressant effects of morphine may not be evident during the initial high plasma concentrations after IV administration of the opioid. Likewise, these same drug effects persist despite decreasing plasma concentrations of morphine. Moderate analgesia probably requires maintenance of plasma morphine concentrations of at least 0.05 µg/mL.⁵⁸

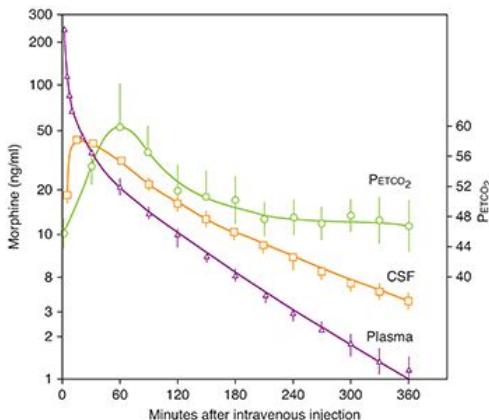

FIGURE 7.6 Cerebrospinal fluid (CSF) concentrations following intravenous administration of morphine decay more slowly than plasma concentrations. The end-tidal CO₂ concentration (PETCO₂) remains increased despite a decreasing plasma concentration of morphine (mean ± standard error). Reprinted with permission from Murphy MR, Hug CC Jr. Pharmacokinetics of intravenous morphine in patients anesthetized with enflurane-nitrous oxide. Anesthesiology. 1981;54(3):187-192. Only a small amount of administered morphine gains access to the CNS. For example, it is estimated that <0.1% of morphine that is administered IV has entered the CNS at the time of peak plasma concentrations. Reasons for poor penetration of morphine into the CNS include (1) relatively poor lipid solubility, (2) high degree of ionization at physiologic pH, (3) protein binding, and (4) rapid conjugation with glucuronic acid. Alkalization of the blood, as produced by hyperventilation of the patient's lungs, will increase the nonionized fraction of morphine and thus enhance its passage into the CNS. Nevertheless, respiratory acidosis, which decreases the nonionized fraction of morphine, results in higher plasma and brain concentrations of morphine than are present during normocarbia (**Figure 7.7**).⁵⁹ This suggests that carbon dioxide–induced increases in cerebral blood flow and enhanced delivery of morphine to the brain are more important than the fraction of drug that exists in either the ionized or nonionized fraction. In contrast to the CNS, morphine accumulates rapidly in the kidneys, liver, and skeletal muscles. Morphine, unlike fentanyl, does not undergo significant first-pass uptake into the lungs.⁶⁰

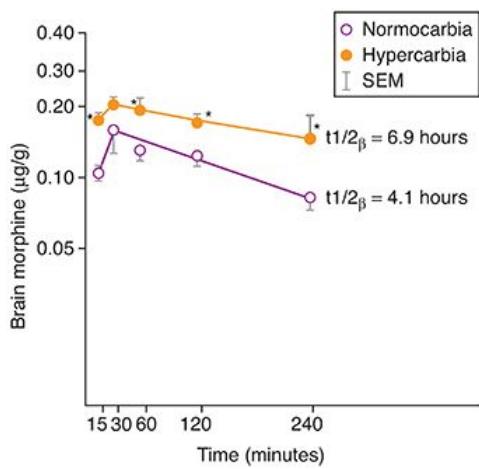

FIGURE 7.7 Hypercarbia, which decreases the nonionized fraction of morphine, results in a higher brain concentration and longer elimination half-time ($t_{1/2\beta}$) than occurs in the presence of normocarbia (* $P < .05$). Metabolism

Metabolism of morphine is primarily conjugation with glucuronic acid in hepatic and extrahepatic sites, especially the kidneys. About 75% to 85% of a dose of morphine appears as morphine-3-glucuronide, and 5% to 10% as morphine-6-glucuronide (a ratio of 9:1). Morphine-3-glucuronide is detectable in the plasma within 1 minute after IV injection, and its concentration exceeds that of unchanged drug by almost 10-fold within 90 minutes (Figure 7.8).⁵⁷ An estimated 5% of morphine is demethylated to normorphine, and a small amount of codeine (methylmorphine) may also be formed. Metabolites of morphine are eliminated principally in the urine, with only 7% to 10% undergoing biliary excretion. Morphine-3-glucuronide is detectable in the urine for up to 72 hours after the administration of morphine. A small fraction (1%-2%) of injected morphine is recovered unchanged in the urine.

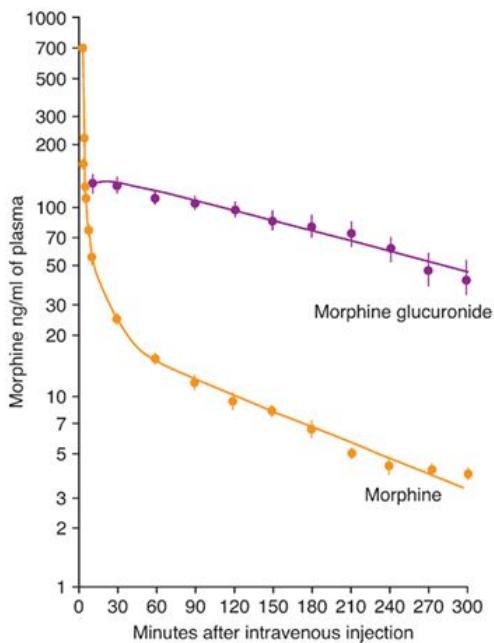

FIGURE 7.8 Morphine glucuronide is detectable in the plasma within 1 minute after intravenous injection, and its concentration exceeds that of unchanged morphine by almost 10-fold within 90 minutes (mean \pm standard error). Copyright © 1981 American Society of Anesthesiologists, Inc.

Morphine-3-glucuronide is pharmacologically inactive, whereas morphine-6-glucuronide produces analgesia and depression of ventilation via its agonist actions at μ receptors.⁶¹ In fact, the ventilatory response to carbon dioxide is impacted similarly by morphine and morphine-6-glucuronide (Figure 7.9).⁶² The duration of action of morphine-6-glucuronide is greater than that of morphine, and it is possible that the majority of analgesic activity attributed to morphine is actually due to morphine-6-glucuronide, especially with long-term administration of morphine.⁶³ Morphine and morphine-6-glucuronide bind to μ -opioid receptors with comparable affinity, whereas the analgesic potency of morphine-6-glucuronide is 650-fold higher than morphine.⁶⁴

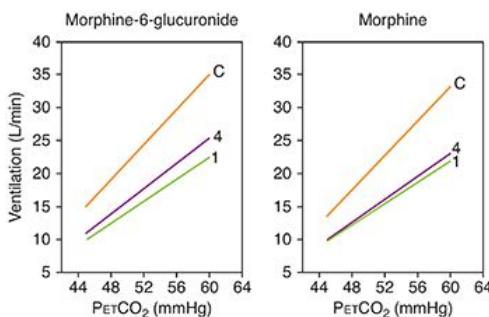

FIGURE 7.9 Influence of 0.2 mg/kg morphine-6-glucuronide intravenously (IV) and 0.13 mg/kg morphine IV on the ventilatory response to carbon dioxide. The effects of both opioids were similar over the 4-hour period of study. Abbreviation: PETCO₂, end-tidal PCO₂. Reprinted with permission from Romberg R, Olofson E, Satron E, et al. Pharmacodynamic effect of morphine-6-glucuronide versus morphine on hypoxic and hypercapnic breathing in healthy volunteers. *Anesthesiology*. 2003;99(4):788-798. Renal metabolism makes a significant contribution to the total metabolism of morphine, which offers a possible explanation for the absence of any decrease in systemic clearance of morphine in patients with hepatic cirrhosis or during the anhepatic phase of orthotopic liver transplantation.⁶⁵

Elimination of morphine glucuronides may be impaired in patients with renal failure, causing an accumulation of metabolites and unexpected ventilatory depressant effects of small doses of opioids (Figure 7.10).⁶⁶ Indeed, prolonged depression of ventilation (<7 days) has been observed in patients in renal failure after administration of morphine.⁶⁷ Formation of glucuronide conjugates may be impaired by monoamine oxidase inhibitors, which is consistent with exaggerated effects of morphine when administered to patients being treated with these drugs.

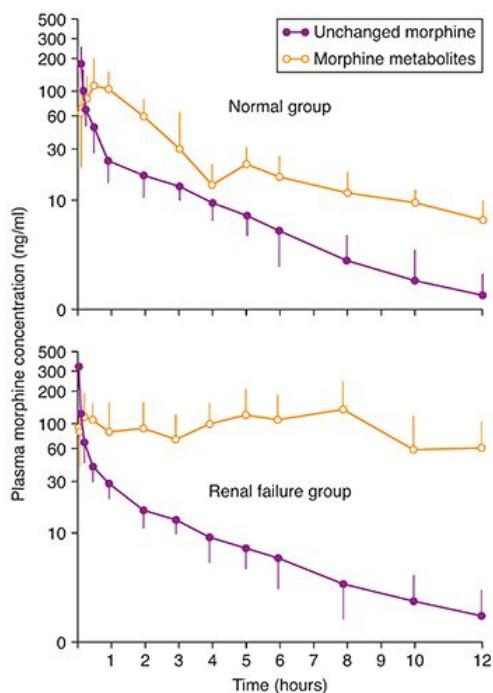

FIGURE 7.10 Plasma concentrations of unchanged morphine (closed circles) and morphine metabolites (open circles) in normal and renal failure patients. Elimination Half-Time

After IV administration of morphine, the elimination of morphine-3-glucuronide is somewhat longer than for morphine (see [Table 7.4](#) and [Figure 7.8](#)).⁵⁷ The decrease in the plasma concentration of morphine after initial distribution of the drug is principally due to metabolism because only a small amount of unchanged opioid is excreted in the urine. Plasma morphine concentrations are higher in the elderly than in young adults ([Figure 7.11](#)).⁵⁸ In the first 4 days of life, the clearance of morphine is decreased and its elimination half-time is prolonged compared with that found in older infants.⁶⁸ This is consistent with the observation that neonates are more sensitive than older children to the respiratory depressant effects of morphine. Patients with renal failure exhibit higher plasma and CSF concentrations of morphine and morphine metabolites than do normal patients, reflecting a smaller volume of distribution (Vd).⁶⁹ Possible accumulation of morphine-6-glucuronide suggests the need for caution when administering morphine to patients with significant renal dysfunction. Concentrations of morphine in colostrum of parturients receiving patient-controlled analgesia (PCA) with morphine are low, and it is unlikely that significant amounts of drug will be transferred to the breast-fed neonate.⁷⁰

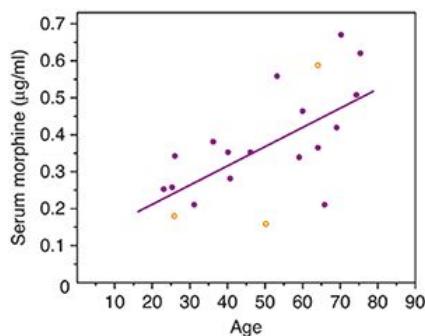

FIGURE 7.11 The plasma (serum) concentration of morphine increases progressively with advancing age. From Berkowitz BA, Ngai SH, Yang JC, et al. *The disposition of morphine in surgical patients*. Sex

Sex may affect opioid analgesia, but the direction and magnitude of these differences depend on many interacting variables including the opioid used.⁷¹ Morphine exhibits greater analgesic potency and slower speed of offset in women than men.⁷² This observation is consistent with higher postoperative opioid consumption in men compared with women. Morphine has also been demonstrated to cause greater respiratory depression in women.⁷³ Making broad assertions about the clinical significance of these differences is difficult because pain perception, opioid-related side effects, and sensitivity to opioids all affect opioid dosing requirements and may lead to differences in some contexts but not others.⁷⁴

Side Effects

Side effects described for morphine are also characteristic of other opioid agonists, although the incidence and magnitude may vary.

Meperidine

First synthesized in 1939, meperidine (also referred to as **pethidine**) is a synthetic opioid agonist at μ - and α -opioid receptors and is derived from phenylpiperidine (see [Figure 7.1](#)). There are several analogues of meperidine, including fentanyl, sufentanil, alfentanil, and remifentanil. Meperidine shares several structural features that are present in local anesthetics including a tertiary amine, an ester group, and a lipophilic phenyl group. Indeed, meperidine administered intrathecally blocks sodium channels to a degree comparable with lidocaine and can be used to provide surgical anesthesia.⁷⁵ Structurally, meperidine is similar to atropine, and it possesses a mild atropine-like antispasmodic effect on smooth muscle.

Pharmacokinetics

Meperidine is about one-tenth as potent as morphine. The duration of action of meperidine is 2 to 4 hours, making it a shorter acting opioid agonist than morphine. In equal analgesic doses, meperidine produces equivalent sedation, euphoria, nausea, vomiting, and depression of ventilation to morphine. Meperidine is absorbed from the gastrointestinal tract, but extensive first-pass hepatic metabolism (up to 80%) limits its oral usefulness.

Metabolism

Hepatic metabolism of meperidine is extensive, with about 90% of the drug initially undergoing demethylation to normeperidine and hydrolysis to meperidinic acid.⁷⁶ Normeperidine subsequently undergoes hydrolysis to normeperidinic acid. Urinary excretion is the principal elimination route and is pH dependent. For example, if the urinary pH is <5, as much as 25% of meperidine is excreted unchanged. Indeed, acidification of the urine can be considered in an attempt to speed elimination of meperidine. Decreased renal function can predispose to accumulation of normeperidine.

Normeperidine has an elimination half-time of 15 hours (35 hours in patients in renal failure) and can be detected in urine for as long as 3 days after administration of meperidine. This metabolite is about one-half as active as meperidine as an analgesic. In addition, normeperidine produces CNS stimulation. Normeperidine toxicity manifesting as myoclonus and seizures is most likely during prolonged administration of meperidine as during PCA, especially in the presence of impaired renal function.⁷⁶ Normeperidine may also be important in meperidine-induced delirium (confusion, hallucinations), which has been observed in patients receiving the drug for longer than 3 days, corresponding to accumulation of this active metabolite.

Elimination Half-Time

The elimination half-time of meperidine is 3 to 5 hours (see [Table 7.4](#)). Because clearance of meperidine primarily depends on hepatic metabolism, it is possible that large doses of opioid would saturate enzyme systems and result in prolonged elimination half-times. Nevertheless, elimination half-time is not altered by doses of meperidine up to 5 mg/kg IV. About 60% of meperidine is bound to plasma proteins. Elderly patients manifest decreased plasma protein binding of meperidine, resulting in increased plasma concentrations of free drug and an apparent increased sensitivity to the opioid. The increased tolerance of alcoholics to meperidine and other opioids presumably reflects an increased Vd, resulting in lower plasma concentrations of meperidine for a given dose.

Clinical Uses

The clinical use of meperidine has declined greatly in recent years. Meperidine is the only opioid considered adequate for surgery when administered intrathecally.⁷⁷ An IM injection of meperidine for postoperative analgesia results in peak plasma concentrations that vary three- to fivefold as well as a time required to achieve peak concentrations that varies three- to sevenfold among patients.⁷⁸ The minimum analgesic plasma concentration of meperidine is highly variable among patients; however, in the same patient, differences in concentrations as small as 0.05 µg/mL can represent a margin between no relief and complete analgesia. A plasma meperidine concentration of 0.7 µg/mL would be expected to provide postoperative analgesia in about 95% of patients.⁷⁹ Normeperidine toxicity has been described in patients receiving meperidine for PCA.⁷⁶ Therefore, because there are other effective agents, PCA with meperidine cannot be recommended.

Meperidine may be effective in suppressing postoperative shivering that may result in detrimental increases in metabolic oxygen consumption. The antishivering effects of meperidine may reflect stimulation of α receptors (estimated to represent 10% of its activity) and a drug-induced decrease in the shivering threshold (not present with alfentanil, clonidine, propofol, or volatile anesthetics).⁸⁰⁻⁸² In addition, meperidine is a potent agonist at α_2 -adrenergic receptors, which might contribute to antishivering effects.⁸³ Indeed, clonidine is even more effective than meperidine in reducing postoperative shivering. Butorphanol (a α -receptor agonist-antagonist) stops shivering more effectively than opioids with a predominant μ -opioid receptor agonist effect. Evidence for a role of α receptors in the antishivering effects of meperidine and butorphanol is the failure of naloxone to completely inhibit this drug-induced effect.

Unlike morphine, meperidine is not useful for the treatment of diarrhea and is not an effective cough suppressant. Meperidine is not used in high doses because of significant negative cardiac inotropic effects plus histamine release in a substantial number of patients.⁸⁴

Side Effects

The side effects of meperidine generally resemble those described for morphine. Meperidine, in contrast to morphine, rarely causes bradycardia but instead may increase heart rate, reflecting its modest atropine-like qualities. Large doses of meperidine result in decreases in myocardial contractility, which, among opioids, is unique for this drug. Delirium and seizures, when they occur, presumably reflect accumulation of normeperidine, which has stimulating effects on the CNS.

Serotonin syndrome (autonomic instability with hypertension, tachycardia, diaphoresis, hyperthermia, behavioral changes including confusion and agitation, and neuromuscular changes manifesting as hyperreflexia) occurs when drugs capable of increasing serotonin administration are administered. In severe cases, coma, seizures, coagulopathy, and metabolic acidosis may develop. Administration of meperidine to patients receiving antidepressant drugs (monoamine oxidase inhibitors, fluoxetine) may elicit this syndrome.⁸⁵

Meperidine readily impairs ventilation and may be even more of a ventilatory depressant than morphine. This opioid promptly crosses the placenta, and concentrations of meperidine in umbilical cord blood at birth may exceed maternal plasma concentrations.⁴² After equal analgesic doses, biliary tract spasm is less after meperidine injection than after morphine injection but greater than that caused by codeine.³⁷ Meperidine does not cause miosis but rather tends to cause mydriasis, reflecting its modest atropine-like actions. A dry mouth and an increase in heart rate are further evidence of the atropine-like effects of meperidine. Transient

neurologic symptoms have been described following the administration of intrathecal meperidine for surgical anesthesia.⁸⁶

The pattern of withdrawal symptoms after abrupt discontinuation of meperidine differs from that of morphine in that there are few autonomic nervous system effects. In addition, symptoms of withdrawal develop more rapidly and are of a shorter duration compared with those of morphine.

Fentanyl

Fentanyl is a phenylpiperidine-derivative synthetic opioid agonist that is structurally related to meperidine (see [Figure 7.1](#)). As an analgesic, fentanyl is 75 to 125 times more potent than morphine. It was first synthesized by Janssen Pharmaceutica in 1960 during an assay of meperidine derivatives and subsequently released as the citrate salt under the trade name Sublimaze.⁸⁷

Pharmacokinetics

A single dose of fentanyl administered IV has a more rapid onset and shorter duration of action than morphine. Despite the clinical impression that fentanyl produces a rapid onset, there is a distinct time lag between the peak plasma fentanyl concentration and peak slowing on the EEG. This delay reflects the effect-site equilibration time between blood and the brain for fentanyl, which is 6.4 minutes. The greater potency and more rapid onset of action reflect the greater lipid solubility of fentanyl compared with that of morphine, which facilitates its passage across the blood–brain barrier. Consequently, plasma concentrations of fentanyl (unlike morphine) correlate well with CSF concentrations. Likewise, the short duration of action of a single dose of fentanyl reflects its rapid redistribution to inactive tissue sites such as fat and skeletal muscles, with an associated decrease in the plasma concentration of the drug ([Figure 7.12](#)).⁸⁸

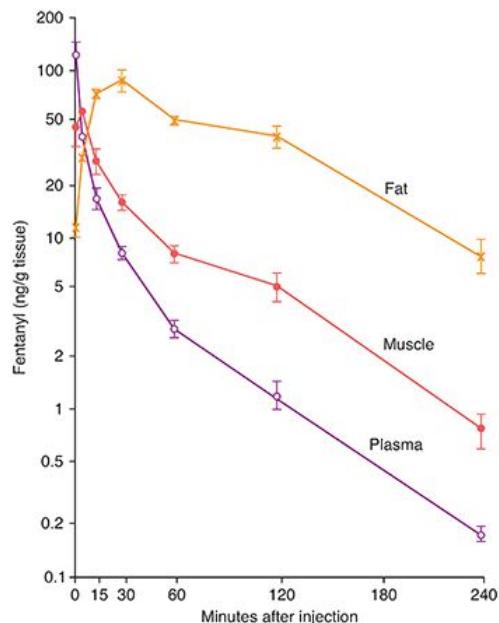

FIGURE 7.12 The short duration of action of a single intravenous dose of fentanyl reflects its rapid redistribution to inactive tissue sites such as fat and skeletal muscles, with associated decreases in the plasma concentration of drug (mean \pm standard error). *Reprinted with permission from Hug CC Jr, Murphy MR. Tissue redistribution of fentanyl and termination of its effects in rats. Anesthesiology. 1981;55(4):369-375. Copyright © 1981 American Society of Anesthesiologists, Inc.*

The lungs also serve as a large inactive storage site, with an estimated 75% of the initial fentanyl dose undergoing first-pass pulmonary uptake.⁶⁰ This nonrespiratory function of the lungs limits the initial amount of drug that reaches the systemic circulation and may play an important role in determining the pharmacokinetic profile of fentanyl. When multiple IV doses of fentanyl are administered or when there is

continuous infusion of the drug, progressive saturation of these inactive tissue sites occurs. As a result, the plasma concentration of fentanyl does not decrease rapidly, and the duration of analgesia, as well as depression of ventilation, may be prolonged. Cardiopulmonary bypass causes clinically insignificant effects on the pharmacokinetics of fentanyl despite associated hemodilution, hypothermia, nonphysiologic blood flow, and cardiopulmonary bypass–induced systemic inflammatory responses.⁸⁹

Metabolism

Fentanyl is extensively metabolized by N-demethylation, producing norfentanyl, hydroxyproprionyl-fentanyl, and hydroxyproprionyl-norfentanyl. Norfentanyl is structurally similar to normeperidine and is the principal metabolite of fentanyl in humans. It is excreted by the kidneys and can be detected in the urine for 72 hours after a single IV dose of fentanyl. Less than 10% of fentanyl is excreted unchanged in the urine. The pharmacologic activity of fentanyl metabolites is believed to be minimal.⁹⁰ Fentanyl is a substrate for hepatic P-450 enzymes (CYP3A) and is susceptible to drug interactions that reflect interference with enzyme activity (less likely than with alfentanil).⁹¹

Elimination Half-Time

Despite the clinical impression that fentanyl has a short duration of action, its elimination half-time is longer than that for morphine (see [Table 7.4](#)). This longer elimination half-time reflects a larger Vd of fentanyl because clearance of both opioids is similar (see [Table 7.4](#)). The larger Vd of fentanyl is due to its greater lipid solubility and thus more rapid passage into tissues compared with the less lipid-soluble morphine. After an IV bolus, fentanyl distributes rapidly from the plasma to highly vascular tissues (brain, lungs, heart). More than 80% of the injected dose leaves the plasma in <5 minutes. The plasma concentrations of fentanyl are maintained by slow reuptake from inactive tissue sites, which accounts for persistent drug effects that parallel the prolonged elimination half-time. In animals, the elimination half-time, Vd, and clearance of fentanyl are independent of the dose of opioid between 6.4 and 640 µg/kg IV.⁹²

A prolonged elimination half-time for fentanyl in elderly patients is due to decreased clearance of the opioid because Vd is not changed in comparison with younger adults.⁹³ This change may reflect age-related decreases in hepatic blood flow, microsomal enzyme activity, or albumin production, as fentanyl is highly bound (79%-87%) to protein. For these reasons, it is likely that a given dose of fentanyl will be effective for a longer period of time in elderly patients than in younger patients. A prolonged elimination half-time of fentanyl has also been observed in patients undergoing abdominal aortic surgery requiring infrarenal aortic cross-clamping.⁹⁴ Somewhat surprising, however, is the failure of hepatic cirrhosis to prolong significantly the elimination half-time of fentanyl.⁹⁵

Context-Sensitive Half-Time

As the duration of continuous infusion of fentanyl increases beyond about 2 hours, the context-sensitive half-time of this opioid becomes greater than sufentanil ([Figure 7.13](#)).^{3,96} This reflects saturation of inactive tissue sites with fentanyl during prolonged infusions and return of the opioid from peripheral compartments to the plasma. This tissue reservoir of fentanyl replaces fentanyl eliminated by hepatic metabolism so as to slow the rate of decrease in the plasma concentration of fentanyl when the infusion is discontinued.

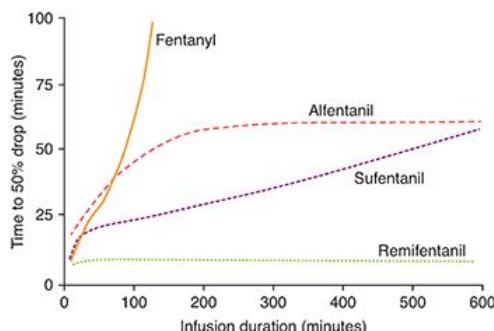

FIGURE 7.13 Computer simulation-derived context-sensitive half-times (time necessary for the plasma concentration to decrease 50% after discontinuation of the infusion) as a function of the duration of the intravenous infusion. Reprinted with permission from Egan TD, Lemmens HJM, Fiset P, et al. The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. *Anesthesiology*. 1993;79(5):881-892. Cardiopulmonary Bypass

All opioids show a decrease in plasma concentration with initiation of cardiopulmonary bypass.⁹⁷ Simulations of multiple anesthetic drugs are provided online by Dr. Steven Shafer (<http://stompump.io>). The degree of this decrease is greater with fentanyl because a significant proportion of the drug adheres to the surface of the cardiopulmonary bypass circuit. The decrease is least with opioids that have a large Vd such that the addition of prime volume is less important. In this respect, sufentanil and alfentanil⁹⁸ may provide more stable plasma concentrations during cardiopulmonary bypass. Elimination of fentanyl and alfentanil has been shown to be prolonged by cardiopulmonary bypass.

Clinical Uses

Fentanyl is administered clinically in a wide range of doses. For example, low doses of fentanyl, 1 to 2 µg/kg IV, are injected to provide analgesia. Larger doses may be administered as an adjuvant to inhaled anesthetics in an attempt to blunt circulatory responses to (1) direct laryngoscopy for intubation of the trachea or (2) sudden changes in the level of surgical stimulation. Timing of the IV injection of fentanyl to prevent or treat such responses should consider the effect-site equilibration time, which for fentanyl is prolonged compared with alfentanil and remifentanil. Injection of an opioid such as fentanyl before painful surgical stimulation may decrease the subsequent amount of opioid required in the postoperative period to provide analgesia.⁵³ Administration of fentanyl 1.5 or 3 µg/kg IV 5 minutes before induction of anesthesia decreases the subsequent doses of isoflurane or desflurane with 60% nitrous oxide needed to block the sympathetic nervous system response to surgical stimulation (Figure 7.14).⁹⁹ Large doses of fentanyl, 50 to 150 µg/kg IV, have been used alone to produce surgical anesthesia. Large doses of fentanyl as the sole anesthetic have the advantage of stable hemodynamics due principally to the (1) lack of direct myocardial depressant effects, (2) absence of histamine release, and (3) suppression of the stress responses to surgery. Disadvantages of using fentanyl as the sole anesthetic include (1) failure to prevent sympathetic nervous system responses to painful surgical stimulation at any dose, especially in patients with good left ventricular function, (2) unpredictable amnestic effects potentially leading to recall, and (3) postoperative depression of ventilation.¹⁰⁰⁻¹⁰² Intrathecal fentanyl (maximal benefit achieved with 25 µg) can produce rapid, profound analgesia for early labor with minimal side effects.¹⁰³

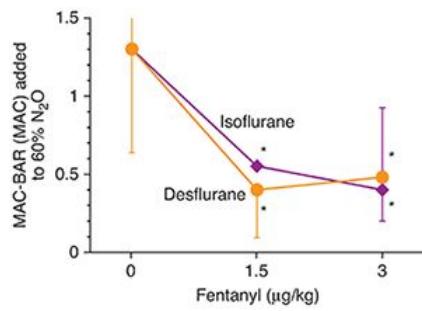

FIGURE 7.14 The anesthetic dose of desflurane and isoflurane required to block the adrenergic response (MAC-BAR) to incision in 50% of patients without and with fentanyl. There was no significant difference between the inhaled anesthetics at any fentanyl dose and both doses of fentanyl significantly and similarly decreased MAC-BAR (*P < .05; mean ± standard deviation). Reprinted with permission from Daniel M, Weiskopf RB, Noorani M, et al. Fentanyl augments the blockade of the sympathetic response to incision

(MAC-BAR) produced by desflurane and isoflurane. Desflurane and isoflurane MAC-BAR without and with fentanyl. Anesthesiology. 1998;88(1):43-49. Copyright © 1998 American Society of Anesthesiologists, Inc.

Fentanyl may be administered as a transmucosal preparation (oral transmucosal fentanyl) in a delivery device (lozenge mounted on a handle) designed to deliver 5 to 20 µg/kg of fentanyl. The goal is to decrease preoperative anxiety and facilitate the induction of anesthesia, especially in children.^{104,105} In children 2 to 8 years of age, the preoperative administration of oral transmucosal fentanyl, 15 to 20 µg/kg 45 minutes before the induction of anesthesia, reliably induces preoperative sedation and facilitates induction of inhalation anesthesia.¹⁰⁶ These same patients, however, are likely to experience decreases in breathing frequency and arterial oxygenation and an increased incidence of postoperative nausea and vomiting. In children 6 years of age and younger, the preoperative administration of oral transmucosal fentanyl, 15 µg/kg, is associated with an unacceptably high incidence of preoperative vomiting.¹⁰⁷ Conversely, another report did not observe an increased incidence of vomiting or arterial oxygen desaturation after premedication with oral transmucosal fentanyl.¹⁰⁸ For treatment of postoperative pain after orthopedic surgery, 1 mg of oral transmucosal fentanyl is equivalent to 5 mg of IV morphine.¹⁰⁹ Patients experiencing pain due to cancer may self-administer this opioid to the extent necessary to produce a desirable level of analgesia.

Transdermal fentanyl preparations delivering 75 to 100 µg/hour result in peak plasma fentanyl concentrations in about 18 hours that tend to remain stable during the presence of the patch, followed by a decreasing plasma concentration for several hours after removal of the delivery system. Transdermal fentanyl systems applied before the induction of anesthesia and left in place for 24 hours decrease the amount of parenteral opioid required for postoperative analgesia.¹¹⁰ Acute toxic delirium has been observed in patients with chronic pain due to cancer being treated with transdermal fentanyl for prolonged periods of time.¹¹¹ It is possible that renal failure and accumulation of norfentanyl contribute to the possible toxic effects of prolonged use of transdermal fentanyl. Evidence of opioid overdose has been observed when an upper body warming blanket was placed intraoperatively and came into contact with the fentanyl patch.¹¹²

Side Effects

The side effects of fentanyl resemble those described for morphine. Persistent or recurrent depression of ventilation due to fentanyl is a potential postoperative problem.¹¹³ Secondary peaks in plasma concentrations of fentanyl and morphine have been attributed to sequestration of fentanyl in acidic gastric fluid (ion trapping). Sequestered fentanyl could then be absorbed from the more alkaline small intestine back into the circulation to increase the plasma concentration of opioid and cause depression of ventilation to recur.¹¹⁴ This, however, may not be the mechanism for the secondary peak of fentanyl because reabsorbed opioid from the gastrointestinal tract or skeletal muscles, as evoked by movement associated with transfer from the operating room, would be subject to first-pass hepatic metabolism. An alternative explanation for the secondary peak of fentanyl is washout of opioid from the lungs as ventilation to perfusion relationships are reestablished in the postoperative period.

Cardiovascular Effects

Unlike morphine, fentanyl, even in large doses (50 µg/kg IV), does not evoke the release of histamine (see [Figure 7.4](#)).²⁶ As a result, dilatation of venous capacitance vessels leading to hypotension is unlikely. Carotid sinus baroreceptor reflex control of heart rate is markedly depressed by fentanyl, 10 µg/kg IV, administered to neonates ([Figure 7.15](#)).¹¹⁵ Therefore, changes in systemic blood pressure occurring during fentanyl anesthesia have to be carefully considered because cardiac output is principally rate dependent in neonates. Bradycardia is more prominent with fentanyl than morphine and may lead to occasional decreases in blood pressure and cardiac output.

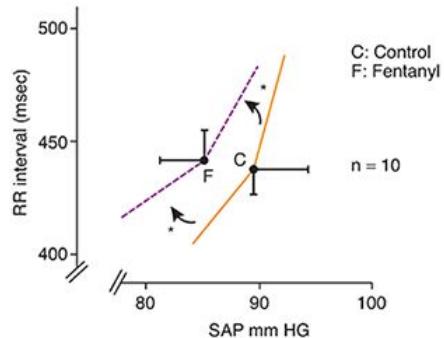

FIGURE 7.15 Fentanyl depresses the carotid sinus reflex-mediated heart rate response to changes in blood pressure in neonates ($*P < .02$). Abbreviation: SAP, systemic arterial pressure. Copyright © 1988 American Society of Anesthesiologists, Inc.

Seizure Activity

Seizure-like activity has been described to follow rapid IV administration of fentanyl, sufentanil, and alfentanil.¹¹⁶ In the absence of EEG evidence of seizure activity, however, it is difficult to distinguish opioid-induced skeletal muscle rigidity or myoclonus from seizure activity. Indeed, recording of the EEG during periods of opioid-induced skeletal muscle rigidity fails to reveal evidence of seizure activity in the brain.¹¹⁷ Even plasma concentrations as high as 1,750 ng/mL after rapid administration of fentanyl, 150 µg/kg IV, do not produce EEG evidence of seizure activity.¹¹⁸ Conversely, opioids might produce a form of myoclonus secondary to depression of inhibitory neurons that would produce a clinical picture of seizure activity in the absence of EEG changes.

Somatosensory-Evoked Potentials and Electroencephalogram

Fentanyl in doses exceeding 30 µg/kg IV produces changes in somatosensory-evoked potentials that, although detectable, do not interfere with the use and interpretation of this monitor during anesthesia.¹¹⁹ Opioids, including fentanyl, attenuate skeletal muscle movement at doses that have little effect on the EEG. This suggests that movement in response to surgical skin incision (used to measure minimum alveolar concentration [MAC]) primarily reflects the ability of a drug to obtund noxious reflexes and may not be the most appropriate measure for assessing consciousness or loss of consciousness.¹²⁰

Intracranial Pressure

Administration of fentanyl and sufentanil to head injury patients has been associated with modest increases (6-9 mm Hg) in ICP despite maintenance of an unchanged PaCO_2 .¹²¹ These increases in ICP are typically accompanied by decreases in mean arterial pressure and cerebral perfusion pressure. In fact, increases in ICP do not accompany the administration of sufentanil when changes in mean arterial pressure are prevented (Figure 7.16).¹²² This suggests that increases in ICP evoked by sufentanil (and presumably fentanyl) may have been due to autoregulatory decreases in cerebral vascular resistance due to decreases in systemic blood pressure resulting in vasodilation, increased blood volume, and increased ICP. Nevertheless, opioid-induced increases in ICP are similar in the presence of intact or impaired autoregulation suggesting that mechanisms other than activation of the vasodilatory cascade need to be considered.¹²³

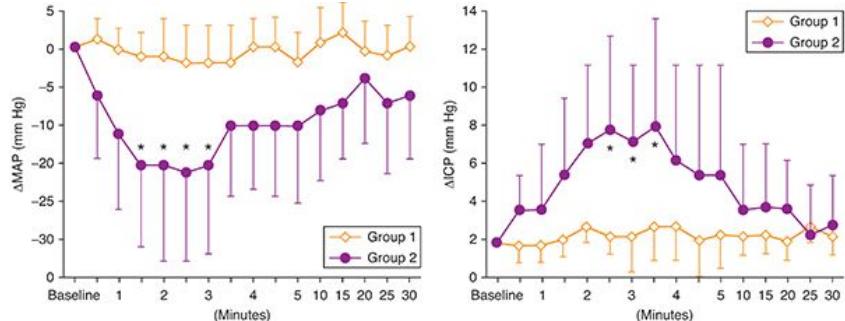

FIGURE 7.16 Changes in mean arterial pressure (MAP) and intracranial pressure (ICP) before and after administration of sufentanil, 3 $\mu\text{g}/\text{kg}$ intravenously, to 30 patients with intracranial hypertension after severe brain trauma. The ICP increased only in those patients who experienced a decrease in MAP after administration of sufentanil (mean \pm standard deviation; * $P < .05$ vs group I). *Reprinted with permission from Werner C, Kochs E, Bause H, et al. Effects of sufentanil on cerebral hemodynamics and intracranial pressure in patients with brain injury. Anesthesiology. 1995;83(4):721-726. Drug Interactions

Analgesic concentrations of fentanyl greatly potentiate the effects of benzodiazepines and decrease the dose requirements of propofol. The opioid-benzodiazepine combination displays marked synergism with respect to hypnosis and depression of ventilation.¹²⁴ In clinical practice, the advantage of synergy between opioids and benzodiazepines for the maintenance of patient comfort is carefully weighed against the disadvantages of the potentially adverse depressant effects of this combination.

Sufentanil

First synthesized in 1974, sufentanil is a thienyl analogue of fentanyl (see [Figure 7.1](#)). The analgesic potency of sufentanil is 5 to 10 times that of fentanyl, which parallels the greater affinity of sufentanil for opioid receptors compared with that of fentanyl. Based on the plasma concentration necessary to cause 50% of the maximum slowing on the EEG (EC50), sufentanil is 12 times more potent than fentanyl.¹²⁵ Transient skeletal muscle spasm has been described after the accidental intrathecal injection of a large dose of sufentanil (40 μg), suggesting an irritant effect of the opioid.¹²⁶

Pharmacokinetics

The elimination half-time of sufentanil is intermediate between that of fentanyl and alfentanil (see [Table 7.4](#)).¹²⁷ A single IV dose of sufentanil has a similar elimination half-time in patients with or without cirrhosis of the liver.¹²⁸ A prolonged elimination half-time has been observed in elderly patients receiving sufentanil for abdominal aortic surgery.¹²⁹ The Vd and elimination half-time of sufentanil is increased in obese patients, which most likely reflects the high lipid solubility of this opioid.¹³⁰

A high tissue affinity is consistent with the lipophilic nature of sufentanil, which permits rapid penetration of the blood-brain barrier and onset of CNS effects (effect-site equilibration time of 6.2 minutes is similar to that of 6.8 minutes for fentanyl).¹²⁵ A rapid redistribution to inactive tissue sites terminates the effect of small doses, but a cumulative drug effect can accompany large or repeated doses of sufentanil.

Sufentanil undergoes significant first-pass pulmonary uptake (approximately 60%) after rapid IV injection.¹³¹ This pulmonary first-pass uptake is similar to fentanyl and greater than morphine (about 7%) and alfentanil (about 10%).

The extensive protein binding of sufentanil (92.5%) compared with that of fentanyl (79%-87%) contributes to a smaller Vd, which is characteristic of sufentanil. Binding to α_1 -acid glycoprotein constitutes a principal proportion of the total plasma protein binding of sufentanil. Levels of α_1 -acid glycoprotein vary over a threefold range in healthy volunteers and are increased after surgery, which could result in a decrease

in the plasma concentration of pharmacologically active unbound sufentanil. Lower concentrations of α_1 -acid glycoprotein in neonates and infants probably account for decreases in protein binding of sufentanil in these age groups compared with that in older children and adults.¹³² The resulting increased free fraction of sufentanil in the neonate might contribute to enhanced effects of this opioid. Indeed, fentanyl and its derivatives produce anesthesia and depression of ventilation at lower doses in neonates than in adults.¹³³

Metabolism

Sufentanil is rapidly metabolized by *N*-dealkylation at the piperidine nitrogen and by *O*-demethylation. The products of *N*-dealkylation are pharmacologically inactive, whereas desmethyl sufentanil has about 10% of the activity of sufentanil. Less than 1% of an administered dose of sufentanil appears unchanged in urine. Indeed, the high lipid solubility of sufentanil results in maximal renal tubular reabsorption of free drug as well as its enhanced access to hepatic microsomal enzymes. Extensive hepatic extraction means that clearance of sufentanil will be sensitive to changes in hepatic blood flow but not to alterations in the drug-metabolizing capacity of the liver. Sufentanil metabolites are excreted almost equally in urine and feces, with about 30% appearing as conjugates. The production of a weakly active metabolite and the substantial amount of conjugated metabolite formation imply the possible importance of normal renal function for the clearance of sufentanil. Indeed, prolonged depression of ventilation in association with an abnormally increased plasma concentration of sufentanil has been observed in a patient with chronic renal failure.¹³⁴

Context-Sensitive Half-Time

The context-sensitive half-time of sufentanil is actually less than that for alfentanil for continuous infusions of up to 8 hours in duration (see [Figure 7.13](#)).³ This shorter context-sensitive half-time can be explained in part by the large *Vd* of sufentanil compared to alfentanil. After termination of a sufentanil infusion, the decrease in the plasma drug concentration is accelerated not only by metabolism but also by continued redistribution of sufentanil into peripheral tissue compartments. Compared with alfentanil, sufentanil may have a more favorable recovery profile when used over a longer period of time. Conversely, alfentanil has a pharmacokinetic advantage for the treatment of discrete and transient noxious stimuli because its short effect-site equilibration time allows rapid access of the drug to the brain and facilitates titration.

Clinical Uses

In volunteers, a single dose of sufentanil, 0.1 to 0.4 $\mu\text{g}/\text{kg}$ IV, produces a longer period of analgesia and less depression of ventilation than does a comparable dose of fentanyl (1-4 $\mu\text{g}/\text{kg}$ IV).¹³⁵ Compared with large doses of morphine or fentanyl, sufentanil, 18.9 $\mu\text{g}/\text{kg}$ IV, results in more rapid induction of anesthesia, earlier emergence from anesthesia, and earlier tracheal extubation.¹³⁶ As observed with other opioids, sufentanil causes a decrease in cerebral metabolic oxygen requirements and cerebral blood flow is also decreased or unchanged.¹³⁷ Bradycardia produced by sufentanil may be sufficient to decrease cardiac output. As observed with fentanyl, delayed depression of ventilation has also been described after the administration of sufentanil.¹³⁸

Although large doses of sufentanil (10-30 $\mu\text{g}/\text{kg}$ IV) or fentanyl (50-150 $\mu\text{g}/\text{kg}$ IV) produce minimal hemodynamic effects in patients with good left ventricular function, the systemic blood pressure and hormonal (catecholamine) responses to painful stimulation such as median sternotomy are not predictably prevented.¹³⁹ It seems unlikely that any clinically useful dose of sufentanil or fentanyl will abolish such responses in all patients. Use of large doses of opioids, including sufentanil or fentanyl, to produce IV induction of anesthesia may result in rigidity of chest and abdominal musculature. This skeletal muscle rigidity makes ventilation of the patient's lungs with positive airway pressure difficult. As with fentanyl, difficult ventilation during sufentanil-induced skeletal muscle rigidity may actually reflect obstruction at the level of the glottis or above, which can be overcome by tracheal intubation.¹⁴⁰

Alfentanil

Alfentanil is an analogue of fentanyl that is less potent (one-fifth to one-tenth) and has one-third the duration of action of fentanyl (see [Figure 7.2](#)). It was first synthesized in 1976. A unique advantage of alfentanil compared with fentanyl and sufentanil is the more rapid onset of action (rapid effect-site equilibration) after the IV administration of alfentanil. For example, the effect-site equilibration time for alfentanil is 1.4 minutes compared with 6.8 and 6.2 minutes for fentanyl and sufentanil, respectively (see [Table 7.4](#)).^{4,141}

Pharmacokinetics

Alfentanil has a short elimination half-time compared with fentanyl and sufentanil (see [Table 7.4](#)). Cirrhosis of the liver, but not cholestatic disease, prolongs the elimination half-time of alfentanil.¹⁴² Renal failure does not alter the clearance or elimination half-time of alfentanil.¹⁴³ The elimination half-time of alfentanil is shorter in children (4–8 years old) than adults, reflecting a smaller Vd in these younger patients.¹⁴⁴

The rapid effect-site equilibration characteristic of alfentanil is a result of the low pK_a of this opioid such that nearly 90% of the drug exists in the nonionized form at physiologic pH. It is the nonionized fraction that readily crosses the blood–brain barrier. The rapid peak effect of alfentanil at the brain is useful when an opioid is required to blunt the response to a single, brief stimulus such as tracheal intubation or performance of a retrobulbar block.

The Vd of alfentanil is 4 to 6 times smaller than that of fentanyl (see [Table 7.4](#)).¹⁴⁵ This smaller Vd compared with that of fentanyl reflects lower lipid solubility and higher protein binding. Despite this lesser lipid solubility, penetration of the blood–brain barrier by alfentanil is rapid because of its large nonionized fraction at physiologic pH. Alfentanil is principally bound to α_1 -acid glycoprotein, a protein whose plasma concentration is not altered by liver disease. Because protein binding is similar, it is likely that a decreased percentage of adipose tissue in children is responsible for the short elimination half-time.

Metabolism

Alfentanil is metabolized predominantly by two independent pathways: piperidine N-dealkylation to noralfentanil and amide N-dealkylation to N-phenylpropionamide. Noralfentanil is the major metabolite recovered in urine, with <0.5% of an administered dose of alfentanil being excreted unchanged. The efficiency of hepatic metabolism is emphasized by clearance of about 96% of alfentanil from the plasma within 60 minutes of its administration.

Attempts to develop reliable infusion regimens to attain and maintain specific plasma concentrations of alfentanil have been confounded by the wide interindividual variability in alfentanil pharmacokinetics. The most significant factor responsible for unpredictable alfentanil disposition is the 10-fold interindividual variability in alfentanil systemic clearance, presumably reflecting variability in hepatic intrinsic clearance. In this regard, it is likely that population variability in P-450 3A4 (CYP3A4) activity (most abundant P-450 hepatic enzyme and the major isoform of P-450 responsible for alfentanil metabolism and clearance) is the mechanistic explanation for the interindividual variability in alfentanil disposition.¹⁴⁶ Alfentanil clearance is markedly influenced by CYP3A activity, and alfentanil is a sensitive and validated probe for CYP3A activity.⁹¹ Alterations in P-450 activity may be responsible for the ability of erythromycin to inhibit the metabolism of alfentanil and a resulting prolonged opioid effect.¹⁴⁷

Context-Sensitive Half-Time

The context-sensitive half-time of alfentanil is actually longer than that of sufentanil for infusions up to 8 hours in duration (see [Figure 7.13](#)).⁹⁶ This phenomenon can be explained in part by the large Vd of sufentanil. After termination of a continuous infusion of sufentanil, the decrease in the plasma drug concentration is accelerated not only by metabolism but also by continued redistribution of sufentanil into peripheral compartments. Conversely, the Vd of alfentanil equilibrates rapidly; therefore, peripheral distribution of drug away from the plasma is not a significant contributor to the decrease in the plasma concentration after discontinuation of the alfentanil infusion. Thus, despite the short elimination half-time of alfentanil, it may not necessarily be a superior choice to sufentanil for ambulatory sedation techniques.

Clinical Uses

Alfentanil has a rapid onset and offset of intense analgesia reflecting its very prompt effect-site equilibration. This characteristic of alfentanil is used to provide analgesia when the noxious stimulation is acute but transient as associated with laryngoscopy and tracheal intubation and performance of a retrobulbar block. For example, administration of alfentanil, 15 µg/kg IV, about 90 seconds before beginning direct laryngoscopy is effective in blunting the systemic blood pressure and heart rate response to tracheal intubation.¹⁴⁸ The catecholamine response to this noxious stimulation is also blunted by alfentanil, 30 µg/kg IV.¹⁴⁸ Alfentanil in doses of 10 to 20 µg/kg IV blunts the circulatory but not the catecholamine release response to the sudden exposure to high inhaled concentrations of desflurane.¹⁴⁹ Alfentanil, 150 to 300 µg/kg IV, administered rapidly, produces unconsciousness in about 45 seconds. After this induction, maintenance of anesthesia can be provided with a continuous infusion of alfentanil, 25 to 150 µg/kg/hour IV, combined with an inhaled anesthetic.¹⁵⁰ Unlike other opioids, supplemental doses of alfentanil seem to be more likely to decrease systemic blood pressure that is increased after painful stimulation. Alfentanil increases biliary tract pressures similarly to fentanyl.

Remifentanil

Remifentanil is a selective µ-opioid agonist with an analgesic potency similar to that of fentanyl (15–20 times as potent as alfentanil) and a blood–brain equilibration (effect-site equilibration) time similar to that of alfentanil (see [Table 7.4](#)).^{23,151–153} Although chemically related to the fentanyl family of short-acting phenylpiperidine derivatives, remifentanil is structurally unique because of its ester linkage (see [Figure 7.1](#)). Remifentanil's ester structure renders it susceptible to hydrolysis by nonspecific plasma and tissue esterases to inactive metabolites.³ This unique pathway of metabolism leads to (1) brief action, (2) precise and rapidly titratable effect due to its rapid onset and offset, (3) lack of accumulation, and (4) rapid recovery after discontinuation of its administration.

Ventilation

After administration of 0.5 µg/kg IV remifentanil, there is a decrease in the slope and downward shift of the carbon dioxide ventilatory response curve that reaches its nadir after about 150 seconds following injection ([Figure 7.17](#)).¹⁵⁴ Recovery after this small dose of remifentanil was complete within about 15 minutes. The combination of remifentanil and propofol is synergistic resulting in severe depression of ventilation ([Figure 7.18](#)).¹⁵⁵

Pharmacokinetics

The pharmacokinetics of remifentanil is characterized by small V_d , rapid clearance, and low interindividual variability compared to other IV anesthetic drugs. The rapid metabolism of remifentanil and its small V_d mean that remifentanil will accumulate less than other opioids. Because of its rapid systemic clearance, remifentanil provides pharmacokinetic advantages in clinical situations requiring predictable termination of drug effect. Remifentanil's pharmacokinetics is similar in obese and lean patients. Therefore, dosing regimens should be based on ideal (lean) body mass rather than total body weight.¹⁵⁶

The most salient pharmacokinetic feature of remifentanil is the extraordinary clearance of nearly 3 L/min, which is about 8 times more rapid than that of alfentanil. Remifentanil has a smaller V_d than alfentanil. The combination of rapid clearance and small V_d produces a drug with a uniquely transient effect. In fact, the rate of decline (context-sensitive half-time) of the remifentanil plasma concentration will be nearly independent of the infusion duration (see [Figure 7.13](#)).^{2,3} The rapid effect-site equilibration means that a remifentanil infusion rate will promptly approach steady state in the plasma and its effect site. It is estimated that remifentanil plasma concentrations will reach a steady state within 10 minutes of beginning an infusion. The relationship between infusion rate and opioid concentration will be less variable for remifentanil than for other opioids. Furthermore, the rapid clearance of remifentanil, combined with the rapid blood–brain equilibration, means changes in infusion rates will be paralleled by prompt changes in drug effect.

Based on analysis of the EEG response, it is estimated that remifentanil is about 19 times more potent than alfentanil (EC50 for EEG depression 20 ng/mL vs 376 ng/mL).³ The effect-site equilibration time, however, is similar for both opioids, suggesting that remifentanil will have an alfentanil-like onset (see [Table 7.4](#)). For example, after a rapid IV injection, the peak effect-site concentration of remifentanil will be present within 1.1 minutes, compared with 1.4 minutes for alfentanil. The effect, however, will be more transient after administration of remifentanil than alfentanil.

Metabolism

Remifentanil is unique among the opioids in undergoing metabolism by nonspecific plasma and tissue esterases to inactive metabolites.³ The principal metabolite, remifentanil acid, is 300- to 4,600-fold less potent than remifentanil as a μ agonist and is excreted primarily by the kidneys. *N*-dealkylation of remifentanil is a minor metabolic pathway in humans. Remifentanil does not appear to be a substrate for butyrylcholinesterases (pseudocholinesterase), and thus, its clearance should not be affected by cholinesterase deficiency or anticholinergics.² Additionally, it is likely that remifentanil's pharmacokinetics will be unchanged by renal or hepatic failure because esterase metabolism is usually preserved in these states.¹⁵⁷ In this regard, the clearance of remifentanil is not altered during the anhepatic phase of liver transplantation. Hypothermic cardiopulmonary bypass decreases clearance of remifentanil by an average of 20%, presumably reflecting the effect of temperature on blood and tissue esterase activity. Esterase metabolism appears to be a very well-preserved metabolic system with little variability between individuals, which contributes to the predictability of drug effect associated with the infusion of remifentanil.

Context-Sensitive Half-Time

Context-sensitive half-time for remifentanil is independent of the duration of infusion and is estimated to be about 4 minutes.^{2,158} This drug's rapid clearance is responsible for the lack of accumulation even during prolonged periods of infusion. In contrast, the context-sensitive half-times for sufentanil, alfentanil, and fentanyl are longer and depend significantly on the duration of the infusion (see [Table 7.4](#)).

Clinical Uses

The clinical uses of remifentanil reflect the unique pharmacokinetics of this drug, which allow rapid onset of drug effect, precise titration to the desired effect, the ability to maintain a sufficient effect site concentration to suppress the stress response, and rapid recovery from the drug's effects. In cases where a profound analgesic effect is desired transiently (performance of a retrobulbar block), remifentanil may be useful. Prompt onset and short duration of action make remifentanil a useful selection for suppression of the transient sympathetic nervous system response to direct laryngoscopy and tracheal intubation in at-risk patients.¹⁵⁹ Intermittent remifentanil administered as PCA is an alternative (albeit not optimal) analgesic strategy during labor and delivery for those unwilling or unable to receive neuraxial analgesia.¹⁶⁰ One additional benefit during labor would be rapid clearance from the neonatal circulation as well, thus reducing the risk of neonatal depression.¹⁶¹ Conceivably, remifentanil could be used for long operations, when a quick recovery time is desired (neurologic assessment, wake-up test) but at a significantly higher cost than other opioids.

Anesthesia can be induced with remifentanil, 1 μ g/kg IV administered over 60 to 90 seconds, or with a gradual initiation of the infusion at 0.5 to 1.0 μ g/kg IV for about 10 minutes, before administration of a standard hypnotic prior to tracheal intubation.¹⁶² The dose of hypnotic drug may need to be decreased to compensate for the synergistic effect with remifentanil. Remifentanil can be used as the analgesic component of a general anesthetic (0.25-1.00 μ g/kg IV or 0.05-2.00 μ g/kg/minute IV) or sedation techniques with the ability to rapidly recover from undesirable effects such as opioid-induced depression of ventilation or excessive sedation. Remifentanil, 0.05 to 0.10 μ g/kg/minute in combination with midazolam, 2 mg IV, provides effective sedation and analgesia during monitored anesthesia care in otherwise healthy adult patients.¹⁶³ Midazolam also produces a dose-dependent potentiation of remifentanil's depressant effect on breathing rate. Changes in remifentanil drug effect predictably follow changes in the infusion rate, making it possible to more precisely titrate to the desired response than with other opioids. Before cessation of the remifentanil infusion, a longer acting opioid should be administered to ensure analgesia when the patient awakens. The spinal or epidural administration of remifentanil is not recommended, as the safety of the vehicle (glycine, which acts as an inhibitory neurotransmitter) or opioid has not been determined.² Remifentanil, 100 μ g IV, attenuates the acute hemodynamic responses to electroconvulsive therapy and does not alter the duration of electroconvulsive-induced seizure activity.¹⁶⁴

Side Effects

The advantage of remifentanil possessing a short recovery period may be considered a disadvantage if the infusion is stopped suddenly, whether it be deliberate or accidental. It is important to administer a longer acting opioid for postoperative analgesia when remifentanil has been administered for this purpose intraoperatively. All fentanyl analogs, including remifentanil, have been reported to induce “seizure-like” activity.¹⁶⁵

Nausea and vomiting, depression of ventilation, and mild decreases in systemic blood pressure and heart rate may accompany the administration of remifentanil. Depression of ventilation produced by remifentanil is not altered by renal or liver dysfunction. Histamine release does not accompany the administration of remifentanil. ICP and intraocular pressure are not changed by remifentanil.^{166,167} High-dose remifentanil decreases cerebral blood flow and cerebral metabolic oxygen requirements without impairing cerebrovascular carbon dioxide reactivity.¹⁶⁸ Remifentanil delays drainage of dye from the gallbladder into the duodenum, but the delay is shorter than with other opioids.¹⁶⁹

Hyperalgesia

Initial reports suggested that intraoperative remifentanil infusion produces acute opioid tolerance and hyperalgesia (**Figure 7.19**).¹⁷⁰ In this regard, NMDA receptor antagonists such as ketamine and magnesium may be helpful. Subanesthetic ketamine has been shown to decrease morphine requirements and the development of hyperalgesia after intraoperative remifentanil use (**Figure 7.20**).^{50,171} Subsequent work, however, has questioned whether remifentanil-induced hyperalgesia is a true phenomenon.¹⁷² Regardless, it is important to know that patients on chronic pain medication preoperatively would require higher doses of opioids postoperatively compared to naive patients and small doses of ketamine would be an alternative therapeutic approach.

Patients receiving subanesthetic ketamine infusions experienced less postoperative pain and required less morphine. *Reprinted with permission from Guignard B, Coste C, Costes H, et al. Supplementing desflurane-remifentanil anesthesia with small-dose ketamine reduces perioperative opioid analgesic requirements. Anesth Analg. 2002;95(1):103-108. Copyright © 2002 International Anesthesia Research Society.*

Opioid-induced hyperalgesia may develop with chronic (or even acute) use.¹⁷³ Although this is a complex topic, interaction of opioids with nonneuronal cells (such as microglia and mast cells) appears to play a central role in this phenomenon.¹⁷⁴

Opioids With Oral Bioavailability

All orally bioavailable opioids have been linked to persistent use and abuse. In the perioperative setting, preoperative oral opioid use is a strong predictor for continued postoperative use. This has been demonstrated for a large variety of surgical procedures.^{175,176}

Codeine

Codeine is the result of the substitution of a methyl group for the hydroxyl group on the number 3 carbon of morphine (see [Figure 7.1](#)). The presence of this methyl group limits first-pass hepatic metabolism and accounts for the efficacy of codeine when administered orally. The elimination half-time of codeine after oral or IM administration is 3.0 to 3.5 hours. About 10% of administered codeine is demethylated by CYP2D6 in the liver to morphine, which may be responsible for the analgesic effect of codeine, although codeine-6-glucuronide may also exert an analgesic effect.¹⁷⁷ Any remaining codeine is demethylated to inactive norcodeine, which is conjugated or excreted unchanged by the kidneys. The large variability in CYP2D6 activity (over 100 identified alleles) leads to variable analgesic effect from codeine-containing drugs; some patients who claim that codeine is an ineffective drug for them may in fact poorly metabolize it to active forms while rapid metabolizers will have an exaggerated effect.¹⁷⁸

Codeine is effective at suppressing cough at oral doses of 15 mg. Maximal analgesia, equivalent to that produced by 650 mg of aspirin, occurs with 60 mg of codeine. When administered IM, 120 mg of codeine is equivalent in analgesic effect to 10 mg of morphine. Most often, codeine is included in medications as an antitussive or is combined with nonopioid analgesics for the treatment of mild to moderate pain. The risk of physical dependence on codeine appears to be less than that of morphine and occurs only rarely after oral analgesic use. Codeine produces minimal sedation, nausea, vomiting, and constipation. Dizziness may occur in ambulatory patients. Even in large doses, codeine is unlikely to produce apnea. Administration of codeine IV is not recommended, because histamine-induced hypotension is likely. Due to reports of overdose and death (perhaps due to genetic variants increasing metabolism to active forms), codeine is also specifically contraindicated for children undergoing tonsillectomy or adenoidectomy and for breastfeeding mothers. The drug carries a US Food and Drug Administration “Black Box” warning for these populations.¹⁷⁹

Hydromorphone

First introduced in 1926, hydromorphone is a derivative of morphine that is about 5 times as potent as morphine but has a slightly shorter duration of action. It is less hydrophilic than morphine, leading to faster onset of analgesia. Hydromorphone is an effective alternative to morphine in the treatment of opioid-responsive moderate to severe pain.¹⁸⁰ The uses and side effects of hydromorphone are the same as those of morphine, although histamine release is less prominent with hydromorphone. Similar to other opioids, large doses of hydromorphone have been reported to cause agitation and myoclonus.¹⁸¹

Oxymorphone

Oxymorphone is the result of the addition of a hydroxyl group to hydromorphone. It is about 10 times as potent as morphine and seems to cause more nausea and vomiting. An oral preparation of oxymorphone

(immediate release) produces maximum plasma concentrations in 30 minutes with associated rapid onset of analgesia.¹⁸²

Oxycodone

Sustained-release oral oxycodone preparations provide stable plasma concentrations for the treatment of moderate to severe pain. Abuse potential is great including tampering (crushing and powdering) for IV or intranasal injection to obtain a rapid and powerful opioid effect.

Hydrocodone

A derivative of codeine, hydrocodone is a useful oral opioid, commonly combined with acetaminophen. The approval by the US Food and Drug Administration of one extended-release formulation (Zohydro) provoked much opposition due to its abuse potential and lack of abuse-deterrent features.¹⁸³ Originally classified as a schedule III drug (moderate abuse potential) in the United States, hydrocodone has subsequently been reclassified as schedule II (high abuse potential) due to increased reports of diversion and abuse.

Methadone

Methadone is a synthetic opioid agonist that produces analgesia in the setting of chronic pain syndromes and is highly effective by the oral route. The efficient oral absorption, prompt onset of action, and prolonged duration of action of methadone render this an attractive drug for one-daily dosing to suppress withdrawal symptoms and relapse in physically dependent persons. The IV formulation of methadone is useful intraoperatively but should not be used for postoperative analgesia in opioid-naïve patients due to increasing concentrations with multiple doses.

Opioid Withdrawal

Methadone can substitute for morphine at about one-fourth the dosage. Some of its analgesic benefit is due to NMDA antagonism. Controlled withdrawal from opioids using methadone is milder and less acute than that from morphine. This drug is metabolized in the liver to inactive substances that are excreted in the urine and bile with small amounts of unchanged drug.

The side effects of methadone (depression of ventilation, miosis, constipation, biliary tract spasm) resemble those of morphine. Its sedative and euphoric actions are less than those produced by morphine. Methadone-induced miosis is less prominent than that caused by morphine, and complete tolerance to this action can develop.

Treatment of Chronic Pain

NMDA receptor antagonist activity may also be useful in treatment of neuropathic pain and minimize the potential for development of tolerance. The principal disadvantage for use of methadone to treat chronic pain is its prolonged and unpredictable half-time. When methadone is administered more than once daily to opioid-naïve patients, as is common in treatment of chronic pain syndromes, the drug may accumulate and result in high plasma concentrations and associated depression of ventilation.¹⁸⁴ For this reason, slow-release formulations (such as oxycodone) may be preferable to methadone for the treatment of outpatient acute postoperative pain.

Tramadol

Tramadol is a centrally acting analgesic that has moderate affinity for μ receptors and weak α - and δ -opioid receptor affinity but is 5 to 10 times less potent than morphine as an analgesic.¹⁸⁵ In addition to μ -opioid agonist effects, tramadol enhances the function of the spinal descending inhibitory pathways by inhibition of neuronal reuptake of norepinephrine and 5-hydroxytryptamine (serotonin) as well as presynaptic stimulation of 5-hydroxytryptamine release. In volunteers, naloxone antagonized only an estimated 30% of the effect of tramadol.¹⁸⁶

Tramadol is a prodrug that is metabolized by CYP2D6 to the active compound O-desmethyltramadol. Thus, the same concerns about variability in effectiveness and adverse effects seen with codeine also apply to

tramadol. It is a racemic mixture of two enantiomers, one of which is responsible for inhibition of norepinephrine uptake, whereas the other is responsible for inhibition of 5-hydroxytryptamine reuptake and facilitation of its release, plus the actions of this drug at μ receptors. In this regard, tramadol may be an exception to the argument that chiral mixtures should be avoided when technology exists to prepare a single, pure isomer.¹⁸⁷

A marked decrease in postoperative shivering has been noted in treated patients, and the minimal depressant effects on breathing are useful.¹⁸⁸ Tramadol slows gastric emptying, although the effect is small compared with other opioids.¹⁸⁹ Toxicity from overdose can manifest as hypotension, bradycardia, seizures, coma, and rhabdomyolysis. Disadvantages of tramadol include its interaction with warfarin (Coumadin) anticoagulants (not all reports confirm this interaction) and the occurrence of serotonin syndrome and drug-related seizures (avoid in patients with epilepsy or those being treated with drugs that lower the seizure threshold such as antidepressants).^{190,191} A further drawback to the perioperative use of this drug as an analgesic is a high incidence of associated nausea and vomiting.

Heroin

Heroin (diacetylmorphine) is a synthetic opioid produced by acetylation of morphine. It was developed in 1898 and was originally claimed to have no addictive potential. When administered parenterally, heroin acts in a markedly different way than morphine. For example, there is rapid penetration of heroin into the brain, where it is hydrolyzed to the active metabolites monoacetylmorphine and morphine. The unique rapid entrance into the CNS is most likely caused by the lipid solubility and chemical structure of heroin. Compared with morphine, parenteral heroin has a (1) more rapid onset, (2) less opioid-induced nausea, and (3) greater potential for physical dependency. This greater liability for physical dependence is the reason that heroin is not available legally for clinical use in the United States.^{192,193}

Opioid Agonist-Antagonists

Opioid agonist-antagonist drugs were touted in the 1970s and 1980s as analgesics that had none of the liability of full agonist opioids. Opioid agonist-antagonists used included pentazocine, butorphanol, nalbuphine, buprenorphine, nalorphine, bremazocine, and dezocine (**Figure 7.21**). As found previously and since, these claims did not hold up. The drugs bind to μ receptors, where they produce responses limited by a ceiling (partial agonists) or no effect (competitive antagonists). In addition, these drugs often exert partial agonist actions at other receptors, including α and δ receptors.¹⁹⁴ Antagonist properties of these drugs can attenuate the efficacy of subsequently administered opioid agonists and can induce profound symptoms of withdrawal when administered to patients who are currently treated with full agonist opioids. The side effects are similar to those of opioid agonists, and, in addition, these drugs may cause dysphoric reactions that largely limit their use in clinical practice. Only pentazocine, nalbuphine, butorphanol, and buprenorphine are used clinically to any degree.

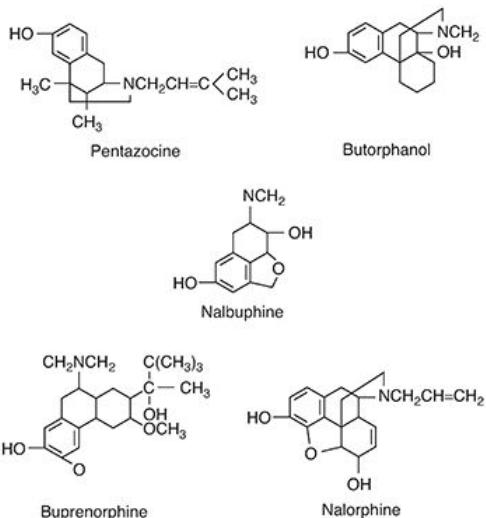

FIGURE 7.21 Opioid agonist-antagonists.

Pentazocine

Pentazocine is a benzomorphan derivative that possesses opioid agonist actions as well as weak antagonist activity. It is presumed to exert its analgesic effects through activation of δ and α receptors. Pentazocine is well absorbed after oral or parenteral administration. First-pass hepatic metabolism is extensive, with only about 20% of an oral dose entering the circulation. Metabolism occurs by oxidation of terminal methyl groups, and resulting inactive glucuronide conjugates are excreted in the urine. The elimination half-time is 2 to 3 hours.

Clinical Uses

Pentazocine, 10 to 30 mg IV or 50 mg orally, can be used for the relief of moderate pain. An oral dose of 50 mg is equivalent in analgesic effect to 60 mg of codeine. Pentazocine is useful for treatment of chronic pain when there is a high risk of physical dependence.

Side Effects

The most common side effect of pentazocine is sedation, followed by diaphoresis and dizziness. Dysphoria, including fear of impending death, is associated with high doses. Pentazocine produces an increase in the plasma concentrations of catecholamines, which may account for increases in heart rate, systemic blood pressure, pulmonary artery blood pressure, and left ventricular end-diastolic pressure that accompany administration of this drug.

Butorphanol

Butorphanol is an agonist-antagonist opioid that resembles pentazocine. Compared with pentazocine, its agonist effects are about 20 times greater, whereas its antagonist actions are 10 to 30 times greater.

Butorphanol has a low affinity for μ receptors to produce antagonism and moderate agonist activity at α receptors. It is used principally for treatment of migraine but is also effective to prevent shivering.

In postoperative patients, 2 to 3 mg IM produces analgesia and depression of ventilation similar to 10 mg of morphine. Intranasal butorphanol has been used for the treatment of postoperative pain and migraine pain. The intraoperative use of butorphanol, like pentazocine, seems to be limited. The elimination half-time of butorphanol is 2.5 to 3.5 hours. Metabolism is principally to inactive hydroxybutorphanol, which is eliminated largely in the bile and to a lesser extent in the urine.

Side Effects

Common side effects of butorphanol include sedation, nausea, and diaphoresis. Dysphoria, reported frequently with other opioid agonist-antagonists, is infrequent after administration of butorphanol. Depression of ventilation is similar to that produced by similar doses of morphine. Like pentazocine, analgesic doses of butorphanol increase systemic blood pressure, pulmonary artery blood pressure, and cardiac output. Also, similar to pentazocine, the effects of butorphanol on the biliary and gastrointestinal tract seem to be milder than those produced by morphine. It may be difficult to use an opioid agonist effectively as an analgesic in the presence of butorphanol.

Nalbuphine

Nalbuphine is an agonist-antagonist opioid that is related chemically to oxymorphone and naloxone. Nalbuphine is metabolized in the liver and has an elimination half-time of 3 to 6 hours. Naloxone reverses the agonist effects of nalbuphine. Nalbuphine is most commonly used to prevent shivering. Depression of ventilation is similar to that of morphine until 30 mg IM of nalbuphine is exceeded, after which no further depression of ventilation occurs (ceiling effect).¹⁹⁵

Buprenorphine

Buprenorphine is an agonist-antagonist opioid derived from the opium alkaloid thebaine. It is an old drug first introduced in the 1970s in a form. It is now available in multiple forms including transdermal, transmucosal, and subcutaneous that are used both for chronic pain and to prevent relapse in recovery from opioid abuse but is also effective in treating moderate to severe pain.¹⁹⁶ Its pharmacokinetics are unique in that it undergoes extensive first-pass metabolism and thus has little oral bioavailability. Absorption of its sublingual form that is commonly used to treat addiction ranges from 40 minutes to 3.5 hours. It is estimated that the affinity of buprenorphine for μ receptors is 50 times greater than that of morphine, and subsequent slow dissociation from these receptors accounts for its prolonged duration of action and resistance to antagonism with naloxone. The only clinically used opioid that has higher affinity of the μ receptor is sufentanil. The high affinity for the μ receptor and slow dissociation poses difficulty when a full agonist opioid is required for severe pain; for example, after surgery. There is debate on whether buprenorphine should be converted to a full agonist opioid before elective surgery. There are many excellent reviews available for more detailed discussion.^{197,198}

Side Effects

The side effects of buprenorphine include drowsiness, nausea, vomiting, and depression of ventilation. These are similar in magnitude to the side effects of morphine but may be prolonged and resistant to antagonism with naloxone. Pulmonary edema has been observed after administration of buprenorphine.¹⁹⁹ Because of its antagonist properties, buprenorphine can precipitate withdrawal in patients who are physically dependent on morphine. Initiation of buprenorphine treatment (induction) in patients receiving long-term treatment with a full agonist for prevention of abuse can be dangerous and should only be done by a provider experienced in this process.

Opioid Antagonists

Minor changes in the structure of an opioid agonist can convert the drug into an opioid antagonist at one or more of the opioid receptor sites ([Figure 7.22](#)).²⁰⁰ The most common change is substitution of an alkyl group for a methyl group on an opioid agonist. For example, naloxone is the *N*-alkyl derivative of oxymorphone (see [Figure 7.21](#)).

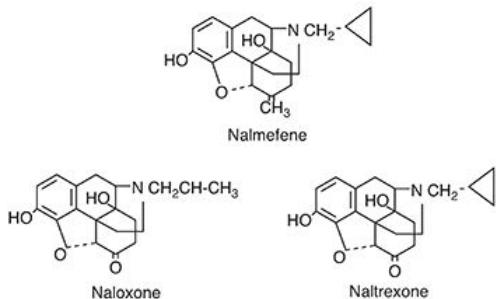

FIGURE 7.22 Opioid antagonists.

Naloxone and naltrexone are pure μ -opioid receptor antagonists with no agonist activity. The high affinity for opioid receptors characteristic of pure opioid antagonists results in displacement of the opioid agonist from μ receptors. After this displacement, the binding of the pure antagonist does not activate μ receptors and antagonism occurs. Nalmefene is an opioid antagonist primarily used for alcohol dependence and other addictions but could counteract full agonist opioids used for surgery.²⁰¹

Naloxone

Naloxone is a nonselective antagonist at all three opioid receptors. Naloxone is selective when used to (1) treat opioid-induced depression of ventilation as may be present in the postoperative period, (2) treat opioid-induced depression of ventilation in the neonate due to maternal administration of an opioid, (3) facilitate treatment of deliberate opioid overdose, and (4) detect suspected physical dependence. Naloxone, 1 to 4 $\mu\text{g}/\text{kg}$ IV, promptly reverses opioid-induced analgesia and depression of ventilation. Supplemental doses of naloxone will likely be necessary for sustained antagonism of opioid agonists. In this regard, a continuous infusion of naloxone, 5 $\mu\text{g}/\text{kg}/\text{hour}$, prevents depression of ventilation without altering analgesia produced by neuraxial opioids.²⁰² Higher doses may be needed to treat overdose with high-dose synthetic opioids. It is available in multiple forms including a nasal spray that can be administered by a first responder or bystander to an unconscious person suspected of opioid overdose.

Naloxone is metabolized primarily in the liver by conjugation with glucuronic acid to form naloxone-3-glucuronide. The elimination half-time is 60 to 90 minutes. Naloxone is absorbed orally, but metabolism during its first pass through the liver renders it only one-fifth as potent as when administered parenterally.

Side Effects

Antagonism of opioid-induced depression of ventilation is accompanied by an inevitable reversal of analgesia. It may be possible, however, to titrate the dose of naloxone such that depression of ventilation is partially but acceptably antagonized to also maintain partial analgesia.

Nausea and vomiting appear to be closely related to the dose and speed of injection of naloxone. Administration of naloxone slowly over 2 to 3 minutes rather than as a bolus seems to decrease the incidence of nausea and vomiting. Awakening occurs either before or simultaneously with vomiting, which ensures that the patient's protective upper airway reflexes have returned and the likelihood of pulmonary aspiration is minimized.

Cardiovascular stimulation after administration of naloxone manifests as increased sympathetic nervous system activity, presumably reflecting the abrupt reversal of analgesia and the sudden perception of pain. This increased sympathetic nervous system activity may manifest as tachycardia, hypertension, pulmonary edema, and cardiac dysrhythmias.²⁰³ Even ventricular fibrillation has occurred after the IV administration of naloxone and the associated sudden increase in sympathetic nervous system activity.²⁰⁴

Naloxone can easily cross the placenta. For this reason, administration of naloxone to an opioid-dependent parturient may produce acute withdrawal in the neonate.

Role in Treatment of Shock

Naloxone produces dose-related improvement in myocardial contractility and survival in animals subjected to hypovolemic shock and, to a lesser extent, in those subjected to septic shock.²⁰⁵ The beneficial effects of naloxone in the treatment of shock occur only with doses >1 mg/kg IV, suggesting that the beneficial effects of this drug are not opioid receptor mediated or, alternatively, are mediated by opioid receptors other than μ receptors—possibly δ and α receptors.

Antagonism of General Anesthesia

The occasional observation that high doses of naloxone seem to antagonize the depressant effect of inhaled anesthetics may represent drug-induced activation of the cholinergic arousal system in the brain, independent of any interaction with opioid receptors.²⁰⁶ A role of endorphins in the production of general anesthesia is not supported by data demonstrating a failure of naloxone to alter anesthetic requirements (MAC) in animals.

Naltrexone

Naltrexone, in contrast to naloxone, is highly effective orally, producing sustained antagonism of the effects of opioid agonists for as long as 24 hours. It has found a role in the treatment of alcoholism, possibly by reducing the pleasure associated with ethanol intoxication.²⁰⁷ It is also used at ultralow doses for chronic pain, thought to be mediated by activity at μ receptors on microglia.

Methylnaltrexone

Methylnaltrexone ([Figure 7.23](#)) is a quaternary opioid receptor antagonist. The highly ionized quaternary methyl group limits the transfer of methylnaltrexone across the blood–brain barrier. As a result, methylnaltrexone is active at peripheral rather than central opioid receptors as demonstrated by its failure to penetrate the CNS sufficiently to promote withdrawal in morphine-dependent animals.

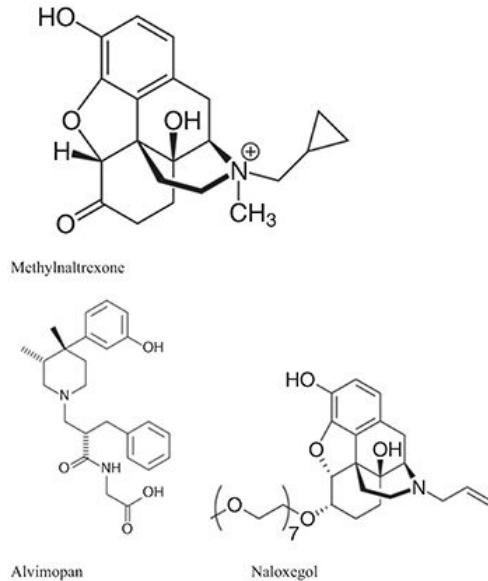

FIGURE 7.23 Chemical structure of methylnaltrexone, alvimopan, and naloxegol—oral peripheral opioid antagonists.

In humans, methylnaltrexone attenuates morphine-induced changes in the rate of gastric emptying and also decreases the incidence of nausea.²⁰⁸ The attenuation of morphine-induced nausea may be due to antagonism of morphine at the chemoreceptor trigger zone (located outside the blood–brain barrier) or through limitation of the delay in gastric emptying, which, in itself, may cause nausea. Presumably, methylnaltrexone could prevent the undesirable effects of opioids on gastric emptying and possibly vomiting without altering centrally mediated analgesia.

Alvimopan

Alvimopan (see [Figure 7.23](#)) is a μ -selective oral peripheral opioid antagonist. Its oral bioavailability is approximately 6%, and its metabolism also relies on gut flora.²⁰⁹ It was approved by the US Food and Drug Administration for treatment of postoperative ileus and has shown mixed results in subsequent clinical trials for treating ileus or opioid-induced constipation. Although likely safe in the acute setting, there is concern about a potential increase in cardiovascular events with long-term use.²¹⁰ It is, however, a component of many “enhanced recovery” programs designed to reduce the duration of hospitalization after surgery.²¹¹

Naloxegol

Naloxegol (see [Figure 7.23](#)) is another peripherally acting μ -opioid receptor antagonist. It is a polyethylene glycosylated derivative of naloxone. It was originally classified as a schedule II drug (high abuse potential) in the United States because it can be derived from opium alkaloids. However, it was subsequently reclassified as a class V prescription drug.²¹² It is approved for treatment of opioid-induced constipation in chronic pain states. The drug is rapidly absorbed after oral administration with principally hepatic elimination.²¹³

Tamper- or Abuse-Resistant Opioids

In recent years, prescribing of opioids for chronic noncancer pain has gained greater social acceptance, although this has led to significant consequences (see “[The ‘Opioid Crisis’](#)”). Along with this increase in prescription use, there has been a dramatic rise in drug diversion and abuse, both of which have a significant human and economic cost.²¹⁴

In an attempt to provide effective oral opioid analgesia with less potential for abuse, oral opioid formulations have been developed to reduce the ability to rapidly ingest the active ingredient (crushing, snorting, injecting) with subsequent euphoric effects.²¹⁵ One strategy involves combining the opioid with an antagonist. Examples of this strategy include Suboxone (buprenorphine plus naloxone), Embeda (extended-release morphine plus naltrexone), and OxyNal (oxycodone plus naltrexone). A second approach involves combining the opioid with a substance that becomes gelatinous when mixed for illicit injection, thus hampering improper use. Convincing evidence on these strategies’ efficacy is currently lacking, but they may prove to fill a useful role in chronic oral analgesic use by preventing opioid overdose due to crushing or injecting the extended-release opioid formulation.

Opioid Allergy

Although many patients claim “allergies” to opioids, true opioid allergy is rare. More often, predictable side effects of opioids such as localized histamine release, orthostatic hypotension, nausea, and vomiting are misinterpreted as an allergic reaction. Patients frequently perceive side effects as “allergy.” Morphine contains a tertiary amine group that causes nonimmune release of histamine. True allergic reactions to morphine are much rarer. Fentanyl is chemically dissimilar to morphine and, as such, does not cross-react with morphine derivatives.²¹⁶

Opioid Immune Modulation

Opioid therapy may alter immunity through neuroendocrine effects or via direct effects on the immune system.^{44,217} Opioid receptors are present on immune cells, including T- and B-lymphocytes, dendritic cells, neutrophils, macrophages, and microglia.⁴⁵ Prolonged exposure to opioids appears more likely than short-term exposure to produce immunosuppression especially in susceptible persons.

Of recent interest is the possible link between opioid-induced immunosuppression and cancer recurrence after resection.^{218–221} Opioids alter the development, differentiation, and function of immune cells and particularly seem to depress natural killer cell activity ([Figure 7.24](#)).^{222–224} Natural killer cells are lymphoid lineage cells that induce apoptosis in target cells via mechanisms distinct from T-lymphocytes and appear to be a major factor in tumor surveillance. Although immunosuppressant effects of opioids raise concerns, it is equally important to recognize that pain itself can impair immune function.

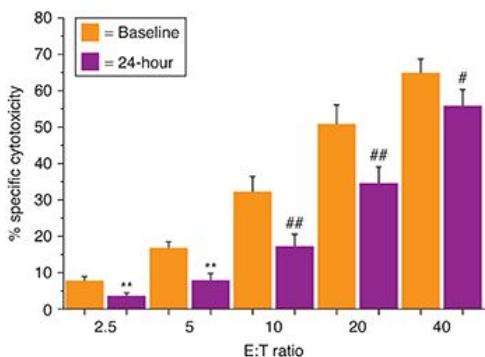

FIGURE 7.24 Depressed peripheral blood natural killer cell cytotoxicity immediately after a 24-hour high-dose morphine infusion in nine participants. Values are percentage-specific cytotoxicity at each effector-target (E:T) ratio tested (mean \pm standard error). **, $P < .05$ versus baseline value; ##, $P < .005$ versus baseline value; #, $P < .01$ versus baseline value. Anesthetic Requirements

The contribution of opioids to total anesthetic requirements can be estimated by determining the decrease in MAC of a volatile anesthetic in the presence of opioids. In animals, morphine decreases the MAC of volatile anesthetics in a dose-dependent manner, but there appears to be a ceiling effect to the anesthetic-sparing ability of morphine, with a plateau at 65% MAC.²²⁵ A single dose of fentanyl, 3 μ g/kg IV 25 to 30 minutes before surgical incision, decreases isoflurane or desflurane MAC by about 50%.²²⁶ In patients, a sufentanil plasma concentration of 0.145 ng/mL produced a 50% decrease in isoflurane MAC, whereas plasma sufentanil concentrations of >0.5 ng/mL exhibited a ceiling effect.^{227,228} The decrease in MAC produced by remifentanil is similar to that produced by other opioids and ranges from 50% to 91%, depending on the plasma concentration of remifentanil.²²⁹ These data cast serious doubt on the ability of opioid agonists to provide reliable amnesia during surgical procedures, even at extremely high doses.

Opioid agonist-antagonists are less effective than opioid agonists in decreasing MAC. For example, butorphanol, nalbuphine, and pentazocine maximally decrease MAC 11%, 8%, and 20%, respectively, even when the dose of these drugs is increased 40-fold.²³⁰ The ceiling effect for MAC parallels the ceiling effect for depression of ventilation and is consistent with the clinical impression that even large doses of opioid agonist-antagonists do not produce unconsciousness or even prevent patient movement in response to painful stimulation. Thus, the intraoperative role for these drugs is minimal and limits the effectiveness of full agonist opioids.

Patient-Controlled Analgesia

As an alternative to intermittent bolus dosing of medication, patients may be provided with a mechanism to address their own analgesic requirements. Termed **patient-controlled analgesia**, this most typically involves a programmable electronic pump that delivers a prescribed dose of medication upon patient demand. The rationale of this technique is that, by using frequent, small doses of opioid, patients will have better control of their pain by keeping effect site concentrations in the therapeutic range for a larger proportion of the time. Rather than wide swings between inadequate analgesia and oversedation, the PCA regimen is designed to allow patients to self-titrate their dosing to optimize their pain management ([Figure 7.25](#)).

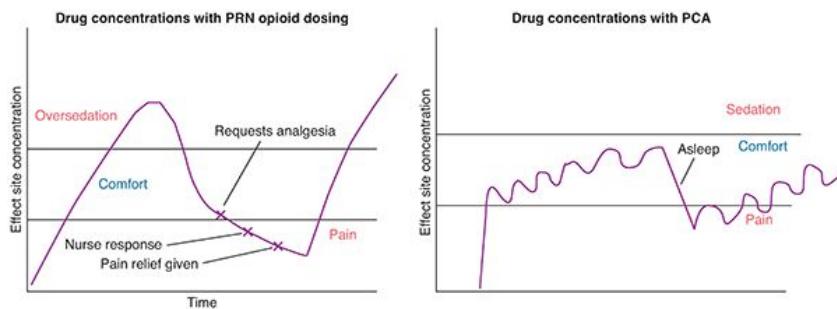

FIGURE 7.25 Effect site concentrations with traditional versus patient-controlled opioid dosing. After achieving effective concentrations, patient-controlled analgesia (PCA) allows patients to self-titrate opioid dosing to maintain effective analgesia.

Proposed advantages of this technique include decreased health care provider workload, increased patient satisfaction, lower opioid consumption, and the inherent safety of needing a conscious patient to self-administer a dose of opioid.²³¹ Despite multiple studies, PCA only provides marginally improved analgesia over conventional opioid therapy. Patient satisfaction, however, is significantly higher with PCA.²³² Typically, PCA uses IV opioids. Morphine, hydromorphone, and fentanyl are the most common choices. Suggested initial dosing regimens are listed in [Table 7.5](#).

TABLE 7.5

Suggested starting intravenous patient-controlled analgesia opioid regimens

Drug	Basal rate ^a	Bolus dose	Bolus interval (minutes)
Morphine	0-2 mg/hour	1-2 mg	6-10
Hydromorphone	0-0.4 mg/hour	0.2-0.4 mg	6-10
Fentanyl	0-60 µg/hour	20-50 µg	5-10

^aBasal infusions are not typically recommended for opioid-naïve patients.

Owing to the unique pharmacokinetic profile of remifentanil, it has found a role in PCA for labor and delivery. Because remifentanil undergoes nonenzymatic hydrolysis in both the maternal and fetal circulations, and is extensively metabolized in the placenta, it has minimal effects on the neonate. The mother must be carefully monitored as the rapid increase in plasma concentration can cause acute respiratory depression. In cases where epidural analgesia is contraindicated, remifentanil PCA has proven to be a viable but not fully efficacious alternative during the first stage of labor.²³³ It is more effective for patient satisfaction than for contemporaneous pain report.²³⁴

Neuraxial Opioids

Placement of opioids in the epidural or subarachnoid space to manage acute or chronic pain is based on the knowledge that opioid receptors (principally μ receptors) are present in the substantia gelatinosa of the spinal cord.²³⁵ Analgesia produced by neuraxial opioids, in contrast to regional anesthesia with local anesthetics, is not associated with sympathectomy, sensory block, or motor block. Analgesia is dose related (epidural dose is 5-10 times the subarachnoid dose) and effective for visceral pain. Neuraxial morphine may decrease the MAC for volatile anesthetics, although not all investigators have demonstrated this effect.²³⁶⁻²³⁸

Analgesia that follows epidural placement of opioids reflects diffusion of the drug across the dura to gain access to μ -opioid receptors in the spinal cord as well as systemic absorption to produce effects similar to those that would follow IV administration of the opioid. For example, the mechanism of postoperative analgesia produced by epidural administration of highly lipophilic opioids (fentanyl, sufentanil) may be primarily a reflection of systemic absorption, but this has been refuted.^{239,240} Poorly lipid-soluble opioids such as morphine result in a slower onset of analgesia but a longer duration of action than lipid-soluble opioids when administered via the neuraxial route.

Pharmacokinetics

Opioids placed in the epidural space may undergo uptake into epidural fat, systemic absorption, or diffusion across the dura into the CSF.²⁴¹ Epidural administration of opioids produces considerable CSF concentrations of drug. Penetration of the dura is highly influenced by lipid solubility, but molecular weight may also be important. Fentanyl and sufentanil are, respectively, approximately 800 and 1,600 times as lipid soluble as morphine. After epidural administration, CSF concentrations of fentanyl peak in about 20 minutes and sufentanil in about 6 minutes. In contrast, CSF concentrations of morphine, after epidural administration, peak in 1 to 4 hours. Furthermore, only about 3% of the dose of morphine administered epidurally crosses the dura to enter the CSF.²⁴²

The epidural space contains an extensive venous plexus, and vascular absorption of opioids from the epidural space is extensive. After epidural administration, fentanyl blood concentrations peak in 5 to 10 minutes, whereas blood concentrations of the more lipid-soluble sufentanil peak even sooner.²⁴³ In contrast, blood concentrations of morphine after epidural administration peak after 10 to 15 minutes. Epidural administration of morphine, fentanyl, and sufentanil produces opioid blood concentrations that are similar to those produced by an IM injection of an equivalent dose.²⁴¹ The addition of epinephrine to the solution placed into the epidural space decreases systemic absorption of the opioid but does not influence the diffusion of morphine across the dura into the CSF. The addition of epinephrine to intrathecal morphine solutions enhances postoperative analgesia compared with intrathecal morphine alone.²⁴⁴ Vascular absorption after intrathecal administration of opioids is clinically insignificant.

Cephalad movement of opioids in the CSF principally depends on lipid solubility. For example, lipid-soluble opioids such as fentanyl and sufentanil are limited in their cephalad migration by uptake into the spinal cord, whereas less lipid-soluble morphine remains in the CSF for transfer to more cephalad locations. After lumbar intrathecal morphine administration, appreciable cervical CSF concentrations occur 1 to 5 hours after injection, whereas cervical CSF concentrations of highly lipid-soluble opioids are minimal after their epidural administration. The underlying cause of ascension of morphine is bulk flow of CSF. CSF ascends in a cephalad direction from the lumbar region, reaching the cisterna magna in 1 to 2 hours and the fourth and lateral ventricles by 3 to 6 hours.²⁴¹ Coughing or straining, but not body position, can affect movement of CSF. The elimination half-time of morphine in CSF is similar to that in plasma.²⁴⁵

Side Effects

Side effects of neuraxial opioids are caused by the presence of drug in either the CSF or systemic circulation.²⁴¹ In general, most side effects are dose dependent. Some side effects are mediated via interaction with specific opioid receptors, whereas others are nonspecific. Side effects are less common in patients chronically exposed to opioids. The four classic side effects of neuraxial opioids are pruritus, nausea and vomiting, urinary retention, and depression of ventilation.

Pruritus

Pruritus is the most common side effect with neuraxial opioids. It may be generalized but is more likely to be localized to the face, neck, or upper thorax. The incidence of pruritus varies widely and is often elicited only after direct questioning. Severe pruritus is rare, occurring in about 1% of patients. Pruritus is more likely to occur in obstetric patients, perhaps due to the interaction of estrogen with opioid receptors. The incidence may or may not be dose related. Pruritus usually occurs within a few hours of injection and may precede the onset of analgesia.

Pruritus induced by neuraxial opioids is likely due to cephalad migration of the opioid in CSF and subsequent interaction with opioid receptors in the trigeminal nucleus. An opioid antagonist such as naloxone is effective in relieving opioid-induced pruritus. Antihistamines may be an effective treatment for pruritus, but this is likely secondary to their sedative effect.

Urinary Retention

Urinary retention with neuraxial opioids is more common than after IV or IM administration of equivalent doses of the opioid. The incidence of this side effect is not dose dependent or related to systemic absorption of the opioid. Urinary retention is most likely due to interaction of the opioid with opioid receptors located in the sacral spinal cord. This interaction promotes inhibition of sacral parasympathetic nervous system outflow, which causes detrusor muscle relaxation and an increase in maximum bladder capacity, leading to urinary retention. In humans, epidural morphine causes marked detrusor muscle relaxation within 15 minutes of injection that persists for up to 16 hours; it is readily reversed with naloxone.²⁰²

Depression of Ventilation

The most serious side effect of neuraxial opioids is depression of ventilation, which may occur within minutes of administration or may be delayed for hours.

Early depression of ventilation occurs within 2 hours of neuraxial injection of the opioid. Most reports of clinically important depression of ventilation involve epidural administration of fentanyl or sufentanil. This depression of ventilation may result from systemic absorption of the lipid-soluble opioid, although cephalad migration of opioid in the CSF may also be responsible. Clinically significant early depression of ventilation after intrathecal injection of morphine is unlikely.

Delayed depression of ventilation occurs more than 2 hours after neuraxial opioid administration and reflects cephalad migration of the opioid in the CSF and subsequent interaction with opioid receptors located in the ventral medulla. All reports of clinically significant delayed depression of ventilation involve morphine.²⁴¹ Delayed depression of ventilation characteristically occurs 6 to 12 hours after epidural or intrathecal administration of morphine. Clinically important depression of ventilation has not been described more than 24 hours after the epidural or intrathecal injection of morphine.

Factors that increase the risk of delayed depression of ventilation, especially concomitant use of any IV opioid or sedative, must be considered in determining the dose of neuraxial opioid (see **Table 7.3**).²⁴¹ Coughing may affect the movement of CSF and increase the likelihood of depression of ventilation. Obstetric patients appear to be at less risk for severe ventilatory depression.²⁴⁶

Detection of depression of ventilation induced by neuraxial opioids may be difficult. Arterial hypoxemia and hypercarbia may develop despite a normal breathing rate (**Figure 7.26**).²⁴⁷ Pulse oximetry reliably detects opioid-induced arterial hypoxemia, and supplemental oxygen (2 L/min) is an effective treatment for hypoxia but may mask hypercarbia. Supplemental oxygen, however, can mask significant hypoventilation. The most reliable clinical sign of depression of ventilation, however, appears to be a depressed level of consciousness, possibly caused by hypercarbia; however, this is a very undesirable late sign.²⁴¹ In patients receiving supplemental oxygen, arterial hypoxemia is a very late sign of hypoventilation; thus, pulse oximetry is of limited value in detection of opioid-induced respiratory depression in these patients. Continuous respiratory rate or carbon dioxide monitoring may be indicated in some settings. Prophylactic infusions of naloxone are of variable efficacy in protecting against depression of ventilation.^{202,248} Naloxone (0.25 µg/kg/hour IV) is effective in attenuating the side effects (nausea and vomiting, pruritus) associated with morphine-induced analgesia delivered by a patient-controlled IV delivery system.²⁴⁹

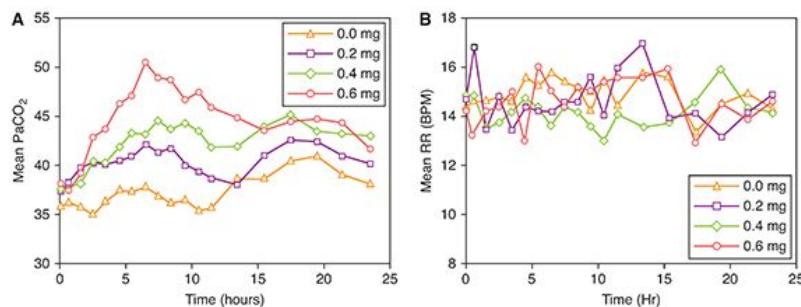

FIGURE 7.26 Mean PaCO_2 (mm Hg) (A) and mean respiratory rate (RR) (B) versus times before (time 0) and after three different doses of intrathecal morphine. Reprinted with permission from Bailey PL, Rhondeau

S, Schafer PG, et al. Dose-response pharmacology of intrathecal morphine in human volunteers. Anesthesiology. 1993;79(1):49-59. Copyright © 1993 American Society of Anesthesiologists, Inc.

Sedation

When sedation occurs with neuraxial opioids, depression of ventilation must be considered. Mental status changes other than sedation may also occur with neuraxial opioids. Naloxone-reversible psychosis, catatonia, and hallucinations have been described.²⁴¹

Central Nervous System Excitation

Tonic skeletal muscle rigidity resembling seizure activity is a well-known side effect of large IV doses of opioids, but this response is rarely observed after neuraxial administration. Myoclonic activity has been observed after neuraxial opioids and, in one report, progressed to a grand mal seizure.²⁵⁰ Although large doses of opioids reliably produce seizures in animals, clinically relevant doses of IV or neuraxial opioids are unlikely to be associated with generalized cortical seizure activity in humans.²⁴¹ Cephalad migration of the opioid in CSF and subsequent interaction with nonopioid receptors in the brainstem or basal ganglia is the most likely explanation for opioid-induced CNS excitation. In this regard, opioids may block glycine or γ -aminobutyric acid-mediated inhibition.

Viral Reactivation

A link exists between the use of epidural morphine in obstetric patients and reactivation of herpes simplex labialis virus. Reactivation of the herpes virus occurs 2 to 5 days after epidural administration of the opioid.²⁵¹ Manifestation of symptoms of herpes labialis (cold sores) characteristically occurs in the same sensory innervation as the primary infection, which are usually facial areas innervated by the trigeminal nerve. The underlying mechanism causing herpes virus reactivation likely involves cephalad migration of opioid in CSF and subsequent interaction with the trigeminal nucleus.

Neonatal Morbidity

Systemic absorption after epidural administration of an opioid results in predictable blood levels of the drug in the neonate immediately after birth. Clinically important depression of ventilation has been observed in the newborns of mothers receiving epidural opioids.²⁴¹ The progress of labor in general does not seem to be adversely affected by neuraxial opioids.²⁵² After administration of epidural fentanyl or sufentanil to parturients, the concentration of opioid in breast milk is negligible.⁴¹ As a general rule, systemic or neuraxial opioid analgesics should not be withheld from women recovering from cesarean delivery due to concerns of neonatal drug exposure in breast milk.

Miscellaneous Side Effects

Epidural morphine has been associated with sustained erection (priapism) and inability to ejaculate.²⁵³ Naloxone-reversible miosis, nystagmus, and vertigo may occur after neuraxial opioids, most commonly morphine. Neuraxial opioids may delay gastric emptying, most likely reflecting an interaction of the opioid with a spinal cord opioid receptor.²⁵⁴ Neuraxial opioids, by inhibiting shivering, may cause decreased body temperature. Neuraxial opioids have been implicated as possible causes of spinal cord damage, especially following accidental use of opioids containing toxic preservatives.²⁴¹ Clinical manifestations in these patients include sensory and motor neurologic dysfunction, myoclonic spasms, paresis, and paralysis. On the other hand, neuraxial opioids have been administered chronically without adverse sequelae.

Opioid Safety Issues

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a clinical syndrome characterized by recurrent episodes of apnea or hypopnea due to upper airway collapse during sleep. Due to their effects on ventilation, opioids pose a particular risk to this population. Additionally, individuals with OSA demonstrate an increased sensitivity to

the respiratory depressant effects of opioids. Many society guidelines on perioperative management of these patients exist,^{255,256} but strong supporting evidence is often lacking.²⁵⁷ General recommendations include minimizing the amount of opioid administered (such as by using multimodal and/or regional analgesia) and carefully evaluating the appropriateness of patients for ambulatory surgery. The first postoperative day appears to be the time of highest risk for opioid-induced respiratory depression, although the exacerbation of patients' OSA severity may peak on the third postoperative night and persist for up to 7 days.²⁵⁸

Practical Issues

A majority of patients prescribed oral opioids do not consume the entire prescription, and many of these prescriptions are not disposed of.²⁵⁹ Improperly stored opioids pose a safety hazard and provide a large opportunity for diversion.²⁶⁰ Thus, proper storage and disposal of prescribed opioids are a simple way to prevent harm. Although package inserts often contain detailed instructions for proper storage and disposal, education efforts for patients are still needed.²⁶¹

The “Opioid Crisis”

Opioids have always posed a public health risk due to their potential for abuse. In recent years, however, the United States has seen a surge in opioid prescribing, diversion, and overdose deaths. Starting in the early 2000s, regulatory and accreditation bodies pushed the measurement of pain as a “fifth vital sign.” Prescription of opioids increased rapidly. Diversion and abuse also increased, with over 33,000 reported opioid (legal and illicit) overdose deaths in 2015.²⁶² Opioid prescribing for acute and/or chronic pain now serves as a gateway for the illicit use of heroin, as it is often less expensive than diverted opioid medications.²⁶³ Potent synthetic opioids such as fentanyl are used illicitly and may also be unwittingly consumed when heroin is “cut” with synthetic opioids, thus contributing to overdose deaths.²⁶⁴ In addition to the human cost, the financial burden to society is enormous, estimated at US \$72.5 billion annually.²⁶⁵ Multiple means of controlling this epidemic have been proposed and/or instituted, including prescription drug monitoring programs, patient education, media coverage, state medical board actions, lawsuits against pharmaceutical companies, and comprehensive prescriber education efforts.²⁶⁶ The appropriate management of patients with pain, however, often still legitimately requires consideration of the risks and the benefits and the rational inclusion of opioids as part of a comprehensive pain management plan.²⁶⁷

Centrally Acting Nonopioid Analgesics*

Updated by: Chihiro Toda • Mohamed A. Naguib[†]

Opioid drugs are widely used drugs for the management of both acute and chronic pain. Side effects of opioids may limit their use, and concerns over drug dependence, misuse, and abuse have recently broadened boundaries on their use. The Centers for Disease Control and Prevention and the Agency for Healthcare Research and Quality have reported that evidence supporting the effectiveness of opioids for most non-cancer-related chronic pain syndromes is limited.^{1,2} This finding is not unexpected given our admittedly incomplete knowledge of physiology. Transition from acute to chronic pain involves release of inflammatory mediators and activation of microglia and changes protein expression in the dorsal horn.³ These complex changes may explain the decreased of opioids when pain transitions from acute to chronic.⁴ Chronic opioid administration induces microglial activation and the release of proinflammatory cytokines and chemokines.^{5,6} Inhibiting microglial activation mitigates the development of tolerance and opioid-induced reward mechanism^{7,8} and restores the analgesic efficacy of opioids.⁹ There are several nonopiate centrally administered analgesics that are supported for the treatment of in the literature.¹⁰ Nonnarcotic medication and treatments forming the base of multimodal analgesia is important to reducing reliance on opioids. Relieve pain by mechanisms mainly unrelated to opioid receptors reduces the risk of respiratory depression, physical dependence, and abuse.

In order to minimize the adverse effects of opioid analgesic medications, anesthesiologists and surgeons are increasingly turning to nonopioid analgesic techniques as adjuvants for managing pain during the perioperative period. Neuraxial drug administration describes techniques that deliver drugs in close proximity to the spinal cord, that is, intrathecally into the cerebrospinal fluid or epidurally into the fatty tissues surrounding the dura, by single injection or continuous infusion through a catheter. The administration of centrally acting agents bypasses the blood-brain barrier resulting in a higher cerebrospinal fluid concentration allowing using reduced amounts of medication to achieve equipotent doses.

The addition of neuraxial nonopioid adjuvants to local anesthetic may improve the quality of analgesia. Nonopioid neuraxial adjuvants have different mechanisms of actions and thus often have additive or synergistic effects. Potential advantages include a reduction in dose of individual drugs and a reduction in opioid requirement for rescue. Neuraxial administration of medications confers an inherent risk of injury to structures of the nervous system, not only by the needles and catheters used but also by neurotoxic effects of the compounds injected. Therefore, the potential neurotoxicity of any drug used in this setting needs careful study and validation before human use.¹¹

It is important to note that the US Food and Drug Administration (FDA) has not approved neuraxial (epidural or subarachnoid) administration of some of the drugs listed in this chapter for use clinically. Any drug considered for intrathecal administration in humans requires histologic, physiologic, and behavioral testing in a number of animal species before being considered for clinical use. Most drugs have not been sufficiently well studied to recommend their neuraxial use. Many drug preparations also contain antioxidants, preservatives, and excipients, which might contribute to neurotoxicity. In previous years, many drugs were tested in the neuroaxis without the required preclinical studies. Currently, many journals will not accept clinical trials of neuraxial drugs without preclinical toxicology and proper regulatory approval for the studies.

α_2 -Adrenergic Agonists

Epidural and intrathecal administration of α_2 -adrenergic agonists provide analgesia by activating α_2 -adrenergic receptors (G protein-coupled inhibitory receptors) on the sympathetic preganglionic neurons that mediate a reduction in norepinephrine (NE) release (via a negative feedback mechanism). Descending

noradrenergic pathways, originating in nuclei A₅ and A₇ in the pons and midbrain, appear to play a major inhibitory role on sympathetic preganglionic neuron activity.¹² The overall effect is sympatholysis resulting in analgesia, hypotension, bradycardia, and sedation.^{13,14}

Clonidine

Clonidine acts as a selective partial agonist of the α₂ receptors. It inhibits nociceptive impulse at postjunctional α₂ receptors in the dorsal horn of spinal cord. Neuraxial clonidine has been shown to be an effective analgesic for chronic cancer and noncancer pain as well as for postoperative pain. Clonidine has antihypertensive effects, and it has been shown to potentiate postoperative analgesia induced by local anesthetics. Spinal clonidine causes a 30% prolongation of sensory and motor block of local anesthetics. Clonidine is commonly administered epidurally in doses ranging from 75 to 150 μg. The doses used for intrathecal (spinal) analgesia ranges from 15 to 40 μg. For caudal analgesia, clonidine is administered as 1 μg/kg dose.

Intrathecal administration of clonidine 37.5 to 150 μg with bupivacaine results in a dose-dependent increase in sensory blockade and more pain-free intervals in the postoperative period. An intrathecal dose of 150 μg was noted to be associated with motor blockade.¹⁴ With combined spinal epidural anesthesia, the intrathecal clonidine doses as low as 15 μg resulted in an increased duration of anesthesia, analgesia, and motor blockade.

Epidural clonidine in the postoperative period reduced visual analog scale score and also decreased morphine consumption. Addition of clonidine intrathecally or epidurally was associated with significant reduction of heart rate and blood pressure.¹⁵ Epidural clonidine 1 μg/mL when added to morphine 0.1 mg/mL in 0.2% ropivacaine significantly reduced postoperative pain scores of total knee arthroplasty patients.

Neuraxially administered opioids and α₂ agonists exhibit synergism.¹³ The addition of clonidine to opioids for postoperative analgesia as a continuous epidural infusion reduces opioid requirements by 20% to 60%.¹⁶ The addition of 75 μg clonidine to epidural ropivacaine results in longer and effective analgesia for cesarean delivery. Clonidine is a useful adjunct for labor epidural analgesia. It has been shown to reduce local anesthetic requirements and improve pain scores when combined with 0.125% bupivacaine with or without fentanyl 2 μg/mL. When used in a concentration of 1 to 2 μg/mL, clonidine has not been shown to have significant effects on fetal heart rate, Apgar scores, or umbilical cord gases. It may have additional beneficial effects in women with preeclampsia by stabilizing blood pressure.

Neuraxial clonidine is indicated for the treatment of intractable pain in cancer patients unresponsive to maximum doses of opioids. This formed the basis for the approval of epidural clonidine by the FDA.¹⁷ Its use as an adjunct has been most widely accepted in pediatric anesthesia, as a means of increasing the duration of analgesia from caudal block, and, to a lesser extent in obstetric anesthesia, to provide analgesia in labor.¹⁸ Clonidine carries a black box warning for neuraxial use in perioperative and obstetric anesthesia and analgesia. “Obstetrical, postpartum, or perioperative pain management: Clonidine hydrochloride injection (epidural clonidine) is not recommended for obstetrical, postpartum, or perioperative pain management. The risk of hemodynamic instability, especially hypotension and bradycardia, from epidural clonidine may be unacceptable in these patients. However, in a rare obstetrical, postpartum or perioperative patient, potential benefits may outweigh the possible risks.”

Intrathecal clonidine appears to have antihyperalgesic properties.^{13,18–21} As hyperalgesia is the physiologic expression of central nervous system (CNS) sensitization, it may be useful in preventing the increased risk of patients with severe postoperative pain and central sensitization from developing persistent, long-term, or chronic pain after surgery.²²

Recent systematic review aimed to quantify beneficial and harmful effects of clonidine when used as an adjuvant to intrathecal local anesthetics for surgery concluded that clonidine prolongs the regression of the sensory block in a dose-dependent manner, prolongs the time to the first request of an analgesic, and prolongs the duration of complete motor block, with weak evidence of dose responsiveness. In addition, clonidine decreases the risk of intraoperative pain and increases the risk of arterial hypotension, without evidence of

dose responsiveness. Finally, clonidine has no relevant impact on the time to achieve complete sensory or motor block, on the extent of the cephalad spread of the sensory block, or on the risk of bradycardia.²³

Dexmedetomidine

Dexmedetomidine has a higher affinity and is more selective for α_2 receptors than clonidine and is associated with a fewer hemodynamic and systemic side effects. Evidence indicates that neuraxial administration of dexmedetomidine produces spinal analgesia as efficiently as clonidine.²⁴⁻²⁶ A dose of 3 μg of intrathecal dexmedetomidine was found to be equipotent with 30 μg of clonidine.²⁷ Intrathecal dexmedetomidine 5 μg and fentanyl 25 μg were compared for vaginal surgeries with bupivacaine anesthesia. Dexmedetomidine caused significantly longer sensory and motor blockade.²⁸ In neuraxial and peripheral nerve blocks, dexmedetomidine exhibits synergism with local anesthetics prolonging sensory and motor block, delaying the time to the first analgesic, and improving postoperative analgesia.²⁹

Clinical studies exhibit potentiation of neuraxial local anesthetics, decrease in intraoperative anesthetic requirements with prevention of intraoperative awareness, and improved postoperative analgesia when epidural dexmedetomidine was used in conjunction with general anesthesia.^{17,24-26,30,31} The addition of 2 $\mu\text{g}/\text{kg}$ dexmedetomidine epidurally prolongs the duration of analgesia and decreases the requirement of rescue analgesics in patients undergoing lower limb orthopedic surgery, abdominal surgeries, and cesarean section albeit associated with a significant fall in heart rate and mean arterial blood pressure. In thoracic surgery, the use of epidural dexmedetomidine decreases the anesthetic requirements, prevents awareness during anesthesia, and improves intraoperative oxygenation and postoperative analgesia.³² Caudal dexmedetomidine in a dose of 2 $\mu\text{g}/\text{kg}$ with bupivacaine used in pediatric patients undergoing hernia repair or orchioepexy was found to cause more sedation, prolonged analgesia, less anesthetic consumption, and less irritability. There were no hemodynamic differences when compared to patients who had received only bupivacaine.³³⁻³⁵

No neurologic deficits have been reported till date in studies on both humans and animals during intrathecal or epidural administration of dexmedetomidine. However, there is some evidence of demyelination of the oligodendrocytes in the white matter, suggesting harmful effects on the myelin sheath when administered via the epidural route in animal studies. Advanced pathologic investigations in at least two animal species are required to establish the safety of dexmedetomidine for general clinical use. Nevertheless, the observed side effects of α_2 -adrenergic agonists are limited to hemodynamic effects (ie, bradycardia and hypotension).

Neostigmine

Neostigmine acts by inhibiting acetylcholinesterase enzyme and preventing the breakdown of acetylcholine. Naguib and Yaksh^{13,36} demonstrated that the intrathecal administration of cholinesterase inhibitors (neostigmine or edrophonium) produces a dose-dependent antinociceptive activity in rats (**Figure 8.1**). These antinociceptive effects are independent of opioid and α_2 -receptor systems and are primarily due to stimulation of muscarinic (but not nicotinic) cholinergic receptors. The use of intrathecal acetylcholinesterase inhibitors, such as neostigmine, result in analgesia in both preclinical and clinical models. Neostigmine is a hydrophilic molecule, like morphine, and when applied to the epidural space, it requires time to diffuse through dura mater into the subarachnoid space.^{37,38} Naguib and Yaksh^{13,36} noted in other studies that the side effects associated with intrathecal neostigmine in animals preclude its potential clinical utility as a sole analgesic. Unlike many adjuvants trialed in clinical studies, neostigmine toxicology was studied in two animal models, and the clinical trials were granted status as an investigational new drug by the FDA.³⁹

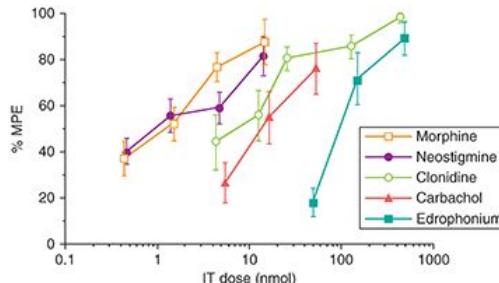

FIGURE 8.1 Log dose-response curves for the effects of intrathecally administered morphine, neostigmine, clonidine, carbachol, and edrophonium on the thermal nociceptive threshold. The response is presented as maximal possible effect (%MPE) versus log dose in nanomoles. Each point on the graph represents the mean \pm standard error of the mean. IT, intrathecal. *Reproduced from Naguib M, Yaksh TL. Antinociceptive effects of spinal cholinesterase inhibition and isobolographic analysis of the interaction with mu and alpha 2 receptor systems. Anesthesiology. 1994;80:1338-1348.*

Intrathecal neostigmine has been used as an adjunct to intrathecal local anesthetic and/or opioid to prolong regional analgesia and improve hemodynamic stability, with variable results. Escalating doses of intrathecal neostigmine (10-100 μ g) followed by 2% epidural lidocaine resulted in improved analgesia in a dose-independent manner after cesarean delivery.⁴⁰ The reduction in morphine requirements lasted up to 10 hours without adverse fetal effects, but the incidence of nausea varied from 50% to 100% in patients. In another study, intrathecal neostigmine (10 μ g) alone was ineffective for labor pain relief but, when combined with intrathecal sufentanil, reduced the effective dose 50 of sufentanil by approximately 25%.⁴¹

Epidural administration (100-200 μ g) appears to avoid these clinically troublesome adverse effects, while still improving local anesthetic-induced analgesia.⁴²⁻⁴³ Combinations of epidural neostigmine with local anesthetics, opioids, or clonidine for labor analgesia displayed analgesic effectiveness, potentiating analgesic effect of opioids and clonidine.⁴⁴⁻⁴⁶ Different doses of epidural neostigmine do not affect the motor blockade. Higher doses of intrathecal neostigmine can cause mild sedation.^{38,47}

Two different meta-analyses evaluated the effectiveness and side effects of intrathecal neostigmine in the perioperative and peripartum settings.^{48,49} They concluded that adding intrathecal neostigmine to other spinal medications improves perioperative and peripartum analgesia marginally when compared with placebo. The incidence of abnormal fetal heart rate or Apgar scores was not different. However, the addition of neostigmine to other epidural medications is associated with significant side effects and the disadvantages outweigh usually the minor improvement in analgesia achieved. Nausea and vomiting were seen less frequently in epidural neostigmine studies compared to intrathecal studies, thought to be arising due to less neostigmine diffusion from dura and absence of cephalic distribution.⁵⁰ Neostigmine stimulates muscarinic receptors in the bronchial smooth muscles and can lead to bronchospasm. In intrathecal neostigmine studies, except at very high doses (eg, 750 μ g), no change has been detected in oxyhemoglobin saturation and in end-tidal carbon dioxide levels.⁵¹

Intrathecal neostigmine at a dose of 1 μ g/kg has been used in pediatric lower abdominal and urologic surgeries where it was found to increase analgesia.^{52,53} Adverse gastrointestinal effects have made neostigmine an unpopular choice for neuraxial adjuvant therapy. Unlike intrathecal neostigmine, epidural neostigmine is not associated with an increased risk of nausea and vomiting; however, doses greater than 100 μ g have been associated with sedation. It does not cause respiratory depression or pruritus either alone or in combination with neuraxial opioids.

Ketamine

Anesthetic and subanesthetic doses of ketamine have analgesic properties as a result of noncompetitive antagonism of *N*-methyl-D-aspartate (NMDA) receptors. With prolonged, repetitive nociceptive stimulation NMDA receptors are activated, releasing excitatory neurotransmitters glutamate, aspartate, and neurokinin.⁵⁴ Its primary analgesic effect is mediated by antagonizing NMDA receptors located on secondary afferent

neurons in the dorsal horn of the spinal cord. These neurotransmitters are associated with many activities including central sensitization, windup, and the generation of plasticity of various systems such as memory, vision, motor function, and spinal sensory transmission.

There is little clinical use of intrathecal ketamine due to the potential risk of neurotoxicity in preservative-free form that caused spinal pathology in dogs⁵⁵ and from its preservative benzalkonium chloride.⁵⁶⁻⁵⁹ Spinal myopathy has been reported in a terminally ill cancer patient after continuous infusion intrathecal ketamine at a rate of 5 mg per day for a duration of 3 weeks of preservative-free ketamine.⁶⁰ Reported side effects of epidural ketamine include sedation, headache, and transient burning back pain during injection with doses greater than 0.5 mg/kg. The burning back pain is concerning for neurologic damage.

However, efficacy has been shown in several clinical trials that were completed before the toxicology was fully evaluated and known to be problematic. Naguib et al⁶¹ studied epidural doses of 10 and 30 mg of ketamine and found that 30-mg dose produced excellent postoperative pain relief for a longer duration. A low dose of ketamine at 4, 6, and 8 mg epidurally was found to be ineffective for postoperative analgesia.⁶²⁻⁶³ Caudally administered ketamine 0.5 mg/kg along with 0.175% levobupivacaine 1 mL/kg has been used successfully without adverse effects in children for lower abdominal and urologic surgeries.⁶⁴ Epidural infusion of 0.25 mg/kg per hour of S(+)-ketamine during thoracic surgery provides better postoperative analgesia than epidural 0.25% ropivacaine (Figure 8.2).⁶⁵ Both epidural infusions started before skin incision and were run at 6 mL per hour for the duration of surgical procedure.

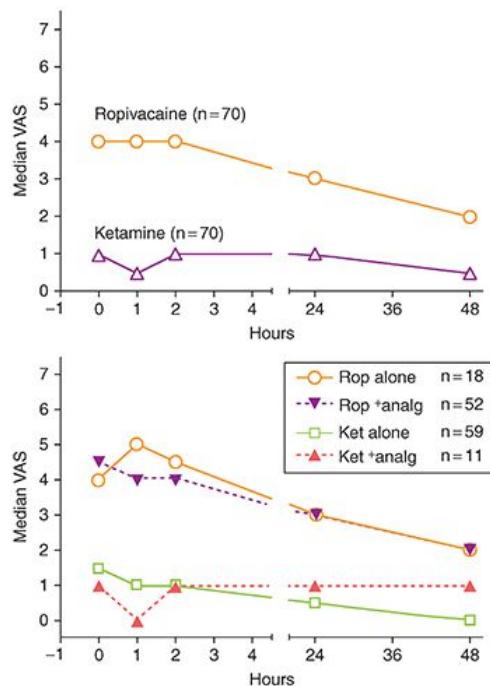

FIGURE 8.2 Postoperative median time courses of visual analog scale (VAS) scores in the ketamine (Ket) and ropivacaine (Rop) groups (upper panel) and in relation to analgesic consumption in the two groups (lower panel). Open symbols refer to no analgesics required; closed symbols refer to analgesics added. *Reprinted with permission from Feltracco P, Barbieri S, Rizzi S, et al. Brief report: perioperative analgesic efficacy and plasma concentrations of S+ -ketamine in continuous epidural infusion during thoracic surgery. Anesth Analg. 2013;116(6):1371-1375. Copyright © 2013 International Anesthesia Research Society.*

Combination of epidural ketamine with local anesthetic and/or opioid infusions results in improved analgesia, without significantly increasing adverse effects.^{11,66,67} The bupivacaine-ketamine mixture provided better analgesia than the bupivacaine solution alone.⁶⁶ Side effects such as motor weakness or urinary

retention were not observed in the ketamine group.⁶⁶ Adding small-dose ketamine to a multimodal epidural analgesia regimen provides better postoperative analgesia and reduces morphine consumption in thoracic, upper abdominal surgery, and lower abdominal surgeries.⁶⁵ Ketamine acts synergistically with opioids, dopaminergic, serotonergic, and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors to produce dissociation between the thalamocortical and limbic systems. α -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid is a non-NMDA-type ionotropic glutamate receptor that mediates fast synaptic transmission in the CNS. Ketamine has shown efficacy in the management of neuropathic pain. In high doses, it may have additional minor analgesic effects by modulating descending inhibitory pathways through inhibition of reuptake of neurotransmitters.

No clinical trials have reported respiratory depression, hallucinations, cardiovascular instability, bladder dysfunction, or neurologic deficit with epidural doses up to 1 mg/kg. There is no increased incidence of nausea, vomiting, or pruritus when combined with neuraxial opioids. Intrathecal ketamine has been shown to decrease morphine requirements in patients with terminal cancer and is useful in opioid-tolerant patients. Intrathecal ketamine with bupivacaine had superior postoperative analgesic effect and prolonged the time to first request of rescue analgesia after major abdominal cancer surgery. When combined with dexmedetomidine and bupivacaine, it also reduced the total consumption of patient-controlled analgesia morphine but increased the incidence of postoperative sedation.⁶⁸ A randomized study comparing intrathecal morphine and ketamine added to bupivacaine concluded that adding 0.1 mg/kg of intrathecal ketamine to 0.3 mg of morphine in patients undergoing major abdominal surgery reduced the total consumption of morphine postoperatively in comparison with either drug alone. Ketamine has been administered intrathecally to 16 patients with war injuries of the lower limbs in varying doses from 5 to 50 mg in a volume of 3 mL of 5% dextrose.⁶⁹ It resulted in a distinct sensory level that was obtained in all patients and satisfactory surgical analgesia. Central effects (drowsiness, dizziness, and nystagmus) occurred in 9 patients, but they remained conscious throughout; 1 patient experienced no central effects, and 1 patient developed dissociative anesthesia. Ketamine alone did not produce motor block, but addition of adrenaline resulted in complete motor block and may have intensified sensory blockade.⁶⁹

Tramadol

Tramadol is an analgesic combining mainly μ -opioid and monoaminergic activity through the inhibition of the neuronal uptake of serotonin and NE.⁷⁰ Animal studies have confirmed the analgesic effect of intrathecally administered tramadol.

The results of intrathecal administration of tramadol to patients showed contradicting results.⁷¹⁻⁷⁴ Tramadol 1 to 2 mg/kg has also administered caudally in children for postoperative analgesia.⁷⁵

Epidural administration of tramadol has been studied in humans with mixed effects.⁷⁶⁻⁸¹

Droperidol

Epidural droperidol is effective for reducing pruritus and postoperative nausea and vomiting.⁸² Long-term intrathecal droperidol is used as an excellent antiemetic in nonmalignant pain.⁸³ It has been suggested that droperidol acts as a dopaminergic antagonist directly at the brainstem chemoreceptor trigger zone, the floor of the fourth ventricle, and other center locations are involved with antiemetic action. Although no side effects were observed, it is important to recognize the lack of laboratory data documenting the safety of neuraxial droperidol (including the potential for neurotoxicity).⁸⁴ In addition, there are many drugs that can be given systemically with a good safety record raising the question of the need for intrathecal delivery of an untested drug.

Conopeptides

Ziconotide

Ziconotide is a synthetic 25-amino acid, polybasic peptide with three disulfide bridges and is a derivative of an omega conotoxin founded in the venom of a *Conus magus* snail. Ziconotide acts as a selective blocker of

neuronal *N*-type voltage-sensitive calcium channels within the dorsal horn in the presynaptic terminals, inhibiting nerve transmission. In animal and healthy human studies, ziconotide directly inhibits central and peripheral NE release and functions as a sympatholytic, thus resulting in decrease in mean and diastolic pressure, mostly profound when administered intravenously and normally negligible when dosed intrathecally.

It is highly polar and water-soluble, hypobaric at clinically useful concentration, and has a relatively large molecular weight. It has narrow therapeutic window, so initial infusion rates should be limited to 0.1 µg per hour with stepwise increase of this rate over time; CNS adverse effects are to be expected.⁸⁵⁻⁸⁷ Ziconotide is the only on-label, FDA-approved, nonopioid intrathecally administered medication to treat neuropathic pain.

It produced spinal antinociception in animal models of acute and persistent pain,⁸⁸ and subsequent reports described its intrathecal administration to relieve severe neuropathic pain.⁸⁹⁻⁹² Intrathecal ziconotide is effective in reducing severe chronic noncancer pain, cancer-related pain, or AIDS-related pain that is refractory to other analgesic regimens.¹⁰

Unfortunately, side effects occurred in the majority of patients (92.9%) studied in a randomized, placebo-controlled study of intrathecal ziconotide in adults with severe chronic pain.⁹³ Significant adverse events reported in the ziconotide group were dizziness, confusion, ataxia, abnormal gait, and memory impairment. Suicidality was increased with ziconotide as compared to placebo. Most of the side effects are self-limiting with cessation of therapy.

Other Investigational Conopeptides

CGX-1160

Conopeptide contulakin-G (CGX-1160) is a conopeptide that produces analgesia by activation of neuropeptidergic receptor type 1. The drug has undergone proper toxicologic studies and has been successful in early clinical trials of patients with neuropathic pain related to spinal cord injury.^{94,95} Neuropeptidergic receptor agonists in general have been implicated in enhanced proliferation in some types of cancer leading along with financial matters to a pause in clinical development.

Another conopeptide that inactivates the $\alpha 9\alpha 10$ neuronal nicotinic receptor has been modified to create RgIA4 that is specific for both rodent and human receptors. This compound was found in animal studies to prevent chemotherapy induced neuropathy. Analgesic effects lasted for at least 3 weeks suggesting that the analgesia may be due to improvement in pathology.^{96,97} This compound is in early clinical development.

Octreotide

Octreotide is a synthetic octapeptide somatostatin derivative of human growth hormone. Octreotide administered spinally causes analgesia.^{98,99} Several clinical trials showed promise. Intrathecal octreotide administered to cancer patients for 5 years reduced pain without any adverse effects.¹⁰⁰ However, octreotide and its analogues have produced severe neurotoxicity in animals leading to a cessation of clinical study except in the setting of palliative care with experimental consent.

Baclofen

γ -Aminobutyric acid (GABA) acts as an inhibitory neurotransmitter in the CNS. Baclofen is an agonist of the GABA-B receptor. Baclofen suppresses neuronal transmission in the cerebral cortex, basal ganglia, thalamus, cerebellum, and spinal cord. The analgesic effects of baclofen are mediated postsynaptically via the activating the G protein-linked GABA-B receptors in laminae II and III that result in increased potassium conductance and membrane hyperpolarization. Baclofen also acts presynaptically to inhibit Ca^{+2} conductance, and, therefore, the release of glutamate and substance P, and postsynaptically to produce membrane hyperpolarization by increased potassium conductance through a G protein and second messenger system.¹⁰¹

Baclofen has low lipid solubility and low molecular weight that makes it an appropriate candidate for spinal action when delivered by the epidural route. However, continuous epidural baclofen infusion failed to prove to alter the pain-spasm cycle experienced by patients with cerebral palsy following orthopaedic

surgery.¹⁰² Intrathecal baclofen has demonstrated efficacy in chronic pain syndromes associated with multiple sclerosis and complex regional pain syndrome type I. For somatic pain, intrathecal baclofen has been used for the treatment of low back pain with root compression syndromes.¹⁰³ Intrathecal baclofen is specifically used for spasticity and dystonia due to various conditions such as cerebral palsy and spastic posttraumatic spinal cord injury. Recent interest has also focused on its use as an analgesic.¹⁰¹

A typical intrathecal dose of baclofen is 25 to 200 µg per day through a programmable intrathecal pump. Intrathecal administration is superior to systemic administration with regard to efficacy and adverse effects.¹⁰⁴ Baclofen has also been observed to relieve central pain syndromes in patients with spasticity,¹⁰⁵ although it is uncertain whether this is primarily an effect on musculoskeletal pain because of reduced spasticity or an effect on neuropathic spinal cord injury pain.¹⁰⁶ Some evidence suggests efficacy against nociceptive and neuropathic pain, particularly in combination with morphine and/or clonidine.

Baclofen has been investigated in the perioperative settings in a randomized, double-blinded study for total knee arthroplasty as an adjuvant with spinal bupivacaine as a 100-µg single dose. The results showed a statistically significant reduction in opioid use in the postanesthesia care unit, reduced pain scores in the 48 to 72 hours postoperatively, and a reduced likelihood and severity of pain at 3 months after total knee arthroplasty in patients who received intrathecal baclofen compared to those who received spinal bupivacaine and saline.¹⁰⁷ Common side effects of baclofen include sedation, drowsiness, headache, nausea, and weakness. More serious side effects such as rhabdomyolysis and multiple organ failure have also been reported.^{108,109}

Cyclooxygenase Inhibitors

Ketorolac

Constitutive expression of cyclooxygenase (COX)-1 and COX-2 in the spinal cord, upregulation of COX-1 and COX-2, and release and production of spinal prostaglandins occur after peripheral injury. Intrathecal injection of prostaglandins are found to cause hyperalgesia and allodynia.^{110,111} Ketorolac is a COX inhibitor drug. Thus, the intrathecal delivery of COX inhibitors theoretically would reduce pain and central sensitization. As such, targeted inhibition of spinal COX may be a viable strategy for treating pain. This has led many investigators to postulate and demonstrate that neuraxial administration of nonsteroidal antiinflammatory drugs produces analgesia following excitatory input into the spinal cord.^{112,113}

The pharmacokinetics of ketorolac in cerebrospinal fluid obtained from dog studies suggests fast elimination and delayed tissue uptake; therefore, continuous infusion of intrathecal ketorolac may be required. Animal data appear promising, and healthy volunteer studies did not identify adverse neurologic side effects. Understanding the relevance of these observations to pain in humans has been hampered by lack of regulatory approval for intrathecal injection of these products.^{114,115} Intrathecal injection of ketorolac was studied in humans in an open-label, dose-escalating safety study. Intrathecal ketorolac 0.25 to 2.0 mg was well tolerated, with the only adverse effect being a mild reduction in heart rate 15 to 60 minutes following injection.¹¹¹ Intrathecal ketorolac did not relieve chronic pain or extend anesthesia or analgesia from intrathecal bupivacaine administered at the beginning of surgery.¹¹¹ A single spinal dose of ketorolac did not reduce acute pain, acute opioid use, or pain incidence or severity 2 and 6 months after hip arthroplasty.¹¹⁶ These studies suggest that spinally produced prostaglandins may have a more limited role in pain and hypersensitivity in humans than predicted by animal studies, and intrathecal ketorolac may have limited analgesic effects in humans.

Magnesium Sulfate

Magnesium has analgesic properties, primarily related to the regulation of calcium influx into cells¹¹⁷ and antagonism of NMDA receptors in the CNS.^{118,119} In a rat, models showed that direct intrathecal administration of magnesium enhanced the antinociceptive effect of opioids for acute incisional pain¹²⁰ and suppresses nociceptive responses in neuropathic pain models.¹²¹ Several trials investigating the analgesic efficacy of perioperative intravenous magnesium have been published with conflicting results.^{122–124} The

earliest clinical trials investigating intrathecal and epidural magnesium reported an increase in the median duration of analgesia¹²⁵ and decrease in opioid consumption by 25%,¹²⁶ respectively.

Animal studies have reported histologic neurotoxicity with weight-adjusted doses similar to those used in most human clinical trials to date,¹²⁷⁻¹²⁹ whereas two case reports have described patients suffering from disorientation¹³⁰ and continuous periumbilical burning pain¹³¹ following the injection of magnesium into the neuroaxis. These findings limit the utility of further human studies.

Conclusion

Neuraxial drug administration via the intrathecal and epidural route remains an important treatment option for the provision of anesthesia as well as analgesia in acute, cancer, and chronic pain. Additional dose-effect studies would strengthen our understanding of the safety profile of drugs administered neuraxially before translation into routine clinical practice can be supported.

Peripherally Acting Analgesics*

Updated by: Chihiro Toda • Mohamed A. Naguib[†]

An analgesic is any member of the group of drugs that are used to decrease pain sensation without loss of consciousness. An analgesic drug may act on the peripheral nervous system and/or central nervous system (CNS). Peripheral analgesics act at the sensory input level by blocking transmission of the impulse at a point peripheral to the brain/spinal cord. Their common denominator was thus believed to be their site of action within or proximal to the affected tissues, and hence, they were termed *peripheral analgesics*. Experimental and clinical studies support the possibility of plasticity within the dorsal root ganglion that is the way station between peripheral sensory afferents and spinal synaptic transmission. Peripheral administration of drugs can potentially optimize drug concentrations at the site of origin of pain, leading to lower systemic levels and fewer adverse systemic effects and drug interactions.

Recent efforts have been focused on peripherally selective compounds with limited ability to cross the blood–brain barrier. Nociceptive, inflammatory, and neuropathic pain all depends to some degree on the peripheral activation of primary sensory afferent neurons. A range of inflammatory mediators such as prostanoids, bradykinin, adenosine triphosphate, histamine, and serotonin can activate primary sensory afferent neurons. Inhibiting the actions of inflammatory mediators represents a strategy for the development of analgesics. Peripheral nerve endings also express a variety of inhibitory receptors including opioid, α -adrenergic, cholinergic, transient receptor potential cation channel subfamily V member 1, adenosine, and cannabinoid receptor, and ligands for these receptors represent viable targets for drug development. Transmission of a pain signal from the periphery to the CNS is complex. Tissue damage results in peripheral release of endogenous chemicals that can directly activate nociceptive afferent fibers, sensitize nociceptors, and/or cause increased local extravasation and vasodilatation. Nociceptive afferents have their cell bodies in the dorsal root ganglion and synapse with second-order neurons in the dorsal horn (for more details, see [Chapter 6](#)).

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are among the most often prescribed drugs in the world and have both central and peripheral effects that are principally due to blockade of the prostaglandin production. The NSAIDs have been shown to increase patient satisfaction and decrease opioid requirements.¹ This diverse class of drugs includes aspirin and other selective or nonselective cyclooxygenase (COX) inhibitors with common analgesic, antiinflammatory, and antipyretic properties.² The COX pathway is shown in [Figure 9.1](#). The NSAIDs inhibit the biosynthesis of prostaglandins by preventing the substrate arachidonic acid from binding to the COX enzyme active site.

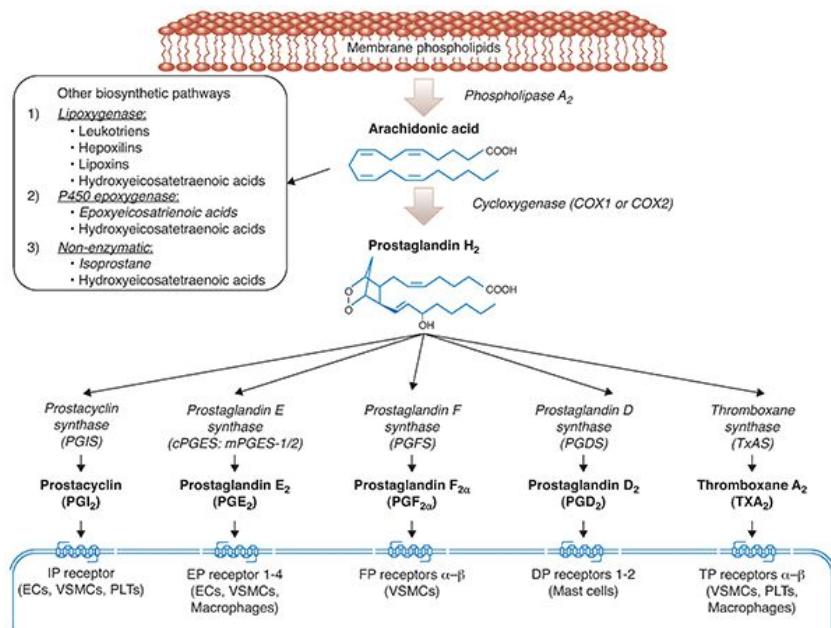

FIGURE 9.1 The cyclooxygenases pathway. Abbreviations: ECs, endothelial cells; EP, PGE₂ receptor; DP, PGD₂ receptor; FP, PGF_{2α} receptor; IP, prostacyclin receptor; PLTs, platelets; TP, thromboxane receptor; VSMCs, vascular smooth muscle cells.

The NSAIDs can be classified according to numerous characteristics, including COX selectivity and chemical and pharmacologic properties. The COX enzyme exist in two isoforms—cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2) isoenzymes.² The COX-1 is constitutively expressed and catalyzes the production of prostaglandins that are involved in numerous physiologic functions, including maintenance of normal renal function in the kidneys, mucosal protection in the gastrointestinal tract, and proaggregatory thromboxane A2 in the platelets. The COX-2 expression can be induced by inflammatory mediators in many tissues and have a role in the mediation of pain, inflammation, and fever. There has been speculation on the existence of a third isoform, cyclooxygenase 3 (COX-3), which would explain the mechanism of action of acetaminophen, a poor inhibitor of COX-1 and COX-2. However, such an isoform has not been identified in humans. Evidence indicates that, in addition to peripheral blockade of prostaglandin synthesis, central inhibition of COX-2 may play an important role in modulating nociception.

No NSAIDs are completely COX-2 selective. The ratio for inhibition of COX-2/COX-1 is shown in [Figure 9.2](#). Two of the most COX-2-selective drugs are no longer clinically available due to an excess of cardiovascular events as described under “Cardiovascular Side Effects” discussed in the following text. Currently, celecoxib is the only partially COX-2-selective inhibitor available for clinical use. However, as shown in [Figure 9.2](#), diclofenac is only slightly less COX-2 selective than celecoxib. Ketorolac is the most COX-1-selective clinically used NSAID.

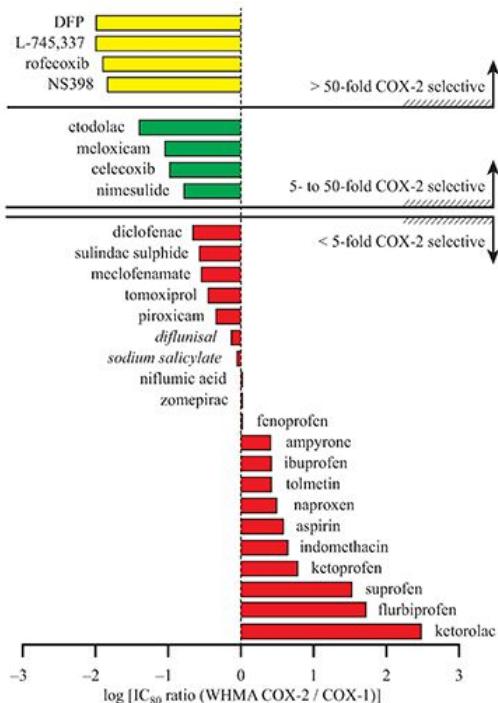

FIGURE 9.2 Relative selectivity of nonsteroidal antiinflammatory drugs for cyclooxygenase (COX) enzymes. Determinable $\log [IC_{80} \text{ ratio (WHMA-COX-2 / COX-1)}]$. The “0 line” indicates equipotency, that is, an IC_{80} ratio of 1. Italics indicate compounds with very low potency.

The COX-2-selective drugs may be a safer alternative to nonselective NSAIDs in the perioperative settings. Although analgesic activity is similar, NSAID use has been limited in the perioperative setting due to concerns about platelet dysfunction and gastrointestinal toxicity. The potential benefits of coxibs include improved quality of analgesia, reduced incidence of gastrointestinal side effects versus conventional NSAIDs, and no platelet inhibition.

Less Selective Nonsteroidal Antiinflammatory Drugs

The NSAIDs belong to a number of chemical families including acetic acids, oxicams, propionic acids, salicylates, fenamates, furanones, and coxibs (**Table 9.1**). All NSAIDs are weakly acidic chemical compounds and share similarities in pharmacokinetic properties.³ The volume of distribution of NSAIDs is low, ranging from 0.1 to 0.3 L/kg, suggesting minimal tissue binding. The plasma half-life of NSAIDs ranges from 0.25 to >70 hours, indicating wide differences in clearance rates. Hepatic or renal disease can alter NSAID protein binding and metabolism.⁴ In healthy, normovolemic patients treated with appropriate NSAIDs at clinically appropriate doses, hepatic and renal dysfunction is normally not problematic.

TABLE 9.1

Characteristics of commonly prescribed nonsteroidal antiinflammatory drugs (NSAIDs)

Generic name (Trade name)	Dose ^a		Pharmacokinetics	
	Available dosages (mg)	Common dosing intervals	Drug metabolism	Elimination half-life (h)
Nonselective NSAIDs				
Acetic acid group				
Diclofenac DR (Voltaren)	25	BID-TID QD-BID	Oxidation	1-2

	50			
Diclofenac XR (<i>Voltaren XR</i>)	75 100			
Etodolac (<i>Lodine</i>)	200 300	BID-TID QD	Oxidation, conjugation	7
Etodolac XL (<i>Lodine XL</i>)	400 500 400 500 600			
Ketorolac IM, IV injection (<i>generic</i>)	30	QD-QID	Conjugation	2.5-8.5
Indomethacin (<i>Indocin</i>)	25 50	BID-TID QD-BID	Oxidation, conjugation	4.5-6
Indomethacin SR (<i>Indocin SR</i>)	75			
Nabumetone (<i>Relafen</i>)	500 750	QD-BID	Oxidation	22-30
Sulindac (<i>Clinoril</i>)	150 200	BID	Oxidation, reduction	16
Tolmetin (<i>Tolectin</i>)	400 600	TID	Conjugation	5
Oxicam group				
Meloxicam (<i>Mobic</i>)	7.5 15	QD	Oxidation	13-20
Piroxicam (<i>Feldene</i>)	10 20	QD	Oxidation	30-86
Propionic acid group				
Fenoprofen (<i>Nalfon</i>)	200 300	TID-QID	Glucuronidation	3
Flurbiprofen (<i>Ocufen</i>)	50 100	BID-QID	Oxidation	3-6
Ibuprofen (<i>Motrin</i>)	400 600 800	TID-QID	Oxidation	2-2.5
Ketoprofen	50 75	TID-QID QD	Conjugation	2-4 3-7
Ketoprofen CR	100 150 200			

Naproxen (<i>Naprosyn</i>) (<i>Naprelan</i>)	250 375 500 375 500	BID QD	Conjugation, oxidation	12-15
Oxaprozin (<i>Daypro</i>)	600	QD-BID	Oxidation, conjugation	50-60
Salicylate				
Aspirin (<i>Ecotrin</i> , <i>Ascriptin</i>)	81 325	QD BID-QID	Hydrolysis, conjugation, glucuronidation	0.25-0.5
Choline magnesium				
Trisalicylate (<i>Trilisate</i>)	750 1000		Conjugation	2-12
Cyclooxygenase 2 agents				
Coxib group				
Celecoxib (<i>Celebrex</i>)	100 200	QD-BID	Conjugation	11-16

Abbreviations: BID, twice a day; IM, intramuscular; IV, intravascular; QD, everyday; TID, three times a day.

^aA dosage range exists for each NSAID that must be individualized depending on patient characteristics and disease mechanism.

The NSAIDs generally have complete, rapid oral bioavailability. After absorption, NSAIDs are more than 90% bound to albumin, which is critical for its volume of distribution and apparent potency.

Hypoalbuminemia (eg, due to alcoholic liver disease) and displacement by other drugs that are albumin bound can result in greater unbound NSAID and increased risk for toxicity.⁴ The liver metabolizes most NSAIDs, with subsequent excretion into urine or bile. Enterohepatic recirculation occurs when a significant amount of an NSAID or its conjugated metabolites are excreted into the bile and then reabsorbed in the distal intestine. Hepatic NSAIDs elimination is dependent on the free fraction of NSAIDs within the plasma and the intrinsic enzyme activities in the liver. The NSAIDs are primarily eliminated by renal and biliary excretion. Moderate to severe liver disease impairs NSAIDs metabolism, increasing the potential for NSAIDs toxicity.

Side Effects of Nonsteroidal Antiinflammatory Drugs

Platelet Function

Platelet aggregation and thus the ability to clot is primarily induced through stimulating thromboxane production following activation of platelet COX-1. There are no COX-2 enzyme platelets. The NSAIDs and aspirin inhibit the activity of COX-1, but the COX-2-specific inhibitors (or COX-1 sparing drugs) have no effect on platelet aggregation.⁵

Gastrointestinal Side Effects

The NSAIDs are associated with a spectrum of upper gastrointestinal complications, ranging from endoscopic ulcers in 10% to 30% of patients, to serious ulcer complications in 1% to 2% of patients.^{6,7} Lower gastrointestinal tract complications are less well characterized.^{8,9} Risk factors for NSAID-associated gastrointestinal complications include high NSAID dose; older age; *Helicobacter pylori* infection; a history of ulcer; and concomitant use of low-dose aspirin, anticoagulants, or corticosteroids.^{10,11} Therefore, it is generally recommended that patients with gastrointestinal risk factors should be treated with COX-2-

selective agents or nonselective NSAIDs with gastroprotective cotherapy.^{12,13} The NSAIDs should be used cautiously in colorectal surgery because there is some association with increase the risk of anastomotic leak.¹

Cardiovascular Side Effects

The NSAIDs are associated with an increased risk of cardiovascular adverse events such as myocardial infarction, heart failure, and hypertension. A COX inhibition is likely to disturb the balance between COX-2-mediated production of proaggregatory thromboxane in platelets and antiaggregatory prostaglandin I₂ in endothelial cells. The COX selectivity alone is not sufficient to define the risk of NSAID-associated cardiovascular complications. Based on two studies, the Vioxx Gastrointestinal Outcomes Research study¹⁴ and the Adenomatous Polyp Prevention on Vioxx study,¹⁵ rofecoxib was withdrawn from the market in 2004. Valdecoxib was subsequently withdrawn in 2005 due to a fourfold increase in the incidence of myocardial infarction.

The cardiovascular safety of nonselective NSAIDs has been under investigation. A meta-analysis of randomized trials found that high-dose ibuprofen and high-dose diclofenac were associated with a moderately increased risk of vascular events compared with placebo, similar to that observed with COX-2-selective agents, but the risks associated with naproxen, although they cannot be completely excluded, were substantially lower.¹⁶

Studies are lacking on the long-term effects of nonselective NSAIDs on gastrointestinal and cardiovascular systems, which limit our understanding of the true benefits and risks of NSAIDs. To reduce the cardiovascular risk, the American Heart Association recommends that all NSAIDs should be used at their lowest effective dose. A recent meta-analysis confirms that vascular and upper gastrointestinal effects of NSAIDs that diclofenac and ibuprofen raise risk of major vascular events as much as celecoxib. Naproxen has no effect on vascular outcomes but still increases upper gastrointestinal complications.¹⁷ There is no apparent relationship to COX enzyme selectivity.

Renal Side Effects

The COX-1 is constitutively expressed in the kidney, and COX-2 is induced in response to injury and inflammation.¹⁸ The production of prostaglandins and thromboxane are regulated by the COX enzymes in conjunction with intravascular volume. The effects of the NSAIDs on renal function include changes in the excretion of sodium, changes in tubular function, the potential for interstitial nephritis, and reversible renal failure due to alterations in filtration rate and renal plasma flow. The COX-1 controls hemodynamics and glomerular filtration rate, and COX-2 affects salt and water balance. As such, drugs such as diuretics and angiotensin blockers put patients at risk for renal dysfunction in response to NSAIDS. Reduced renal function prolongs NSAID half-life, and the dose should be lowered proportionally in patients with impaired kidney function.^{3,4} Prostaglandins and prostacyclins are important for maintenance of intrarenal blood flow and tubular transport. All NSAIDs, except nonacetylated salicylates, have the potential to induce reversible impairment of glomerular filtration rate; this effect occurs more frequently in patients with congestive heart failure; established renal disease with altered intrarenal plasma flow including diabetes, hypertension, or atherosclerosis; and with induced hypovolemia, salt depletion, or significant hypoalbuminemia.^{19,20}

Liver Side Effects

The use of aspirin was associated with reduced risk of developing hepatocellular carcinoma and of death due to chronic liver disease, whereas nonaspirin NSAID use was only associated with reduced risk of death due to chronic liver disease.²¹ Elevations in hepatic transaminase levels and liver failure have been reported.²²

Pulmonary Side Effects

Many adverse reactions attributed to NSAIDs are due to inhibition of prostaglandin synthesis in local tissues. For example, patients with allergic rhinitis, nasal polyposis, and/or a history of asthma, in whom all NSAIDs effectively inhibit prostaglandin synthase, are at increased risk for anaphylaxis.²³ The use of selective COX-2 inhibitors as an alternative to aspirin and other NSAIDs has been suggested for patients with aspirin-

exacerbated respiratory disease. The highly selective COX-2 inhibitor etoricoxib has been shown to be tolerated in most but not all patients tested.²⁴ An oral provocation test is therefore recommended before prescribing etoricoxib for patients with aspirin-exacerbated respiratory disease.²⁴ Etoricoxib is not currently available in the United States.

Hypersensitivity Reactions

Hypersensitivity reactions to NSAIDs occur rarely, and they are more common in individuals with nasal polyps or asthma. Allergic reactions include bronchoconstriction, rhinitis, and urticaria. Recent data suggest a role of altered COX-2 regulation associated with the aspirin-intolerant asthma/rhinitis syndrome.²³ Because of the potential for cross-reactivity, avoidance of all NSAIDs is recommended after severe reaction. In rare cases, NSAIDs have been implicated in causing aseptic meningitis and, in children, Reye syndrome.²⁵ The most common toxicities associated with NSAIDs are gastrointestinal, cardiovascular, and renal and are related primarily to COX inhibition and decreased synthesis of prostaglandins.

Idiosyncratic Adverse Effects

A typical nonspecific reaction includes skin rash and photosensitivity, tinnitus, hearing loss, and neutropenia. The effect of prostaglandin inhibition may result in premature closure of the ductus arteriosus. Prenatal aspirin use has been associated with smaller babies and neonatal bruising; however, it has been used for many years in the treatment of patients who require NSAIDs while pregnant.²⁶ It is not clear whether the indication for aspirin use such as history of preeclampsia and pregnancy loss is responsible for the smaller for gestational age infants or a direct effect of aspirin.

Drug-Drug Interactions With Nonsteroidal Antiinflammatory Drugs

Drug-drug interactions with NSAID therapy may result from pharmacodynamic or pharmacokinetic interactions. Nonselective NSAIDs affect other antiplatelet agents via additive inhibition of platelet aggregation. The result is an increased bleeding risk with the concomitant use of NSAIDs and other antiplatelet agents.^{25,27}

Significant drug-drug interactions have been documented with use of NSAIDs and lithium. The NSAIDs decrease lithium clearance and increase serum lithium concentrations by inhibiting renal prostaglandin production and altering intrarenal blood flow.^{25,27,28} Data are conflicting regarding the drug-drug interaction potential of angiotensin-converting enzyme inhibitors and NSAIDs.²⁹

As previously mentioned, NSAIDs are highly albumin bound and can be displaced by other drugs that strongly bind albumen. Concurrent administration of digoxin and NSAIDs can decrease renal clearance of digoxin, increase plasma drug concentration, and potentiate digoxin toxicity. The NSAIDs interact with anticonvulsant agents such as phenytoin and valproic acid by displacing the anticonvulsants from their protein-binding sites, which increases the free drug concentration. Combination use of corticosteroids and aspirin can increase renal clearance of salicylate and significantly decrease plasma salicylate concentrations.^{27,28}

The NSAIDs can be used in selected critically ill patients but should be used judiciously because of the potential for toxic adverse events. The lowest effective dose of the NSAID should be used for the shortest duration indicated. Appropriate clinical and laboratory surveillance and follow-up is necessary.

Acetaminophen

Acetaminophen (Tylenol, also known as paracetamol, *N*-acetyl-*p*-aminophenol, and nAPAP) is a popular antipyretic and analgesic found in many over-the-counter and prescription products. Acetaminophen is antipyretic and analgesic but has little, if any, antiinflammatory action. Acetaminophen is the leading cause of acute liver failure in the United States, and nearly half of acetaminophen-associated cases are due to unintentional overdose. With current U.S. Food and Drug Administration (FDA) regulation, it is hard to imagine that acetaminophen would be available without a prescription due to its toxicity.

Acetaminophen's mechanism of action is not known. It is complex and includes the effects of both peripheral and central antinociception processes.³⁰ Acetaminophen has a central analgesic effect that is mediated through activation of descending serotonergic pathways. Debate exists about its primary site of action, which may be inhibition of prostaglandin synthesis. In animal models, acetaminophen has been shown to inhibit COX-3. At the spinal cord level, it antagonizes neurotransmission by *N*-methyl-D-aspartate (NMDA), substance P, and nitric oxide pathways. Various metabolites of acetaminophen such as *N*-acylphenolamine and *N*-acetyl-*p*-benzoquinoneimine induce antinociception by modulating transient receptor potential vanilloid 1 (TRPV1) and transient receptor potential ankyrin 1 in the spinal cord.^{31,32} There is also evidence that acetaminophen metabolites appear to mediate analgesia through stimulation of cannabinoid type 1 receptors in the rostral ventromedial medulla.³³

Oral acetaminophen has excellent bioavailability. Acetaminophen is suitable for analgesic or antipyretic uses; it is the first-line analgesic in osteoarthritis and particularly valuable for patients in whom aspirin is contraindicated (eg, those with peptic ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional oral dose of acetaminophen is 325 to 650 mg every 4 to 6 hours; total daily doses should not exceed 4,000 mg (2,000 mg per day for chronic alcoholics). In 2009, an FDA advisory panel recommended a lower maximum daily dose of acetaminophen of 2,600 mg and a decrease in the maximum single dose from 1,000 to 650 mg.

Preparations of intravenous (IV) acetaminophen are currently available for clinical use. Optimal analgesia for moderate to severe postoperative pain cannot be achieved using a single agent alone.³⁴ The IV acetaminophen provides around 4 hours of effective analgesia for about 37% of patients with acute postoperative pain.³⁵ With its inherent safety and demonstrated efficacy, IV acetaminophen can prove to be an asset in managing perioperative pain. Current evidence suggests that a combination of acetaminophen and an NSAID may offer superior analgesia compared with either drug alone.³⁶ Studies in animals suggest synergy.³⁷

Acetaminophen is well tolerated and has a low incidence of gastrointestinal side effects. However, acute overdose can cause severe hepatic damage, and the number of accidental or deliberate poisonings with acetaminophen continues to grow. Chronic use of <2 g per day is not typically associated with hepatic dysfunction, but overuse of acetaminophen-containing narcotic and over-the-counter combination products marketed in the United States has led to heightened awareness of the possibility of toxicity.

Acetylsalicylic Acid (Aspirin)

Aspirin is the oldest and most widely used medicinal compound known in the world. It is considered separately from the other NSAIDs due to its predominant use in the treatment of cardiovascular and cerebrovascular diseases. It is an irreversible inhibition of COX enzymes. Aspirin is found in hundreds of over-the-counter medicines worldwide and remains at the forefront of medicine, with newly discovered applications for the prevention and treatment of several life-threatening diseases. Aspirin is a derivative of salicylic acid. Aspirin and salicylate are rapidly metabolized in the plasma (eg, plasma esterases), erythrocyte, and liver to salicylate in vivo.³⁸ Despite its rapid metabolism, it has long-lasting effects due to the fact that the COX enzymes are inhibited until new protein is produced.

Aspirin has several different approved uses. Aspirin acts as a general analgesic by blocking the action of the COX enzymes and thus prevents the production of prostaglandins. Aspirin effectively treats headaches, back and muscle pain, and other general aches and pains. In addition, aspirin produces inhibition of COX and, thus, prostanoid synthesis³⁹ and also protein kinase.⁴⁰ However, these are not necessarily the most likely mechanisms.⁴¹

Overdose

The mechanism of NSAIDs toxicity in overdose is related to both their acidic nature and their inhibition of prostaglandin production. The severity typically depends on the dose ingested and the salicylate concentration that correlates with the degree of acid-base disturbance.^{29,42} Salicylate levels of 300 to 600 mg/L are associated with mild toxicity, 600 to 800 mg/L with moderate toxicity, and greater than 800 mg/L

with severe toxicity. For nonselective NSAIDs, plasma concentrations are not commonly measured because the half-life of many of these agents is relatively short.⁴²

Symptoms include nausea, vomiting, abdominal pain, tinnitus, hearing impairment, and CNS depression (**Table 9.2**). With higher dose aspirin ingestion, metabolic acidosis, renal failure, CNS changes (eg, agitation, confusion, coma), and hyperventilation with respiratory alkalosis due to stimulation of the respiratory center. The presence of acidemia permits more salicylic acid to cross the blood–brain barrier.⁴³ With other nonselective NSAID ingestions, symptoms are similar.^{42–44}

TABLE 9.2

Adverse effects of nonsteroidal antiinflammatory drugs

System	Adverse effects
Cardiovascular	Hypertension; can exacerbate or induce heart failure, thrombotic events, possible increased risk of thrombotic/cardiovascular events with long-term use (use with caution in patients with preexisting disease; more likely with COX-2 inhibitors)
Respiratory	Nasal polyps, rhinitis, dyspnea, bronchospasm, angioedema; may exacerbate asthma
Hepatic	Hepatitis
Gastrointestinal	Gastropathy (can be asymptomatic), gastric bleeding, esophageal disease, pancreatitis
Hematologic	Increased intraoperative bleeding due to platelet inhibition/dysfunction (coxibs do not affect platelet function), will potentiate anticoagulation effect
Dermatologic	Urticaria, erythema multiforme, rash
Genitourinal	Renal insufficiency (use with caution in patients with preexisting renal disease), sodium/fluid retention, papillary necrosis, interstitial nephritis
Central nervous system	Headache, aseptic meningitis, hearing disturbances
Skeletal	Potential to inhibit bone growth/healing/formation
Pharmacologic interactions	NSAIDs displace albumin-bound drugs and can potentiate their effects (eg, warfarin).

Abbreviations: COX-2, cyclooxygenase 2; NSAIDs, nonsteroidal antiinflammatory drugs.

Management should be directed at symptomatic support, prevention of further absorption, and correction of acid-base imbalance.^{42–43} There is no antidote for salicylate or NSAID poisoning. Appropriate hydration and activated charcoal should be considered within 1 hour after aspirin ingestion. Urine alkalinization increases salicylate elimination.⁴² In severe cases of aspirin overdose, hemodialysis is effective at removing salicylate and correcting acid-base imbalances and has been shown to reduce morbidity and mortality.⁴³

Steroids

Glucocorticoids have been used to reduce inflammation and tissue damage in a variety of conditions, including inflammatory bowel disease and rheumatoid arthritis. The antiinflammatory action likely results from decreased production of various inflammatory mediators that play a major role in amplifying and maintenance of pain perception. Another proposed mechanism is by inhibition of phospholipase A2 as well as changes in cell function induced by glucocorticoid receptor activation.

Glucocorticoids have the most powerful antiinflammatory characteristics of all steroids. Corticosteroids are a subgroup of compounds known as adrenocorticoids that are naturally secreted from the adrenal gland. The primary corticosteroid is hydrocortisone, which is the standard against which the pharmacologic properties of various synthetic corticosteroids are judged. Many synthetic agents that are more potent, have longer durations of action, have greater antiinflammatory activity, and generate fewer unwanted mineralocorticoid side effects than hydrocortisone have been developed. Mineralocorticoids are adrenal cortical steroid hormones that have a greater effect on water and electrolyte balance. The main endogenous hormone is aldosterone.

Different steroids vary with respect to their duration of action and relative corticosteroid and mineralocorticoid activity. Corticosteroids are divided into short-, intermediate-, and long-acting groups ([Table 9.3](#)). Short- and long-acting preparations cause less inhibition of the hypothalamic-pituitary-adrenal axis. Many of the unwanted side effects are related to the mineralocorticoid properties.

Nearly all routes of administration can be used for corticosteroids. Although associated with significant toxicity when administered in large doses for long periods, adverse effects with a single dose of dexamethasone are usually minor but may increase plasma glucose in diabetics.[45](#)

TABLE 9.3

Comparative pharmacology of endogenous and synthetic corticosteroids

	Antiinflammatory potency	Sodium-retaining potency	Equivalent dose (mg)	Elimination half-time (h)	Duration of action (h)	Route of administration
Cortisol	1	1	20	1.5-3.0	8-12	Oral, topical, IV, IM, IA
Cortisone	0.8	0.8	25	0.5	8-36	Oral, topical, IV, IM, IA
Prednisolone	4	0.8	5	2-4	12-36	Oral, topical, IV, IM, IA
Prednisone	4	0.8	5	2-4	12-36	Oral
Methylprednisolone	5	0.5	4	2-4	12-36	Oral, topical, IV, IM, IA, epidural
Betamethasone	25	0	0.75	5	36-54	Oral, topical, IV, IM, IA
Dexamethasone	25	0	0.75	3.5-5.0	36-54	Oral, topical, IV, IM, IA
Triamcinolone	5	0	4	3.5	12-36	Oral, topical, IV, IM, epidural
Fludrocortisone	10	250	2	—	24	Oral, topical, IV, IM
Aldosterone	0	3,000				

Abbreviations: IA, intraarticular; IM, intramuscular; IV, intravenous.

The use of corticosteroids for pain relief, although popular, has yet to gain wider acceptance because of concerns over side effects, such as adrenal suppression, osteonecrosis, impaired wound healing ([Table 9.4](#)), and concerns about efficacy. There is evidence supporting the use of corticosteroids in multimodal analgesia protocols to contribute to the postoperative recovery of the patient by minimizing opioid doses and therefore side effects. However, the optimal mode, dose, and timing of administration remain unclear.[46](#)

In a meta-analysis,⁴⁷ patients treated with dexamethasone experienced less postoperative pain, required less postoperative opioids, had longer time to first analgesic dose, needed less rescue analgesia, and had shorter postanesthesia care unit stays. However, there was significant heterogeneity, and the differences between the groups were however small and may not be clinically relevant. Perioperative dose of dexamethasone had small but statistically significant analgesic benefits.⁴⁷ Investigators have begun to evaluate glucocorticoids as adjuvants for regional anesthesia. There is some evidence showed the analgesic effect of local spinal and systemic corticosteroids in combination with bupivacaine.⁴⁸ Dexamethasone have been found to prolong the block duration in animal and human studies, and adding methylprednisolone to local anesthetic increases the duration of axillary brachial block.⁴⁹

Dexamethasone also prolongs the analgesia from interscalene blocks using ropivacaine or bupivacaine, with the effect being stronger with ropivacaine; the combined effect of dexamethasone and either drug produced nearly 22 hours of analgesia. However, systemic glucocorticoids have also been shown to reduce postoperative pain. This raises the question whether the beneficial effects of adding glucocorticoid to a regional anesthetic is solely due to local effect or is mediated at least in part by systemic action.⁵⁰

Steroids are often administered to patients with arthritis and other chronic pain conditions locally (eg, intra-articularly) to limit the systemic side effect profiles. Pain relief from glucocorticoid treatment has been reported to last for up to 3 weeks in osteoarthritis and 2 months in rheumatoid arthritis.⁵¹

Epidural steroid injection has been used to treat back pain (mainly due to nerve root irritation) in patients with a wide variety of spine pathologies including radiculopathy, spinal stenosis, disk-space narrowing, annular tears, spondylosis, spondylolisthesis, vertebral fractures, and postlaminectomy syndrome.⁵¹

Systemic Local Anesthetics

Lidocaine produces analgesia by suppressing the activity of sodium channels in neurons that respond to noxious stimuli, thereby preventing nerve conduction and pain transmission. Voltage-gated sodium channels play a fundamental role in the control of neuronal excitability. Local anesthetics that block voltage-gated sodium channels have long been used to abolish pain temporarily by blocking nerve conduction.

Systemically administered local anesthetics, such as lidocaine, and orally administered mexiletine and tocainide are effective in a number of chronic pain conditions. Early studies described successful treatment of acute pain syndromes such as postoperative pain,⁵² burn pain,⁵³ and cancer pain.⁵⁴ Subsequent clinical reports have demonstrated the effectiveness in reducing pain associated with many chronic pain conditions.^{55,56} The exact mechanism of action of systemic local anesthetics in pain control is unknown. Evidence suggests that the effect may involve selective, dose-dependent blockade of pain fibers within the spinal cord or the dorsal root ganglia.⁵⁷ A Cochrane review assessed the effects of perioperative IV lidocaine infusion and concluded that it had a beneficial impact on pain scores in the early postoperative phase and on gastrointestinal recovery, postoperative nausea, and opioid consumption. However, the quality of evidence was limited due to inconsistency, imprecision, and quality of studies. Perioperative lidocaine infusion probably has no clinically relevant effect on pain scores later than 24 hours.⁵⁸ In contrast, when used for chronic neuropathic pain, there is evidence for long-term efficacy. At low concentrations, the analgesic effect is through sodium channel blockade. At increasing concentrations, there are off-target effects that are associated toxicity ([Figure 9.3](#)).⁵⁹

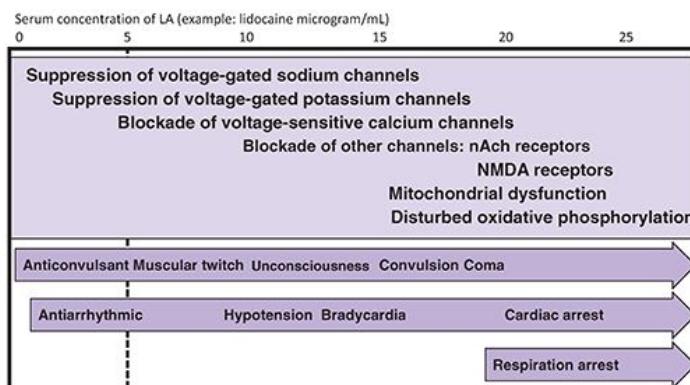

FIGURE 9.3 Systemic lidocaine concentration and toxicity. Intravenous lidocaine is kept between 1 and 5 µg/mL for the treatment of perioperative and chronic pain. Toxicity increases as specificity for voltage-gated sodium channels increases. nAch, nicotinic acetylcholine; NMDA, *N*-methyl-D-aspartate. *From Sekimoto K, Tobe M, Saito S. Local anesthetic toxicity: acute and chronic management. Acute Med Surg. 2017;4(2):152-160. <https://creativecommons.org/licenses/by/4.0/>.*

Orally administered lidocaine has poor bioavailability. The elimination half-life is 1.5 to 2 hours and can increase in the event of decreased liver blood flow (eg, congestive heart failure). Mexiletine has excellent oral bioavailability. The mean elimination half-life is 10 to 12 hours, which can increase to 25 hours with hepatic impairment. Only 10% of the drug is excreted unchanged by the kidney, and therefore, renal impairment has minimal effect on half-life.⁶⁰ A meta-analysis of studies of lidocaine and mexiletine used for neuropathic pain found that the drugs were superior to placebo, not different than other commonly used analgesics for this condition, and had no major adverse events when used within prescribed dosing and concentration guidelines.^{59,61}

At low doses, initial CNS symptoms include light-headedness, dizziness, tinnitus, vertigo, blurred vision, and altered taste. Seizures occur at higher doses. Cardiovascular side effects include hypotension, bradycardia, and cardiovascular collapse, which can lead to cardiac arrest.

Topical Application of 5% Lidocaine

The topical application of 5% lidocaine has been used in postherpetic neuralgia, and the topical application of 5% lidocaine (as a gel or patch) has been demonstrated to significantly relieve pain and reduce pain intensity with a fast onset (within 30 minutes) and lasting for the duration of drug application.⁶² Additionally, studies have also shown that lidocaine patches can provide pain relief in patients with other painful neuropathies.⁶³

Transdermal lidocaine has also been found to be effective after several different surgical procedures.^{64,65} The most common adverse events generally involve mild skin reactions. There has been no reported drug-drug interaction in clinical trials. Recent evidence suggests that extended application does not result in A β -mediated sensory loss at the application site, which is particularly important in patients who already have a degree of sensory loss due to their underlying condition. Heating a lidocaine patch can cause high systemic concentrations. Otherwise, the lidocaine patch provides a treatment option that carries a relatively low systemic adverse event and drug-drug interaction risk burden, even with continuous application of up to three patches per day. The efficacy of this approach alone can be a useful adjuvant for postoperative pain management.

Capsaicin

Capsaicin is a TRPV1 channel agonist.⁶⁶ A TRPV1 is a receptor that is activated in inflammatory conditions and is present on unmyelinated C fiber endings in the periphery.⁶⁷ The activation of the TRPV receptors releases high-intensity impulses and releases substance P and other inflammatory mediators, which results in the initial phase of burning. Continued release of substance P in the presence of capsaicin leads to the depletion of capsaicin and a subsequent decrease in C fiber activation.⁶⁸ Capsaicin is the major pungent ingredient of hot chili peppers and other botanicals. Capsaicin 0.025%, 0.075%, and 0.25% creams and/or transdermal patches are available over-the-counter for the temporary relief of pain from arthritis, myalgias, arthralgias, and neuralgias. The FDA has granted capsaicin orphan drug status in the treatment of postherpetic neuralgia, intermetatarsal neuroma, erythromelalgia, and human immunodeficiency virus-associated neuropathy. When used in the treatment of postherpetic neuralgia, a single transdermal application of a high-dose capsaicin patch (8%) provided a pain intensity decrease of $\geq 30\%$ for $> 35\%$ of treated patients in weeks 2 to 12.⁶⁹ Acute treatment with the high-dose capsaicin patch can be painful and requires pretreatment with topical or regional analgesia. The FDA approved the prescription-only capsaicin 8% patch for the management of neuropathic pain associated with postherpetic neuralgia. Topically applied capsaicin has moderate to poor efficacy in the treatment of chronic musculoskeletal or neuropathic pain.⁷⁰

Ketamine

There has been a renewed interest in the use of subanesthetic doses of ketamine as an adjunct to provide postoperative pain relief in opioid-dependent patients.⁷¹ The NMDA receptor antagonists have been used in perioperative pain management. At low subanesthetic doses, ketamine exerts NMDA blockade and modulates central sensitization than can be induced both by the incision and tissue damage and by long-term perioperative analgesics such as opioids. A Cochrane review that included 130 studies noted that IV ketamine probably reduced postoperative analgesic consumption and pain intensity.⁷²

There is a role of ketamine in preventing opioid-induced hyperalgesia in patients receiving high doses of opioid for their postoperative pain relief.⁷³ However, ketamine treatment can be limited due to psychotomimetic adverse effects. Other common adverse effects include dizziness, blurred vision, and nausea and vomiting that can be treated acutely or prophylactically.⁷⁴

Topical ketamine has been investigated. The NMDA and other glutamate receptors are present on sensory nerve endings and on cells adjacent to nerve endings. Inflammation and tissue damage result in elevated glutamate release from primary afferent nerve endings and keratinocytes. These findings suggest potential utility of topical application of NMDA receptor antagonists. Several controlled studies have compared topical ketamine with placebo. Ketamine 0.5% to 1.0% had no effect compared with placebo on neuropathic pain.⁷⁵ However, some controlled trial showed that topical ketamine with other drugs produced reduction in pain compared with placebo.⁷⁶ Currently, topical ketamine is only available as a compounded treatment.

Clonidine

Clonidine was developed as an antihypertensive drug in the 1960s that acts via nonspecific activation of α_1 - and α_2 -adrenergic receptors. In the intervening years, clonidine has been found to be effective for other indications including treating the symptoms of drug withdrawal. Clonidine has been used in the neuraxial and in combination with peripheral nerve blocks.⁷⁷ There is mixed data about how topical and systemic administration of clonidine could support the usefulness of low-dose IV administration.⁷⁸

Dexmedetomidine

Dexmedetomidine is a highly selective central α_2 agonist with little effect on α_1 -adrenergic receptors. Its sedative, proanesthetic, and proanalgesic effects at 0.5 to 2 $\mu\text{g}/\text{kg}$ given intravenously stem mainly from its ability to blunt the central sympathetic response. It minimizes opioid-induced muscle rigidity, lessens postoperative shivering, causes minimal respiratory depression, and has hemodynamic stabilizing effects. Dexmedetomidine, when used as an adjunct, can reduce postoperative morphine consumption in various surgical settings.^{79,80} A Cochrane database review showed that dexmedetomidine had some opioid-sparing effect but no clinically important differences in postoperative pain when compared with placebo.⁸¹ A recent meta-analysis evaluated the analgesic effect of intraarticular dexmedetomidine in knee arthroscopy and revealed that intraarticular dexmedetomidine significantly improved postoperative pain without any change in the incidence of nausea and vomiting, hypotension, bradycardia, or somnolence. More evidence is needed to confirm these findings.⁸²

Opioids

Since the detection of morphine in 1806 when morphine was extracted from opium, tested, and then marketed by the pharmacologist/pharmacist Friedrich Sertürner, it has been a mainstay of analgesic treatment. In addition to the central site of action, peripheral endogenous opioid analgesic systems have been extensively studied. The three classes of opioid receptors are widely distributed in peripheral as well as central neurons. Opioid receptors are synthesized in the dorsal root ganglia and transported centrally and peripherally to the nerve terminals.⁸³ They are also found in nonneuronal cells (neuroendocrine [pituitary, adrenals], ectodermal cells, and immune cells). The importance of the expression and activity of opioid receptors in microglia are increasingly found to be important to the transition to and the maintenance of chronic pain.⁸⁴

Efforts to develop peripherally restricted opioid analgesics (unable to cross the blood–brain barrier) that provide analgesia without central side effects are ongoing. Although peripheral opioid receptors expressed by the primary sensory neurons are functionally inactive under basal conditions, they are activated after surgery and trauma.⁸⁵ Several studies indicate that a large portion of the analgesic effects produced by systemically administered opioids can be mediated by peripheral opioid receptors.⁸⁶ Inflammation not only increases expression, transport, and accumulation of peripheral opioid receptors on peripheral terminals of sensory nerves but also triggers migration of opioid-containing immunocytes.⁸⁷ The peripheral effectiveness of opioids depends on the presence of inflammation, which triggers an enhanced expression of opioid receptors on primary afferents. Opioids were shown to have peripheral antinociceptive effects via modulation of inflammation.^{88,89} Interestingly, this recruitment of opioid-containing cells to inflamed tissue has been shown to be suppressed by the administration of centrally acting opioids.⁹⁰

Opioids injected locally into soft tissues or joints produce potent analgesic effects that are mediated by peripheral opioid receptors, occurring in the absence of central analgesic activity.⁹¹ Pain relief has been reported after knee arthroscopy on intra-articular injections of morphine⁹² and after submucosal injection of morphine in patients undergoing dental surgery.⁹³ There is some question about the complete peripheral restriction in these studies. The peripherally restricted μ -opioid agonist, loperamide, that is widely used for the treatment of diarrhea has only been implicated in animal models with antinociceptive activity except for the relief of cramping.⁹⁴ It may be that compounds that act on other peripheral opioid receptor subtypes could have more utility.⁹⁵ Opioid receptor activation plays a role in wound healing.⁹⁶ Peripherally acting opioids can reduce plasma extravasation, vasodilation, proinflammatory neuropeptides, immune mediators, and tissue

destruction. Local administration of opioid agonists at low concentrations may offer a promising therapeutic strategy.^{93,97}

There is strong evidence for a cardioprotective effect of both peripheral and central opioid receptors. There is some evidence that opioids may have infarct-sparing effects and ischemic preconditioning.⁹⁸ The endogenous opioid system is involved in the analgesic effect of the nonopioid analgesic celecoxib. There is evidence for both central⁹⁹ and peripheral¹⁰⁰ opioid receptor activation. In addition, there is evidence from animal models for antinociception from peripherally acting opioid agonists in models of inflammatory arthropathy and inflammatory bowel disease.^{101,102} Taken together, these findings underscore the potential utility of novel peripherally restricted opioids. In conclusion, peripherally acting analgesics have the benefit of avoiding central toxic side effects. We have provided examples of drugs that are given through local, regional, and systemic administration that have significant peripheral analgesic activity. In many cases, it is difficult to completely separate peripheral from central activity. The promise of peripherally restricted analgesics that can be used systemically as an opioid alternative is under active investigation.⁹⁵

Local Anesthetics

Kamal Maheshwari • Mohamed A. Naguib[†]

Local anesthetics are used to provide analgesia and anesthesia for various surgical and nonsurgical procedures. Also, these drugs are used for acute and chronic pain management to reduce perioperative stress, to improve perioperative outcomes, and to treat dysrhythmias. Local anesthetics produce reversible conduction blockade of impulses along central and peripheral nerve pathways. With progressive increases in concentrations of local anesthetics, the transmission of autonomic, somatic sensory, and somatic motor impulses is interrupted, producing autonomic nervous system blockade, sensory anesthesia, and skeletal muscle paralysis in the area innervated by the affected nerve.

Koller introduced cocaine as the first local anesthetic in 1884, for use in ophthalmology. Halsted recognized the ability of injected cocaine to interrupt nerve impulse conduction, leading to the introduction of peripheral nerve block anesthesia and spinal anesthesia.¹ Cocaine (an ester of benzoic acid) is present in large amounts in the leaves of *Erythroxylum coca*, a plant growing in the Andes Mountains, where its cerebral-stimulating qualities are well known. Another unique feature of cocaine is its ability to produce localized vasoconstriction, making it useful to shrink the nasal mucosa in rhinolaryngologic procedures and nasotracheal intubation. The first synthetic local anesthetic was the ester derivative procaine, introduced by Einhorn in 1905. Lidocaine was synthesized as an amide local anesthetic by Lofgren in 1943. It produces more rapid, intense, and longer lasting conduction blockade than procaine. Unlike procaine, lidocaine is effective topically and is a highly efficacious cardiac antidysrhythmic drug. For these reasons, lidocaine is the standard to which all other anesthetics are compared.

Molecular Structure

Local anesthetics consist of a lipophilic and a hydrophilic portion separated by a connecting hydrocarbon chain (**Figure 10.1**). The hydrophilic group is usually a tertiary amine, such as diethylamine, whereas the lipophilic portion is usually an unsaturated aromatic ring, such as para-aminobenzoic acid. The lipophilic portion is essential for anesthetic activity, and therapeutically useful local anesthetics require a delicate balance between lipid solubility and water solubility. An ester (–CO–) or an amide (–NHC–) bond links the hydrocarbon chain to the lipophilic aromatic ring. The nature of this bond is the basis for classifying drugs that produce conduction blockade of nerve impulses as ester local anesthetics or amide local anesthetics (**Figure 10.2**). The important differences between ester and amide local anesthetics relate to the site of metabolism and the potential to produce allergic reactions. Local anesthetics are poorly soluble in water and therefore are marketed most often as water-soluble hydrochloride salts. These hydrochloride salt solutions are acidic (pH 6), contributing to the stability of the local anesthetic. An acidic pH is also important if epinephrine is present in the local anesthetic solution because this catecholamine is unstable at an alkaline pH. Sodium bisulfite, which is strongly acidic, may be added to commercially prepared local anesthetic-epinephrine solutions (pH 4) to prevent oxidative decomposition of epinephrine.

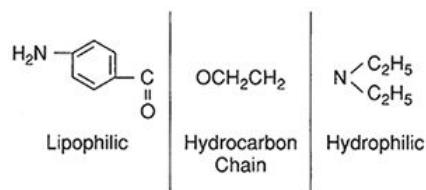

FIGURE 10.1 Local anesthetics consist of a lipophilic and hydrophilic portion separated by a connecting hydrocarbon chain.

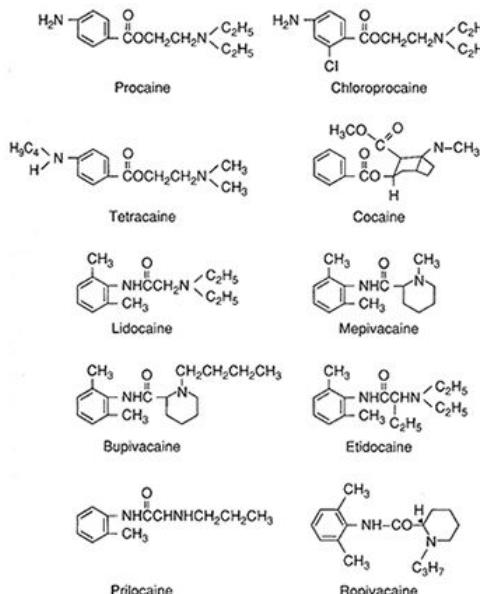

FIGURE 10.2 Ester and amide local anesthetics. Mepivacaine, bupivacaine, and ropivacaine are chiral drugs because the molecules possess an asymmetric carbon atom.

Structure-Activity Relationships

Modifying the chemical structure of a local anesthetic alters its pharmacologic effects. Lengthening the connecting hydrocarbon chain or increasing the number of carbon atoms on the tertiary amine or aromatic ring often results in a local anesthetic with a different lipid solubility, potency, rate of metabolism, and duration of action (**Table 10.1**). For example, substituting a butyl group for the amine group on the benzene ring of procaine results in tetracaine. Compared with procaine, tetracaine is more lipid soluble, is 10 times more potent, and has a longer duration of action corresponding to a 4- to 5-fold decrease in the rate of metabolism. Halogenation of procaine to chloroprocaine results in a 3- to 4-fold increase in the hydrolysis rate of chloroprocaine by plasma cholinesterase. This rapid hydrolysis rate of chloroprocaine limits the duration of action and systemic toxicity of this local anesthetic. Etidocaine resembles lidocaine, but substituting a propyl group for an ethyl group at the amine end and adding an ethyl group on the alpha carbon of the connecting hydrocarbon chain produces a 50-fold increase in lipid solubility and a 2- to 3-fold increase in the duration of action.

TABLE 10.1

Comparative pharmacology of local anesthetics

Classification	Potency	Onset	Duration after infiltration (minutes)	Maximum single dose for infiltration (mg)	Toxic plasma concentration ($\mu\text{g/mL}$)	pK binding (%)
Esters						
Procaine	1	Slow	45-60	500		8.9 6
Chloroprocaine	4	Rapid	30-45	600		8.7
Tetracaine	16	Slow	60-180	100 (topical)		8.5 76
Amides						
Lidocaine	1	Rapid	60-120	300	>5	7.9 70
Prilocaine	1	Slow	60-120	400	>5	7.9 55
Mepivacaine	1	Slow	90-180	300	>5	7.6 77

Bupivacaine	4	Slow	240-480	175	>3	8.1	95
Levobupivacaine	4	Slow	240-480	175		8.1	>97
Ropivacaine	4	Slow	240-480	200	>4	8.1	94
Classification	Fraction nonionized (%) at pH 7.4	Fraction nonionized (%) at pH 7.6	Lipid solubility	Volume of distribution (L)	Clearance (L per minute)	Elimination half-time (minutes)	
Esters							
Procaine	3	5	0.6	65		9	
Chlorprocaine	5	7		35		7	
Tetracaine	7	11	80				
Amides

Adapted from Denson DD. Physiology and pharmacology of local anesthetics. In: Sinatra RS, Hord AH, Ginsberg B, Preble LM, eds. *Acute Pain. Mechanisms and Management*. St Louis, MO: Mosby Year Book; 1992:124 and Burn AG, van der Meer AD, van Kleef JW, et al. Pharmacokinetics of the enantiomers of bupivacaine following intravenous administration of the racemate. *Br J Clin Pharmacol*. 1994;38:125-129.

Mepivacaine, bupivacaine, and ropivacaine are characterized as pipecoloxylidides (see [Figure 10.2](#)). Mepivacaine has a methyl group on the piperidine nitrogen atom (amine end) of the molecule. Addition of a butyl group to the piperidine nitrogen of mepivacaine results in bupivacaine, which is 35 times more lipid soluble and has a potency and duration of action 3 to 4 times that of mepivacaine. Ropivacaine structurally resembles bupivacaine and mepivacaine, with a propyl group on the piperidine nitrogen atom of the molecule. Despite the similar structure, ropivacaine causes less central nervous system (CNS) symptoms and is at least 25% less toxic than bupivacaine in regard to the dose tolerated,² highlighting even small difference in structure can lead to marked difference in pharmacokinetics and pharmacodynamics of local anesthetics.

Racemic Mixtures or Pure Isomers

The pipecoloxylidide local anesthetics (mepivacaine, bupivacaine, ropivacaine, levobupivacaine) are chiral drugs because their molecules possess an asymmetric carbon atom (see [Figure 10.2](#)). As such, these drugs may have a left- (S) or right- (R) handed configuration. Mepivacaine and bupivacaine are available for clinical use as racemic mixtures (50:50 mixture) of the enantiomers. The enantiomers of a chiral drug may vary in their pharmacokinetics, pharmacodynamics, and toxicity.³ These differences in pharmacologic activity reflect the fact that individual enantiomers bind to receptors or enzymes that are chiral amino acids with stereoselective properties. The S enantiomers of bupivacaine and mepivacaine appear to be less toxic than the commercially available racemic mixtures of these local anesthetics.⁴ In contrast to mepivacaine and bupivacaine, ropivacaine and levobupivacaine have been developed as a pure S enantiomers.⁵ These S enantiomers are considered to produce less neurotoxicity and cardiotoxicity than racemic mixtures or the R enantiomers of local anesthetics, perhaps reflecting decreased potency at sodium ion channel.⁶

Mechanism of Action

Local anesthetics bind to specific sites in voltage-gated sodium ion channels. They block sodium ion current, thereby reducing excitability of neuronal, cardiac, or CNS tissue.⁷ Local anesthetics prevent transmission of nerve impulses (conduction blockade) by inhibiting passage of sodium ions through ion-selective sodium channels in nerve membranes.⁸ The sodium channel itself is a specific receptor for local anesthetic molecules.

Failure of sodium ion channel permeability to increase slows the rate of depolarization such that threshold potential is not reached, and thus, an action potential is not propagated ([Figure 10.3](#)). Local anesthetics do not alter the resting transmembrane potential or threshold potential.

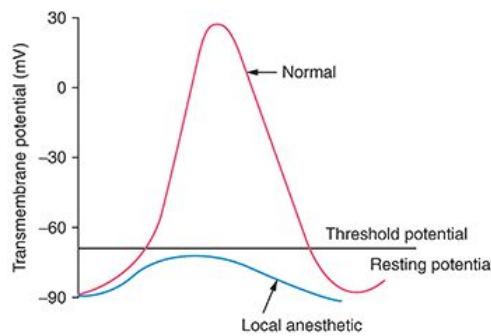

FIGURE 10.3 Local anesthetics slow the rate of depolarization of the nerve action potential such that the threshold potential is not reached. As a result, an action potential cannot be propagated in the presence of local anesthetic, and conduction blockade results.

Sodium Channels

The sodium channel is a dynamic transmembrane protein consisting of the large sodium-conducting pore (α subunit) and varying numbers of adjacent smaller β subunits. Nine distinct functional subtypes of voltage-gated sodium ion channels are recognized, corresponding to nine genes for their pore-forming α subunits. These have different tissue distributions in the adult and are differentially regulated at the cellular level by receptor-coupled cell signaling systems.⁹ Different isoforms of voltage-gated sodium ion channels, based on biophysical and pharmacologic studies, can provide distinct targets for interventions in various pain syndromes.^{10,11} The large polypeptide that forms the α subunit is further divided into four subunits (D I-D IV) ([Figure 10.4](#)). H is the α subunit that allows ion conduction and binds to local anesthetics. However, β subunits may modulate local anesthetic binding to the α subunit. Binding affinities of local anesthetics to the sodium ion channels are stereospecific and depend on the conformational state of the sodium channel.¹² Sodium channels exist in activated-open, inactivated-closed, and rested-closed states during various phases of the action potential.¹³ Voltage-gated sodium ion channels undergo fast and slow inactivation process, and this is critical for membrane excitability. The structural changes associated with inactivation process are poorly understood.¹⁴ In the resting nerve membrane, sodium channels are distributed in equilibrium between the rested-closed and inactivated-closed states. By selectively binding to sodium channels in inactivated-closed states, local anesthetic molecules stabilize these channels in this configuration and prevent their change to the rested-closed and activated-open states in response to nerve impulses. Sodium channels in the inactivated-closed state are not permeable to sodium, and thus, conduction of nerve impulses in the form of propagated action potentials cannot occur. It is speculated that local anesthetics bind to specific sites located on the inner portion of sodium channels (internal gate or H gate) as well as obstructing sodium channels near their external openings to maintain these channels in inactivated-closed states.⁸ This binding appears to be weak and to reflect a relatively poor fit of the local anesthetic molecule with the receptor. This is consistent with the broad variety of chemical structures that exhibit local anesthetic activity on sodium channels.¹²

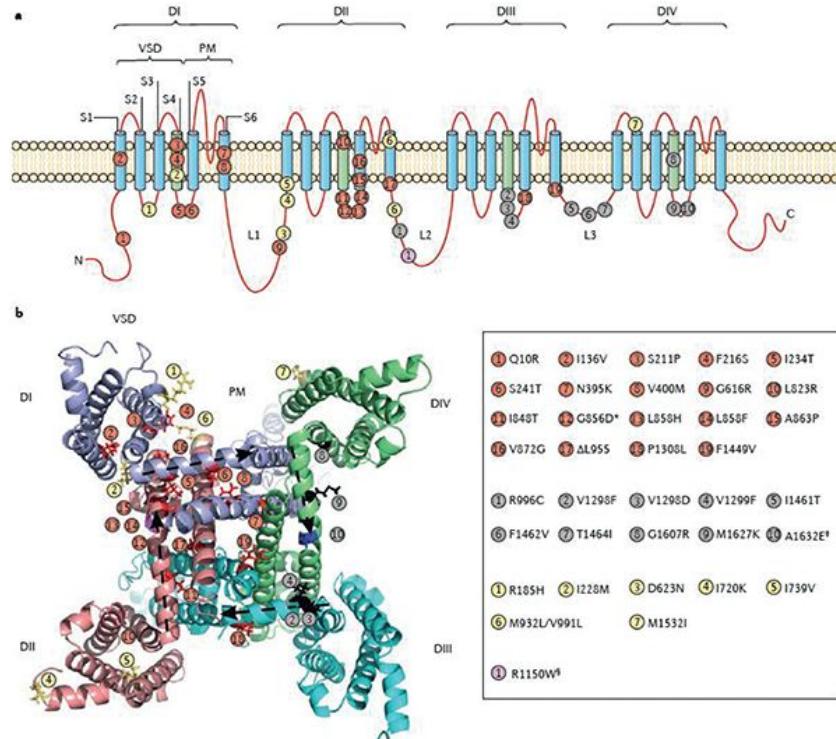

FIGURE 10.4 A, The sodium channel α subunit is a long polypeptide that folds into four homologous domains (DI-DIV), each of which consists of six transmembrane segments (S1-S6). The four domains are joined by three loops (L1-L3). Within each domain, S1-S4 comprise the voltage-sensing domain (VSD; S4, depicted in green, characteristically contains positively charged arginine and lysine residues), and S5-S6 and their extracellular linker comprise the pore module (PM). The linear schematic of the full-length channel shows the locations of amino acids affected by the gain-of-function *SCN9A* mutations that are linked to inherited erythromelalgia (red symbols), paroxysmal extreme pain disorder (gray symbols), and small-fiber neuropathy (yellow symbols). B, View of the folded $\text{Na}_V1.7$ from the intracellular side of the membrane based on the recently determined crystal structure of a bacterial sodium channel. The structure shows the central ion-conducting PM and four peripheral VSDs. Conformational changes in the VSDs in response to membrane depolarization are transmitted to the PMs through the S4-S5 linkers (identified by arrows through the helices). *Reprinted by permission from Nature: Dib-Hajj SD, Yang Y, Black JA, et al. The $\text{Na}_V1.7$ sodium channel: from molecule to man. Nat Rev Neurosci. 2013;14(1):49-62. Copyright © 2012 Springer Nature.*

Frequency-Dependent Blockade

Sodium ion channels tend to recover from local anesthetic-induced conduction blockade between action potentials and to develop additional conduction blockade each time sodium channels open during an action potential (frequency-dependent blockade). Therefore, local anesthetic molecules can gain access to receptors only when sodium channels are in activated-open states. For this reason, selective conduction blockade of nerve fibers by local anesthetics may be related to the nerve's characteristic frequencies of activity as well as to its anatomic properties, such as diameter. Indeed, a resting nerve is less sensitive to local anesthetic-induced conduction blockade than is a nerve that has been repetitively stimulated. The pharmacologic effects of other drugs, including anticonvulsants and barbiturates in addition to local anesthetics, may reflect frequency-dependent blockade (see [Chapter 13](#)).

Other Site of Action Targets

In addition to sodium ion channels, local anesthetics block voltage-dependent potassium ion channels. Compared with sodium ion channels, local anesthetics exhibit a much lower affinity. However, blockade of

potassium ion channels might explain broadening of the action potential in the presence of local anesthetics. Considering the structural similarity between voltage-dependent calcium ion channels and sodium ion channels, it is not surprising that calcium ion currents (L-type most sensitive) may also be blocked by local anesthetics.¹⁵ Although local anesthetics are considered principally ion channel blockers, there is evidence these drugs may also act on G protein-coupled receptors.¹⁶

Minimum Effective Concentration

The minimum concentration of local anesthetic necessary to produce conduction blockade of nerve impulses is termed the **C_m**. The C_m is analogous to the minimum alveolar concentration for inhaled anesthetics. Nerve fiber diameter influences C_m, with larger nerve fibers requiring higher concentrations of local anesthetic for production of conduction blockade. An increased tissue pH or high frequency of nerve stimulation decreases C_m.

Each local anesthetic has a unique C_m, reflecting differing potencies of each drug. The C_m of motor fibers is approximately twice that of sensory fibers; thus, sensory anesthesia may not always be accompanied by skeletal muscle paralysis. Despite an unchanged C_m, less local anesthetic is needed for subarachnoid anesthesia than for epidural anesthesia, reflecting greater access of local anesthetics to unprotected nerves in the subarachnoid space.

Peripheral nerves are composed of myelinated A and B fibers and nonmyelinated C fibers. A minimal length of myelinated nerve fiber must be exposed to an adequate concentration of local anesthetic for conduction blockade of nerve impulses to occur. For example, if only one node of Ranvier is blocked (site of change in sodium permeability), the nerve impulse can jump (skip) across this node and conduction blockade does not occur. For conduction blockade to occur in an A fiber, it is necessary to expose at least two and preferably three successive nodes of Ranvier (approximately 1 cm) to an adequate concentration of local anesthetic. Both types of pain-conducting fibers (myelinated A-δ and nonmyelinated C fibers) are blocked by similar concentrations of local anesthetics despite the differences in the diameters of these fibers.

Preganglionic B fibers are more readily blocked by local anesthetics than any fiber, even though these fibers are myelinated.

Differential Conduction Blockade

Differential conduction blockade is illustrated by selective blockade of preganglionic sympathetic nervous system B fibers using low concentrations of local anesthetics. Slightly higher concentrations of local anesthetics interrupt conduction in small C fibers and small- and medium-sized A fibers, with loss of sensation for pain and temperature. Nevertheless, touch, proprioception, and motor function are still present such that the patient will sense pressure but not pain with surgical stimulation. In an anxious patient, however, any sensation may be misinterpreted as failure of the local anesthetic.

Pharmacokinetics

Local anesthetics are weak bases that have pK values somewhat above physiologic pH (see **Table 10.1**). As a result, <50% of the local anesthetic exists in a lipid-soluble nonionized form at physiologic pH. For example, at pH 7.4, only 5% of tetracaine exists in a nonionized form. Acidosis in the environment into which the local anesthetic is injected (as is present with tissue infection) further increases the ionized fraction of drug. This is consistent with the poor quality of local anesthesia that often results when a local anesthetic is injected into an acidic infected area. Local anesthetics with pKs nearest to physiologic pH have the most rapid onset of action, reflecting the presence of an optimal ratio of ionized to nonionized drug fraction (see **Table 10.1**).

Intrinsic vasodilator activity will also influence apparent potency and duration of action. For example, the enhanced vasodilator action of lidocaine compared with mepivacaine results in the greater systemic absorption and shorter duration of action of lidocaine. Bupivacaine and etidocaine produce similar vasodilation, but plasma concentrations of bupivacaine after epidural placement exceed those of etidocaine.

Absorption and Distribution

Absorption of a local anesthetic from its site of injection into the systemic circulation is influenced by the site of injection and dosage, use of epinephrine, and pharmacologic characteristics of the drug ([Figure 10.5](#)). The ultimate plasma concentration of a local anesthetic is determined by the rate of tissue distribution and the rate of clearance of the drug. For example, the infusion of lidocaine for 1 minute is followed by a rapid decrease in the drug's plasma concentration that is paralleled by an initial high uptake into the lungs and distribution of the local anesthetic to highly perfused tissues (brain, heart, and kidneys).¹⁷ Lipid solubility of the local anesthetic is important in this redistribution as well as being a primary determinant of intrinsic local anesthetic potency. After distribution to highly perfused tissues, the local anesthetic is redistributed to less well-perfused tissues, including skeletal muscles and fat. Consideration of cardiac output is important for describing the overall tissue distribution of local anesthetics and presumably their intercompartmental clearance.¹⁸ Ultimately, the local anesthetic is eliminated from the plasma by metabolism and excretion.

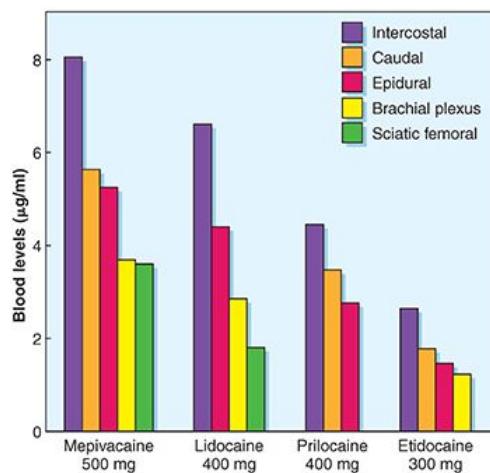

FIGURE 10.5 Peak plasma concentrations of local anesthetic are influenced by the site of injection for accomplishment of regional anesthesia.

In addition to the tissue blood flow and lipid solubility of the local anesthetic, patient-related factors such as age, cardiovascular status, and hepatic function will also influence the absorption and resultant plasma concentrations of local anesthetics. Protein binding of local anesthetics will influence their distribution and excretion. In this regard, protein binding parallels lipid solubility of the local anesthetic and is inversely related to the plasma concentration of drug ([Figure 10.6](#); see [Table 10.1](#)).¹⁹ Overall, after systemic absorption, amide local anesthetics are more widely distributed in tissues than ester local anesthetics.

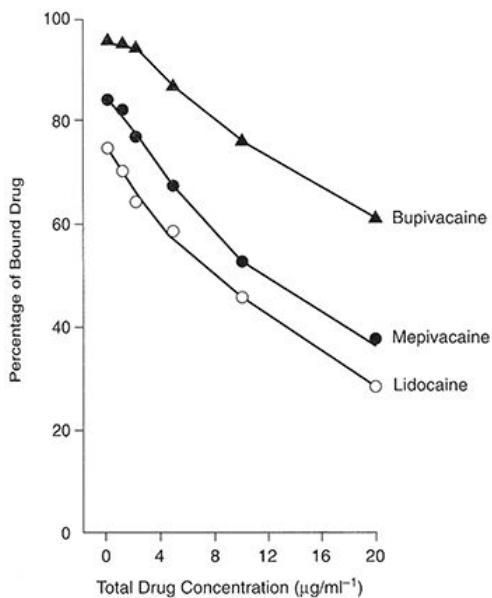

FIGURE 10.6 The percentage of local anesthetic bound to protein is inversely related to the plasma concentration of drug. Reprinted with permission from Tucker GT, Boyes RN, Bridenbaugh PO, et al. Binding of anilide-type local anesthetics in human plasma: I. Relationships between binding, physiochemical properties, and anesthetic activity. *Anesthesiology*. 1970;33(3):287-303. Copyright © 1970 American Society of Anesthesiologists, Inc.

Lung Extraction

The lungs are capable of extracting local anesthetics such as lidocaine, bupivacaine, and prilocaine from the circulation.²⁰ After rapid entry of local anesthetics into the venous circulation, this pulmonary extraction will limit the concentration of drug that reaches the systemic circulation for distribution to the coronary and cerebral circulations. For bupivacaine, this first-pass pulmonary extraction is dose dependent, suggesting that the uptake process becomes saturated rapidly.²¹ Propranolol impairs bupivacaine extraction by the lungs, perhaps reflecting a common receptor site for the two drugs.²² Furthermore, propranolol decreases plasma clearance of lidocaine and bupivacaine, presumably reflecting propranolol-induced decreases in hepatic blood flow or inhibition of hepatic metabolism.²³

Changes During Pregnancy (see also Chapter 45)

Increased sensitivity (more rapid onset of conduction blockade) may be present during pregnancy.²⁴ Alterations in protein-binding characteristics of bupivacaine may result in increased concentrations of pharmacologically active unbound drug in the parturient's plasma.²⁵ Nevertheless, progesterone, which binds to the same α_1 -acid glycoprotein as bupivacaine, does not influence protein binding of this local anesthetic.²⁵ This evidence suggests that bupivacaine and progesterone bind to discrete but separate sites on protein molecules.

Placental Transfer

There may be clinically significant transplacental transfer of local anesthetics between the mother and fetus. Plasma protein binding influences the rate and degree of diffusion of local anesthetics across the placenta (see **Table 10.1**). Bupivacaine, which is highly protein bound (approximately 95%), has an umbilical vein-maternal arterial concentration ratio of about 0.32 compared with a ratio of 0.73 for lidocaine (approximately 70% protein bound) and a ratio of 0.85 for prilocaine (approximately 55% protein bound).²⁶ Ester local anesthetics, because of their rapid hydrolysis, are not available to cross the placenta in significant amounts.

Acidosis in the fetus, which may occur during prolonged labor, can result in accumulation of local anesthetic molecules in the fetus (ion trapping) ([Figure 10.7](#)).²⁷

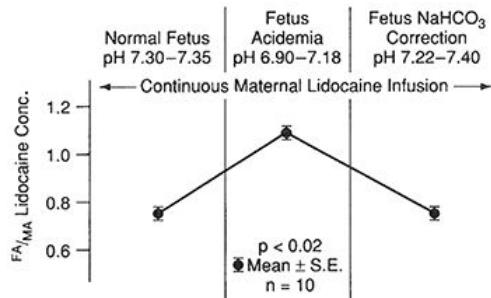

FIGURE 10.7 Fetal-maternal arterial (FA/MA) lidocaine ratios are greater during acidemia compared with a normal pH. *Reprinted with permission from Biehl D, Shnider SM, Levinson G, et al. Placental transfer of lidocaine: effects of fetal acidosis. Anesthesiology. 1978;48(6):409-412. Copyright © 1978 American Society of Anesthesiologists, Inc.*

Renal Elimination and Clearance

The poor water solubility of local anesthetics usually limits renal excretion of unchanged drug to <5%.²⁸ The exception is cocaine, of which 10% to 12% of unchanged drug can be recovered in urine. Water-soluble metabolites of local anesthetics, such as para-aminobenzoic acid resulting from metabolism of ester local anesthetics, are readily excreted in urine. Clearance values and elimination half-times for amide local anesthetics probably represent mainly hepatic metabolism because renal excretion of unchanged drug is minimal (see [Table 10.1](#)). Pharmacokinetic studies of ester local anesthetics are limited because of a short elimination half-time due to their rapid hydrolysis in the plasma by esterases.

Metabolism of Amide Local Anesthetics

Amide local anesthetics undergo varying rates of metabolism by microsomal enzymes located primarily in the liver. Prilocaine undergoes the most rapid metabolism; lidocaine and mepivacaine are intermediate; and etidocaine, bupivacaine, and ropivacaine undergo the slowest metabolism among the amide local anesthetics. The initial step is conversion of the amide base to aminocarboxylic acid and a cyclic aniline derivative. Complete metabolism usually involves additional steps, such as hydroxylation of the aniline moiety and *N*-dealkylation of the aminocarboxylic acid.

Compared with that of ester local anesthetics, the metabolism of amide local anesthetics is more complex and slower. This slower metabolism means that sustained increases of the plasma concentrations of amide local anesthetics, and thus systemic toxicity, are more likely than with ester local anesthetics. Furthermore, cumulative drug effects of amide local anesthetics are more likely than with ester local anesthetics.

Lidocaine

The principal metabolic pathway of lidocaine is oxidative dealkylation in the liver to monoethylglycinexylidide followed by hydrolysis of this metabolite to xylidide. Monoethylglycinexylidide has approximately 80% of the activity of lidocaine for protecting against cardiac dysrhythmias in an animal model. This metabolite has a prolonged elimination half-time, accounting for its efficacy in controlling cardiac dysrhythmias after the infusion of lidocaine is discontinued. Xylidide has only approximately 10% of the cardiac antidysrhythmic activity of lidocaine. In humans, approximately 75% of xylidide is excreted in the urine as 4-hydroxy-2,6-dimethylaniline.

Hepatic disease or decreases in hepatic blood flow, which may occur during anesthesia, can decrease the rate of metabolism of lidocaine. For example, the elimination half-time of lidocaine is increased more than fivefold in patients with liver dysfunction compared with normal patients. Decreased hepatic metabolism of

lidocaine should be anticipated when patients are anesthetized with volatile anesthetics. Maternal clearance of lidocaine is prolonged in the presence of pregnancy-induced hypertension, and repeated administration of lidocaine can result in higher plasma concentrations than in normotensive parturients.²⁹ Lidocaine has intrinsic vasodilator property.³⁰

Prilocaine

Prilocaine is an amide local anesthetic that is metabolized to ortho-toluidine. Ortho-toluidine is an oxidizing compound capable of converting hemoglobin to its oxidized form, methemoglobin, resulting in a potentially life-threatening complication, methemoglobinemia (see “[Methemoglobinemia](#)” section). When the dose of prilocaine is >600 mg, there may be sufficient methemoglobin present (3-5 g/dL) to cause the patient to appear cyanotic, and oxygen-carrying capacity is decreased. Methemoglobinemia is readily reversed by the administration of methylene blue, 1 to 2 mg/kg intravenously (IV), over 5 minutes (total dose should not exceed 7-8 mg/kg). The ability of prilocaine to cause dose-related methemoglobinemia limits its clinical usefulness, with the exception of IV regional anesthesia. Prilocaine causes less vasodilation than other local anesthetics and thus can be used without epinephrine added to the local anesthetic solution.

Mepivacaine

Mepivacaine has pharmacologic properties similar to those of lidocaine, although the duration of action of mepivacaine is somewhat longer. Clearance of mepivacaine is decreased in neonates, leading to a prolonged elimination half-time. In contrast to lidocaine, mepivacaine has limited vasodilator activity. As such, mepivacaine is an alternate selection when addition of epinephrine to the local anesthetic solution is not recommended.

Bupivacaine

Possible pathways for metabolism of bupivacaine include aromatic hydroxylation, *N*-dealkylation, amide hydrolysis, and conjugation.³¹ Only the *N*-dealkylated metabolite *N*-desbutylbupivacaine, has been measured in blood or urine after epidural or spinal anesthesia. The mean total urinary excretion of bupivacaine and its dealkylation and hydroxylation metabolites account for >40% of the total anesthetic dose.³¹ α_1 -Acid glycoprotein is the most important plasma protein binding site of bupivacaine, and its concentration is increased in many clinical situations, including postoperative trauma.³²

Ropivacaine

Ropivacaine is metabolized to 2,6-pipercoloxylidide and 3-hydroxyropivacaine by hepatic cytochrome P-450 enzymes. Both metabolites have significantly less local anesthetic potency than ropivacaine. Because only a very small fraction of ropivacaine is excreted unchanged in the urine (about 1%) when the liver is functioning normally, dosage adjustments based on renal function do not seem necessary. However, in uremic patients, 2,6-pipercoloxylidide may accumulate and produce toxic effects.³³ Overall, clearance of ropivacaine is higher than that determined for bupivacaine, and its elimination half-time is shorter.⁵ The higher clearance of ropivacaine may offer an advantage over bupivacaine in terms of systemic toxicity. The lipid solubility of ropivacaine is intermediate between lidocaine and bupivacaine. Ropivacaine is highly bound to α_1 -acid glycoprotein.

Dibucaine

Dibucaine is a quinoline derivative with an amide bond in the connecting hydrocarbon chain. This local anesthetic is metabolized in the liver and is the most slowly eliminated of all the amide derivatives. Interestingly, dibucaine inhibits pseudocholinesterase and is used to differentiate individuals who have substitution mutations of the plasma cholinesterase enzyme.³⁴ The dibucaine number is the percentage of plasma cholinesterase enzyme inhibited by dibucaine. A normal enzyme will be 80% inhibited by dibucaine, whereas an abnormal enzyme will be 20% inhibited.³⁵

Metabolism of Ester Local Anesthetics

Ester local anesthetics undergo hydrolysis by cholinesterase enzyme, principally in the plasma and to a lesser extent in the liver. The rate of hydrolysis varies, with chloroprocaine being most rapid, procaine being intermediate, and tetracaine being the slowest. The resulting metabolites are pharmacologically inactive, although para-aminobenzoic acid may be an antigen responsible for subsequent allergic reactions. The exception to hydrolysis of ester local anesthetics in the plasma is cocaine, which undergoes significant metabolism in the liver.

Systemic toxicity is inversely proportional to the rate of hydrolysis; thus, tetracaine is more likely than chloroprocaine to result in excessive plasma concentrations. Because cerebrospinal fluid contains little to no cholinesterase enzyme, anesthesia produced by subarachnoid placement of tetracaine will persist until the drug has been absorbed into the systemic circulation. Plasma cholinesterase activity and the hydrolysis rate of ester local anesthetics are slowed in the presence of liver disease or an increased blood urea nitrogen concentration. Plasma cholinesterase activity may be decreased in parturients and in patients being treated with certain chemotherapeutic drugs. Patients with atypical plasma cholinesterase may be at increased risk for developing excess systemic concentrations of an ester local anesthetic due to absent or limited plasma hydrolysis.

Procaine

Procaine is hydrolyzed to para-aminobenzoic acid, which is excreted unchanged in urine, and to diethylaminoethanol, which is further metabolized because only 30% is recovered in urine. Overall, <50% of procaine is excreted unchanged in urine. Increased plasma concentrations of para-aminobenzoic acid do not produce symptoms of systemic toxicity.

Chloroprocaine

Addition of a chlorine atom to the benzene ring of procaine to form chloroprocaine increases by 3.5 times the rate of hydrolysis of the local anesthetic by plasma cholinesterase, as compared with procaine. Resulting pharmacologically inactive metabolites of chloroprocaine are 2-chloro-aminobenzoic acid and 2-diethylaminoethanol. Maternal and neonatal plasma cholinesterase activity may be decreased up to 40% at term, but minimal placental passage of chloroprocaine confirms that even this decreased activity is adequate to hydrolyze most of the chloroprocaine that is absorbed from the maternal epidural space.^{36,37}

Tetracaine

Tetracaine undergoes hydrolysis by plasma cholinesterase, but the rate is slower than for procaine.

Benzocaine

Benzocaine (ethyl aminobenzoate) is unique among clinically useful local anesthetics because it is a weak acid (pK_a 3.5) so that it exists only in the nonionized form at physiologic pH. As such, benzocaine is ideally suited for topical anesthesia of mucous membranes prior to tracheal intubation, endoscopy, transesophageal echocardiography, and bronchoscopy. Onset of topical anesthesia is rapid and lasts 30 to 60 minutes. A brief spray of 20% benzocaine delivers the recommended dose of 200 to 300 mg. Systemic absorption of topical benzocaine is enhanced by defects in the skin and mucosa as well as from the gastrointestinal tract should any of the local anesthetic be swallowed. Cetacaine is a combination of 14% benzocaine, 2% tetracaine, and 2% butamben. Methemoglobinemia is a rare but potentially life-threatening complication following topical application of benzocaine, especially when the dose exceeds 200 to 300 mg (see “[Methemoglobinemia](#)” section).

Cocaine

Cocaine is metabolized by plasma and liver cholinesterases to water-soluble metabolites that are excreted in urine. Plasma cholinesterase activity is decreased in parturients, neonates, the elderly, and patients with severe underlying hepatic disease. Cocaine may be present in urine for 24 to 36 hours, depending on the route

of administration and cholinesterase activity. Assays for the metabolites of cocaine in urine are useful markers of cocaine use or absorption (see “[Cocaine Toxicity](#)” section).

Alkalization of Local Anesthetic Solutions

Alkalization of local anesthetic solutions shortens the onset of neural blockade, enhances the depth of sensory and motor blockade, and increases the spread of epidural blockade.³⁸ The pH of commercial preparations of local anesthetic solutions ranges from 3.9 to 6.5 and is especially acidic if prepackaged with epinephrine (increased acidity prolongs the shelf life of epinephrine). The pKa of local anesthetics used clinically is near 8 so that only a small fraction (about 3%) of the local anesthetic exists in the lipid-soluble form. Alkalization increases the percentage of local anesthetic existing in the lipid-soluble form that is available to diffuse across lipid cellular barriers. Adding sodium bicarbonate will speed the onset of peripheral nerve block and epidural block by 3 to 5 minutes.

Adjvant Mixed With Local Anesthetics

Dexmedetomidine has been used as an adjvant in local anesthetic admixtures, and the central effect is postulated for prolongation of the local anesthetic affect. The IV dexmedetomidine, in a recent systematic review and meta-analysis, showed increased duration of motor and sensory block after spinal anesthesia and time to first analgesic request was increased.³⁹ Magnesium has also shown promising initial results when introduced in intrathecal space as an addition to local anesthetic with or without opioids. Duration of spinal anesthesia was increased in magnesium group.⁴⁰ In pediatric patients, addition of clonidine and ketamine to the locoregional anesthesia showed good pharmacokinetic and pharmacodynamic profiles of efficacy and safety, improving and prolonging the action of associated local anesthetics.⁴¹

Combinations of Local Anesthetics

Local anesthetics may be combined in an effort to produce a rapid onset (chloroprocaine) and prolonged duration (bupivacaine) of action. Nevertheless, placement of chloroprocaine in the epidural space may decrease the efficacy of subsequent epidural bupivacaine-induced analgesia during labor. It is speculated that the low pH of the chloroprocaine solution could decrease the nonionized pharmacologically active fraction of bupivacaine.⁴² Tachyphylaxis to the local anesthetic mixture could also reflect local acidosis due to the low pH of the bathing solution. For these reasons, adjustment of the pH of the chloroprocaine solution with the addition of 1 mL of 8.4% sodium bicarbonate added to 30 mL of chloroprocaine solution just before placement into the epidural space may improve the efficacy of the chloroprocaine-bupivacaine combination.⁴³ Local anesthetic toxicity of combinations of drugs is additive rather than synergistic.⁴⁴

Use of Vasoconstrictors

The duration of action of a local anesthetic is proportional to the time the drug is in contact with nerve fibers. For this reason, epinephrine (1:200,000 or 5 µg/mL) may be added to local anesthetic solutions to produce vasoconstriction, which limits systemic absorption and maintains the drug concentration in the vicinity of the nerve fibers to be anesthetized. Indeed, addition of epinephrine to a lidocaine or mepivacaine solution prolongs the duration of conduction blockade and decreases systemic absorption of local anesthetics by 20% to 30% ([Figure 10.8](#)).^{45,46} For bupivacaine, addition of epinephrine also increases the duration of conduction blockade but to a lesser degree, and the reduction in systemic absorption is by 10% to 20%. Most local anesthetics, with the exception of ropivacaine, possess intrinsic vasodilator properties, and it is possible that epinephrine-induced vasoconstriction will slow clearance from the injection site, thus prolonging the time the drug is in contact with nerve fibers.

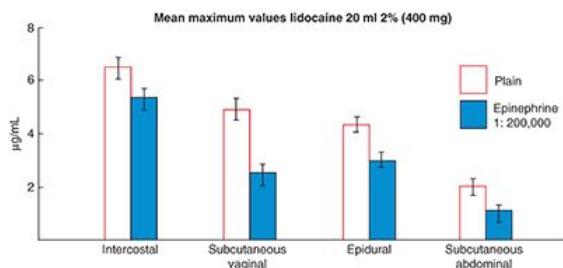

FIGURE 10.8 Addition of epinephrine to the solution containing lidocaine or prilocaine decreases systemic absorption of the local anesthetic by about one-third. *Reprinted from Scott DB, Jebson PJ, Braid DP, et al. Factors affecting plasma levels of lignocaine and prilocaine. Br J Anaesth. 1972;44(10):1040-1049.* Copyright © 1972 Elsevier. With permission.

The impact of adding epinephrine to the local anesthetic solution is influenced by the specific local anesthetic selected and the level of sensory blockade required if a spinal or epidural anesthetic is chosen. For example, the impact of epinephrine in prolonging the duration of conduction blockade and decreasing systemic absorption of bupivacaine and etidocaine is less than that observed with lidocaine, presumably because the greater lipid solubility of bupivacaine and etidocaine causes them to bind avidly to tissues. The duration of sensory anesthesia in the lower extremities, but not the abdominal region, is extended when epinephrine (0.2 mg) or phenylephrine (2 mg) is added to local anesthetic solutions of bupivacaine or lidocaine placed into the subarachnoid space. Vasoconstrictors prolong the effect of tetracaine for spinal anesthesia. Epinephrine added to a low dose of tetracaine (6 mg) increases the success rate of spinal anesthesia, whereas the success rate is not altered by epinephrine when the subarachnoid dose of tetracaine is 10 mg.⁴⁷ In addition to decreasing systemic absorption to prolong conduction blockade, epinephrine may also enhance conduction blockade by increasing neuronal uptake of the local anesthetic. The α -adrenergic effects of epinephrine may be associated with some degree of analgesia that could contribute to the effects of the conduction blockade. The addition of epinephrine to local anesthetic solutions has little, if any, effect on the onset rate of local anesthesia.

Decreased systemic absorption of local anesthetic due to vasoconstriction produced by epinephrine increases the likelihood that the rate of metabolism will match that of absorption, thus decreasing the possibility of systemic toxicity. Systemic absorption of epinephrine may accentuate systemic hypertension in vulnerable patients.

Adverse Effects of Local Anesthetics

The principal side effects related to the use of local anesthetics are allergic reactions and systemic toxicity due to excessive plasma and tissue concentrations of the local anesthetic. Systemic toxicity in association with regional anesthesia is estimated to result in seizures in 1 to 4 per 1,000 patient exposures to local anesthetics, with bupivacaine being the drug most likely to be associated with this adverse response.⁴⁸ In orthopedic patients receiving peripheral nerve blocks, 0.18% of patients suffered local anesthetic systemic toxicity (LAST) or surrogate outcomes including cardiac arrest, seizures, and use of lipid emulsion on the day of surgery.⁴⁹

Allergic Reactions

Allergic reactions to local anesthetics are rare despite the frequent use of these drugs. It is estimated that less than 1% of all adverse reactions to local anesthetics are due to an allergic mechanism.⁵⁰ Instead, the overwhelming majority of adverse responses that are often attributed to an allergic reaction are instead manifestations of excess plasma concentrations of the local anesthetic.

Esters of local anesthetics that produce metabolites related to para-aminobenzoic acid are more likely than amide local anesthetics, which are not metabolized to para-aminobenzoic acid, to evoke an allergic reaction. An allergic reaction after the use of a local anesthetic may be due to methylparaben or similar substances used as preservatives in commercial preparations of ester and amide local anesthetics. These

preservatives are structurally similar to para-aminobenzoic acid. As a result, an allergic reaction may reflect prior stimulation of antibody production by the preservative and not a reaction to the local anesthetic.

Cross-Sensitivity

Cross-sensitivity between local anesthetics reflects the common metabolite para-aminobenzoic acid. A similar cross-sensitivity, however, does not exist between classes of local anesthetics. Therefore, a patient with a known allergy to an ester local anesthetic can receive an amide local anesthetic without an increased risk of an allergic reaction. Likewise, an ester local anesthetic can be administered to a patient with a known allergy to an amide local anesthetic. It is important that the “safe” local anesthetic be preservative free.

Documentation of Allergy

Documentation of allergy to a local anesthetic is based on the clinical history and perhaps the use of intradermal testing. The occurrence of rash, urticaria, and laryngeal edema, with or without hypotension and bronchospasm, is highly suggestive of a local anesthetic-induced allergic reaction. Conversely, hypotension associated with syncope or tachycardia when an epinephrine-containing local anesthetic solution is administered suggests an accidental intravascular injection of drug. Use of an intradermal test requires injection of preservative-free preparations of local anesthetic solutions to eliminate the possibility that the allergic reaction was caused by a substance other than the local anesthetic.

Local Anesthetic Systemic Toxicity

The LAST is due to an excess plasma concentration of the drug. Plasma concentrations of local anesthetics are determined by the rate of drug entrance into the systemic circulation relative to their redistribution to inactive tissue sites and clearance by metabolism. Accidental direct intravascular injection of local anesthetic solutions during performance of peripheral nerve block anesthesia or epidural anesthesia is the most common mechanism for production of excess plasma concentrations of local anesthetics. A variety of factors influence the likelihood and severity of LAST, including individual patient risk factors, concurrent medications, location and technique of block, specific local anesthetic compound, total local anesthetic dose (the product of concentration and volume), timeliness of detection, and adequacy of treatment.⁵¹ The magnitude of this systemic absorption depends on the (1) dose administered into the tissues, (2) vascularity of the injection site, (3) presence of epinephrine in the solution, and (4) physicochemical properties of the drug (see [Table 10.1](#)). For example, systemic absorption of local anesthetics is greatest after injection for an intercostal nerve block, intermediate for epidural anesthesia, and least for a brachial plexus block.⁵² Addition of 5 µg of epinephrine to every milliliter of local anesthetic solution (1:200,000 dilution) decreases systemic absorption of local anesthetics by approximately one-third (see “[Use of Vasoconstrictors](#)”).⁴⁶ Systemic toxicity of local anesthetics involves the CNS and cardiovascular system.

Local anesthetics differ with regard to their CNS toxicity and cardiac toxicity. The cardiovascular system/CNS ratio describes the dose required to produce cardiovascular arrhythmias versus that required to produce seizures.⁵³ If the ratio is lower, it implies a reduced safety margin for the local anesthetic compounds compared to the compound with higher ratio to detect impending cardiotoxicity based on premonitory CNS signs. Bupivacaine is a more potent local anesthetic and generates arrhythmias at lower concentrations compared with lidocaine and mepivacaine. Also in animal studies (dogs), at comparable dosages, bupivacaine and etidocaine caused severe arrhythmias without decreased contractility, whereas lidocaine caused the opposite, that is, depressed myocardial contractility without arrhythmia.⁵⁴

Central Nervous System Effects

Low plasma concentrations of local anesthetics are likely to produce numbness of the tongue and circumoral tissues, presumably reflecting delivery of drug to these highly vascular tissues ([Table 10.2](#)). As the plasma concentrations continue to increase, local anesthetics readily cross the blood–brain barrier and produce a predictable pattern of CNS changes. Restlessness, vertigo, tinnitus, and difficulty in focusing occur initially. Further increases in the CNS concentration of local anesthetic result in slurred speech and skeletal muscle twitching. Skeletal muscle twitching is often first evident in the face and extremities and signals the

imminence of tonic-clonic seizures. Vivid fear of imminent death and a delusional belief of having died have been described in patients experiencing toxic reactions to local anesthetics administered for regional anesthesia and pain relief.⁵⁵

TABLE 10.2

Dose-dependent effects of lidocaine

Plasma lidocaine concentration ($\mu\text{g}/\text{mL}$)	Effect
1-5	Analgesia
5-10	Circumoral numbness Tinnitus Skeletal muscle twitching Systemic hypotension Myocardial depression
10-15	Seizures Unconsciousness
15-25	Apnea Coma
>25	Cardiovascular depression

Lidocaine and other amide local anesthetics may cause drowsiness before the onset of seizures. Seizures are classically followed by CNS depression, which may be accompanied by hypotension and apnea. The onset of seizures may reflect selective depression of inhibitory cortical neurons by local anesthetics, leaving excitatory pathways unopposed. An alternative explanation for seizures is local anesthetic-induced inhibition of the release of neurotransmitters, particularly γ -aminobutyric acid. The precise site of local anesthetic-induced seizures is not known, although it appears to be in the temporal lobe or the amygdala.

Plasma concentrations of local anesthetics producing signs of CNS toxicity depend on the specific drug involved. Lidocaine, mepivacaine, and prilocaine demonstrate effects on the CNS at plasma concentrations of 5 to 10 $\mu\text{g}/\text{mL}$. The typical plasma concentration of bupivacaine associated with seizures is 4.5 to 5.5 $\mu\text{g}/\text{mL}$.^{52,56} Ropivacaine and bupivacaine produce convulsions in awake animals at similar doses.⁵ The threshold plasma concentration at which CNS toxicity occurs may be related more to the rate of increase of the serum concentration than to the total amount of drug injected.²⁸

The active metabolites of lidocaine, including monoethylglycinexylidide, may exert an additive effect in causing systemic toxicity after epidural administration of lidocaine. For this reason, it has been recommended that the plasma venous concentration of lidocaine be monitored when the cumulative epidural dose of lidocaine is >900 mg.⁵⁷ The seizure threshold for lidocaine may be related to CNS levels of serotonin (5-hydroxytryptophan). For example, accumulation of serotonin decreases the seizure threshold of lidocaine and prolongs the duration of seizure activity.

There is an inverse relationship between the Paco_2 and seizure thresholds of local anesthetics, presumably reflecting variations in cerebral blood flow and resultant delivery of drugs to the brain. Increases in the serum potassium concentration can facilitate depolarization and thus markedly increase local anesthetic toxicity. Conversely, hypokalemia, by creating hyperpolarization, can greatly decrease local anesthetic toxicity. The threshold for neurotoxicity of lidocaine may be decreased when patients being treated with the antidysrhythmic drug mexiletine receive lidocaine during the perioperative period,⁵⁸ presumably by displacement of lidocaine from tissue binding sites.⁵⁹

Cardiovascular System Effects

The cardiovascular system is more resistant to the toxic effects of high plasma concentrations of local anesthetics than is the CNS. For example, lidocaine in plasma concentrations of <5 $\mu\text{g}/\text{mL}$ is devoid of adverse cardiac effects, producing only a decrease in the rate of spontaneous phase 4 depolarization (automaticity). Nevertheless, plasma lidocaine concentrations of 5 to 10 $\mu\text{g}/\text{mL}$, and equivalent plasma

concentrations of other local anesthetics, may produce profound hypotension due to relaxation of arteriolar vascular smooth muscle and direct myocardial depression (see [Table 10.2](#)). As a result, hypotension reflects both decreased systemic vascular resistance and cardiac output.

Part of the cardiac toxicity that results from high plasma concentrations of local anesthetics occurs because these drugs also block cardiac sodium channels. At low concentrations of local anesthetics, this effect on sodium channels probably contributes to cardiac antidysrhythmic properties of these drugs. However, when the plasma concentrations of local anesthetics are excessive, sufficient cardiac sodium channels become blocked so that conduction and automaticity become adversely depressed. For example, excessive plasma concentrations of lidocaine may slow conduction of cardiac impulses through the heart, manifesting as prolongation of the P-R interval and QRS complex on the electrocardiogram. Effects of local anesthetics on calcium ion and potassium ion channels and local anesthetic-induced inhibition of cyclic adenosine monophosphate production may also contribute to cardiac toxicity.⁶⁰

Selective Cardiac Toxicity

Accidental IV injection of bupivacaine may result in precipitous hypotension, cardiac dysrhythmias, and atrioventricular heart block.⁶¹ After accidental IV injection, the protein-binding sites (α_1 -acid glycoprotein and albumin) for bupivacaine are quickly saturated, leaving a significant mass of unbound drug available for diffusion into the conducting tissue of the heart. The IV injection of bupivacaine or lidocaine to awake animals produces serious cardiac dysrhythmias only in animals receiving bupivacaine. Premature ventricular contractions, wide QRS complexes, and ventricular tachycardia are most common arrhythmias seen, although other arrhythmias like supraventricular tachycardia, atrioventricular heart block, and ST-T wave changes can also occur but at lesser rate.⁶² Cardiotoxic plasma concentrations of bupivacaine are 8 to 10 $\mu\text{g}/\text{mL}$.⁶³

Physiologic changes and concomitant drug therapy may make patients more vulnerable to bupivacaine cardiac toxicity. For example, pregnancy may increase sensitivity to cardiotoxic effects of bupivacaine, but not ropivacaine, as emphasized by occurrence of cardiopulmonary collapse with a smaller dose of bupivacaine in pregnant compared with nonpregnant animals ([Figure 10.9](#)).^{5,64} The threshold for cardiac toxicity produced by bupivacaine may be decreased in patients being treated with drugs that inhibit myocardial impulse propagation (β -adrenergic blockers, digitalis preparations, calcium channel blockers).⁶⁵ Indeed, in the presence of propranolol, atrioventricular heart block and cardiac dysrhythmias occurred at plasma bupivacaine concentrations of 2 to 3 $\mu\text{g}/\text{mL}$.⁶³ This suggests that caution must be taken in the use of bupivacaine in patients who are on antidysrhythmic drugs or other cardiac medications known to depress impulse propagation. Inhibition of basal and epinephrine-stimulated cyclic adenosine monophosphate production by bupivacaine may limit the success of resuscitative measures using epinephrine administered for bupivacaine cardiovascular toxicity.⁶⁶ The cardiac toxicity of bupivacaine in animals is enhanced by arterial hypoxemia, acidosis, or hypercarbia.

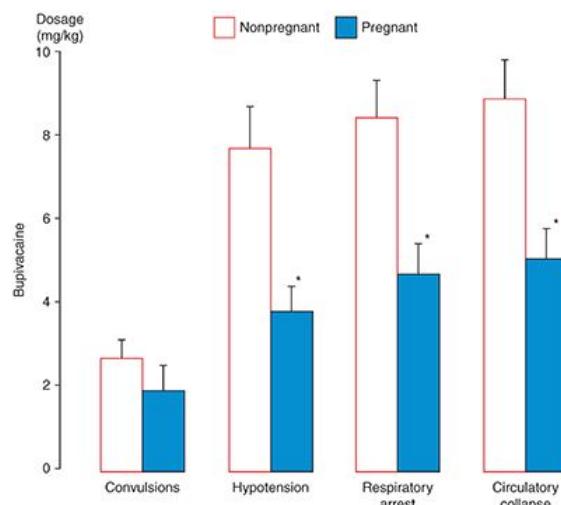

FIGURE 10.9 The dose of bupivacaine required to evoke toxic effects is less in pregnant than in nonpregnant ewes (mean \pm standard error; $*P < .05$). Reprinted with permission from Morishima HO, Pedersen H, Finster M, et al. Bupivacaine toxicity in pregnant and nonpregnant ewes. *Anesthesiology*. 1985;63(2):134-139. Copyright © 1985 American Society of Anesthesiologists, Inc.

All local anesthetics depress the maximal depolarization rate of the cardiac action potential (V_{max}) by virtue of their ability to inhibit sodium ion influx via sodium channels. In isolated papillary muscle preparations, bupivacaine depresses V_{max} considerably more than lidocaine, whereas ropivacaine is intermediate in its depressant effect on V_{max} (Figure 10.10).^{5,67} The resulting slowed conduction of the cardiac action potential manifests on the electrocardiogram as prolongation of the P-R and QRS intervals and reentry ventricular cardiac dysrhythmias. Both bupivacaine and lidocaine block cardiac sodium ion channels during systole, whereas during diastole, highly lipid soluble bupivacaine dissociates off these channels at a slow rate compared with lidocaine, thus accounting for the drug's persistent depressant effect on V_{max} and subsequent cardiac toxicity.⁶⁸ At normal heart rates, diastolic time is sufficiently long for lidocaine dissociation, but bupivacaine block intensifies and depresses electrical conduction, causing reentrant-type ventricular dysrhythmias. Less lipid-soluble lidocaine dissociates rapidly from cardiac sodium channels and cardiac toxicity is low. Furthermore, high plasma concentrations of bupivacaine may cause ventricular cardiac dysrhythmias through a direct brainstem effect. The R enantiomer of bupivacaine is more toxic than the S enantiomer. For example, seizure activity following an interscalene block with levobupivacaine was not associated with cardiac dysrhythmias or other signs of cardiovascular toxicity.⁶⁹ In animals, levobupivacaine compared with bupivacaine was associated with a lower incidence of ventricular cardiac dysrhythmias, and successful resuscitation was more likely in the presence of levobupivacaine.^{70,71} Ropivacaine is a pure S enantiomer that is less lipid soluble and less cardiotoxic than bupivacaine but more cardiotoxic than lidocaine.^{2,72} Although ropivacaine-induced cardiac arrest has been described following peripheral nerve block anesthesia, in contrast to bupivacaine, cardiac resuscitation is more likely to be successful.⁷³⁻⁷⁵

Tachycardia can enhance frequency-dependent blockade of cardiac sodium channels by bupivacaine, further contributing to the selective cardiac toxicity of this local anesthetic.⁷⁶ Conversely, a low degree of frequency-dependent blockade may contribute to the antidysrhythmic properties of lidocaine. In anesthetized dogs, bretylium, 20 mg/kg IV, reverses bupivacaine-induced cardiac depression and increases the threshold for ventricular tachycardia.⁷⁷ In an effort to decrease the potential for cardiotoxicity should accidental intravascular injection occur, it may be prudent to limit the concentration of bupivacaine to be used for epidural anesthesia to 0.5%. In addition, slow or fractionated administration of all local anesthetics, but

particularly bupivacaine, to detect systemic toxicity from accidental intravascular injection, should help decrease the risk of cardiotoxicity.⁷⁸

Treatment of Local Anesthetic Systemic Toxicity

Treatment of LAST has undergone swift changes in last decade and includes prompt airway management, circulatory support, and mechanisms to remove local anesthetic from the receptor sites. Treatment should be instituted at earliest suspicion of toxicity. Treatment of local anesthetic-induced seizures includes ventilation of the patient's lungs with oxygen because arterial hypoxemia and metabolic acidosis occur within seconds.⁷⁹ The IV administration of a benzodiazepine such as midazolam or diazepam is effective in suppressing local anesthetic-induced seizures. Propofol can be used for seizures treatment if hemodynamic stability is confirmed. For persistent seizures patient should be paralyzed using succinylcholine or nondepolarizing blockers, to prevent prevent acidosis and hypoxia. Early use of lipid emulsion for the treatment of local anesthetic toxicity is becoming standard of care. Multiple published cases have shown that intralipid can be successfully used for resuscitation; the mean total (bolus plus infusion) intralipid dose over the first 30 minutes was 3.8 mL/kg (range, 1.2–6.0 mL/kg). American Society of Regional Anesthesia and Pain Medicine has published specific recommendations and a checklist for treatment of LAST (**Figure 10.11**).^{51,80,81} Use of lipid emulsion is recommended at earliest sign of toxicity after airway management. An initial bolus of 1.5 mL/kg 20% lipid emulsion followed by 0.25 mL/kg per minute of infusion continued for at least 10 minutes after circulatory stability is attained is recommended. Epinephrine should be used at lower dose, 10 to 100 µg, and vasopressin use is not recommended. Calcium channel blockers and β blockers should be avoided. Nonresponse to treatment should prompt institution of cardiopulmonary bypass.

- A. If signs and symptoms of LAST occur, prompt and effective airway management is crucial to preventing hypoxia and acidosis, which are known to potentiate LAST.
- B. If seizures occur, they should be rapidly halted with benzodiazepines. If benzodiazepines are not readily available, small doses of propofol or thiopental are acceptable.
- C. Although propofol can stop seizures, large doses further depress cardiac function; propofol should be avoided when there are signs of CV compromise. If seizures persist despite benzodiazepines, small doses of succinylcholine or similar neuromuscular blocker should be considered to minimize acidosis and hypoxemia.
- D. If cardiac arrest occurs, we recommend standard Advanced Cardiac Life Support with the following modifications:
 - If epinephrine is used, small initial doses (10–100 µg boluses in the adult) are preferred.
 - Vasopressin is not recommended.
 - Avoid calcium channel blockers and β-adrenergic receptor blockers.
 - If ventricular arrhythmias develop, amiodarone is preferred.
- E. Lipid emulsion therapy
 - Consider administering at the first signs of LAST, after airway management.
 - Dosing:
 - 1.5 mL/kg 20% lipid emulsion bolus
 - 0.25 mL/kg per minute of infusion, continued for at least 10 minutes after circulatory stability is attained
 - If circulatory stability is not attained, consider rebolus and increasing infusion to 0.5 mL/kg per minute.
 - Approximately 10 mL/kg lipid emulsion for 30 minutes is recommended as the upper limit for initial dosing
- F. Propofol is not a substitute for lipid emulsion.
- G. Failure to respond to lipid emulsion and vasopressor therapy should prompt institution of cardiopulmonary bypass (CPB). Because there can be considerable lag in beginning CPB, it is reasonable to notify the closest facility capable of providing it when CV compromise is first identified during an episode of LAST.

FIGURE 10.11 American Society of Regional Anesthesia and Pain Medicine recommendations for managing local anesthetic systemic toxicity (LAST). CV, cardiovascular. *From Neal JM, Bernards CM, Butterworth JF IV, et al. ASRA practice advisory on local anesthetic systemic toxicity. Reg Anesth Pain Med. 2010;35:152–161.*

Neural Tissue Toxicity (Neurotoxicity)

Neurotoxicity from placement of local anesthetic-containing solutions into the epidural or subarachnoid space can lead various complications. The spectrum of this neurotoxicity may range from patchy groin numbness and persistent isolated myotomal weakness to cauda equina syndrome.⁸² Myofascial pain may be erroneously diagnosed as transient neurologic symptoms after intrathecal placement of local anesthetics.⁸³ Overall,

permanent neurologic injury after regional anesthesia remains a very rare event.^{84,85} Lidocaine-induced increases in intracellular calcium ion concentrations may be the mechanism for this toxicity.⁸⁶

Transient Neurologic Symptoms

Transient neurologic symptoms manifest as moderate to severe pain in the lower back, buttocks, and posterior thighs that appears within 6 to 36 hours after complete recovery from uneventful single-shot spinal anesthesia.⁸⁷ The etiology of transient neurologic symptoms is not known, but relief of pain with trigger point injections and nonsteroidal antiinflammatory drugs suggests a musculoskeletal component. In transient neurologic symptoms, the sensory and motor neurologic examination is not abnormal and full recovery from symptoms usually occurs within 1 to 7 days.

The incidence of transient neurologic symptoms is greatest following the intrathecal injection of lidocaine (as high as 30%).⁸⁸ Initial reports of transient neurologic symptoms involved spinal anesthesia produced by hyperbaric 5% lidocaine, suggesting that the observed neurotoxicity might be, at least in part, concentration dependent. Nevertheless, the incidence of transient neurologic symptoms is similar after intrathecal placement of 1 mg/kg of either 5% or 2% lidocaine in 7.5% glucose.^{89,90} For ambulatory patients undergoing arthroscopy, the incidence of transient neurologic symptoms is not altered by decreasing spinal lidocaine concentrations from 2% to 1% or 0.5% and are similar to the incidence of symptoms described with 5% lidocaine.⁹¹ The risk of transient neurologic symptoms associated with bupivacaine, tetracaine, mepivacaine, prilocaine, or procaine is significantly less than with lidocaine.⁹² In a recent Cochrane review, spinal anesthesia with lidocaine was associated with significantly higher incidence of transient neurologic symptoms when compared to bupivacaine, prilocaine, or procaine.⁹³

Lithotomy position,⁹⁴ early ambulation,⁹⁵ the glucose concentration, and osmolarity of the anesthetic solution do not influence the incidence of transient neurologic symptoms.⁹⁴ Vasoconstrictors can decrease blood supply to the nerve, and there is evidence that adding phenylephrine to the local anesthetic solution increases the incidence of transient neurologic symptoms after spinal anesthesia with tetracaine.⁹⁴ There are some clinical data suggesting that addition of epinephrine to local anesthetic solutions does not alter the incidence of transient neurologic symptoms.⁹⁶

Cauda Equina Syndrome

Cauda equina syndrome occurs when diffuse injury across the lumbosacral plexus produces varying degrees of sensory anesthesia, bowel and bladder sphincter dysfunction, and paraplegia. Cauda equina syndrome is most frequently associated with large central lumbar disc herniation, prolapse, or sequestration with 50% to 60% patients having urinary retention on presentation.⁹⁷ In the regional anesthesia literature, initial reports of cauda equina syndrome were associated with the use of hyperbaric 5% lidocaine for continuous spinal anesthesia.^{98,99} In these cases, it was postulated that microcatheters used during continuous spinal anesthesia (28 gauge or smaller) contributed to nonhomogeneous distribution of the local anesthetic solution, with pooling of high concentrations of the local anesthetic solution on certain dependent or stretched (lithotomy position) nerves. Nevertheless, this same complication has also been reported after intrathecal injection of 100 mg of 5% lidocaine through a 25-gauge needle.¹⁰⁰

Anterior Spinal Artery Syndrome

Anterior spinal artery syndrome consists of lower extremity paresis with a variable sensory deficit that is usually diagnosed as the neuraxial blockade fails to resolve. The etiology of this syndrome is uncertain, although thrombosis or spasm of the anterior spinal artery is possible as well as effects of hypotension or vasoconstrictor drugs. Although the addition of epinephrine to local anesthetic solutions has been implicated as a theoretical cause, spinal cord perfusion studies do not show a deleterious effect of the catecholamine.¹⁰¹ Advanced age and the presence of peripheral vascular disease may predispose patients to development of anterior spinal artery syndrome. It may be difficult to distinguish symptoms due to anterior spinal artery syndrome from those caused by spinal cord compression produced by an epidural abscess or hematoma.

Methemoglobinemia

Methemoglobinemia is a rare but potentially life-threatening complication (decreased oxygen-carrying capacity) that may follow the administration of certain drugs or chemicals that cause oxidation of hemoglobin to methemoglobin more rapidly than methemoglobin is reduced to hemoglobin. Known oxidant substances include topical local anesthetics (prilocaine, benzocaine, cetacaine, lidocaine), nitroglycerin, phenytoin, and sulfonamides.¹⁰² Neonates may be at greater risk because of more readily oxidized fetal hemoglobin.

Methemoglobin cannot bind oxygen or carbon dioxide, resulting in loss of the hemoglobin molecule's transport function. Methemoglobin normally constitutes <1% of the total hemoglobin. Central cyanosis usually occurs when methemoglobin concentrations exceed 15%. The presence of methemoglobinemia is suggested by a difference between the calculated and measured arterial oxygen saturation. The diagnosis is confirmed by qualitative measurements of methemoglobin by co-oximetry.

Methemoglobinemia is readily reversed by the administration of methylene blue, 1 to 2 mg/kg IV, over 5 minutes (total dose should not exceed 7-8 mg/kg). Methylene blue is reduced to leukomethylene blue, which then acts as an electron donor and nonenzymatically reduces methemoglobin to hemoglobin. Normal levels of methemoglobin should be achieved within 20 to 60 minutes after the administration of methylene blue. This therapeutic effect, however, is short lived because methylene blue may be cleared before conversion of all the methemoglobin to hemoglobin. Furthermore, continued absorption of highly lipophilic local anesthetics such as benzocaine from adipose tissue stores may continue to occur after methylene blue plasma concentrations are no longer therapeutic.

Ventilatory Response to Hypoxia

Lidocaine at clinically useful plasma concentrations depresses the ventilatory responses to arterial hypoxemia.¹⁰³ In this regard, patients with carbon dioxide retention whose resting ventilation depends on hypoxic drive may be at risk of ventilatory failure when lidocaine is administered for treatment of cardiac dysrhythmias. Conversely, systemic absorption of bupivacaine, such as follows a brachial plexus block, stimulates the ventilatory response to carbon dioxide.

Hepatotoxicity

Continuous or intermittent epidural administration of bupivacaine to treat postherpetic neuralgia has been associated with increased plasma concentrations of liver transaminase enzymes that normalized when bupivacaine infusion was discontinued or lidocaine was substituted for bupivacaine.¹⁰⁴ The preservative present in both local anesthetics was the same. Drug-induced liver injury can be a direct toxic injury, an allergic reaction, or an idiosyncratic metabolic abnormality. The hepatic dysfunction described seems most likely to represent an allergic reaction.¹⁰⁵

Uses of Local Anesthetics

Local anesthetics are most often used to produce topical, infiltration, and regional anesthesia.^{52,106} Less common reasons to select local anesthetics are to prevent or treat cardiac dysrhythmias, prevent or treat increases in intracranial pressure, provide analgesia, and treat grand mal seizures. Antiinflammatory effects of local anesthetics may be responsible for beneficial effects in the perioperative period that are attributed to spinal or epidural anesthesia.¹⁰⁷

Regional Anesthesia

Regional anesthesia is classified according to the following six sites of placement of the local anesthetic solution: (1) topical or surface anesthesia, (2) local infiltration, (3) peripheral nerve block, (4) IV regional anesthesia (Bier block), (5) epidural anesthesia, and (6) spinal (subarachnoid) anesthesia (**Table 10.3**). Maximum doses of local anesthetics (based on body weight) as recommended for topical or peripheral nerve block anesthesia must be viewed as imprecise guidelines that often do not consider the pharmacokinetics of the drugs.²

TABLE 10.3

Clinical uses of local anesthetics

	Clinical use	Concentration (%)	Onset	Duration (minutes)	Recommended maximum single dose (mg)
Lidocaine	Topical	4	Fast	30-60	300
	Infiltration	0.5-1	Fast	60-240	300 or 500 with epinephrine
	IVRA	0.25-0.5	Fast	30-60	300
	PNB	1-1.5	Fast	60-180	300 or 500 with epinephrine
	Epidural	1.5-2	Fast	60-120	300 or 500 with epinephrine
	Spinal	1.5-5	Fast	30-60	100
Mepivacaine	Infiltration	0.5-1	Fast	60-240	400 or 500 with epinephrine
	PNB	1-1.5	Fast	120-240	400 or 500 with epinephrine
	Epidural	1.5-2	Fast	60-180	400 or 500 with epinephrine
	Spinal	2-4	Fast	60-120	100
Prilocaine	Infiltration	0.5-1	Fast	60-120	600
	IVRA	0.25-0.5	Fast	30-60	600
	PNB	1.5-2	Fast	90-180	600
	Epidural	2-3	Fast	60-180	600
Bupivacaine	Infiltration	0.25	Fast	120-480	175 or 225 with epinephrine
	PNB	0.25-0.5	Slow	240-960	175 or 225 with epinephrine
	Epidural	0.5-0.75	Moderate	120-300	175 or 225 with epinephrine
	Spinal	0.5-0.75	Fast	60-240	20
Levobupivacaine	Infiltration	0.25	Fast	120-480	150
	PNB	0.25-0.5	Slow	840-1,020	150
	Epidural	0.5-0.75	Moderate	300-540	150
	Spinal	0.5-0.75	Fast	60-360	20
Ropivacaine	Infiltration	0.2-0.5	Fast	120-360	200
	PNB	0.5-1	Slow	300-480	250
	Epidural	0.5-1	Moderate	120-360	200
Chloroprocaine	Infiltration	1	Fast	30-60	800 or 1,000 with epinephrine
	PNB	2	Fast	30-60	800 or 1,000 with epinephrine
	Epidural	2-3	Fast	30-60	800 or 1,000 with epinephrine

Philadelphia, PA: Lippincott-Raven; 1998:97-128 and Foster RH, Markham A. Levobupivacaine: a review of its pharmacology and use as a local anesthetic. *Drugs*. 2000;59:551-559.

Topical Anesthesia

Local anesthetics are used to produce topical anesthesia by placement on the mucous membranes of the nose, mouth, tracheobronchial tree, esophagus, or genitourinary tract. Cocaine (4%-10%), tetracaine (1%-2%), and lidocaine (2%-4%) are most often used. Cocaine's popularity for topical anesthesia reflects its unique ability to produce localized vasoconstriction, thus decreasing blood loss and improving surgical visualization (see "[Cocaine Toxicity](#)" section). There is no difference between the intranasal anesthetic or vasoconstrictive effects of cocaine and those of a lidocaine-oxymetazoline or tetracaine-oxymetazoline mixture, emphasizing the usefulness of these combinations as substitutes for cocaine.¹⁰⁸ Procaine and chloroprocaine penetrate mucous membranes poorly and are ineffective for topical anesthesia.

Nebulized lidocaine is used to produce surface anesthesia of the upper and lower respiratory tract before fiberoptic laryngoscopy and/or bronchoscopy and as a treatment for patients experiencing intractable coughing.¹⁰⁹ The inhalation of local anesthetics by normal subjects does not alter airway resistance and may even produce mild bronchodilation.¹¹⁰ In contrast, inhalation of nebulized lidocaine can cause bronchoconstriction in some patients with asthma, which may become an important consideration when bronchoscopy is planned in these patients.¹⁰⁹ Local anesthetics are absorbed into the systemic circulation after topical application to mucous membranes. Systemic absorption of tetracaine, and to a lesser extent lidocaine, after placement on the tracheobronchial mucosa produces plasma concentrations similar to those present after IV injection of the local anesthetic. For example, plasma lidocaine concentrations 15 minutes after laryngotracheal spray of the local anesthetic are similar to those concentrations present at the same time after an IV injection of lidocaine.¹¹¹ This systemic absorption reflects the high vascularity of the tracheobronchial tree and the injection of the local anesthetic as a spray that spreads the solution over a wide surface area.

Eutectic Mixture of Local Anesthetics

The keratinized layer of the skin provides an effective barrier to diffusion of topical drugs, making it difficult to achieve anesthesia of intact skin by topical application. A popular use of prilocaine is for topical anesthesia when used in an eutectic mixture. A 5% lidocaine-prilocaine cream (2.5% lidocaine and 2.5% prilocaine) allows the use of high concentrations of the anesthetic bases without concern about local irritation, uneven absorption, or systemic toxicity.^{112,113} This combination of local anesthetics is considered a eutectic mixture of local anesthetics (EMLA), as the melting point of the combined drugs is lower than lidocaine or prilocaine alone. The EMLA cream acts by diffusing through intact skin to block neuronal transmission from dermal receptors. Usually, 1 to 2 g of EMLA cream are applied per a 10-cm² area of skin and covered with an occlusive dressing. The duration of application varies according to the type of procedure being undertaken and the site of application. For example, skin-graft harvesting requires 2 hours, whereas cautery of genital warts can be undertaken after only a 10-minute application. The EMLA cream is effective in relieving the pain of venipuncture, arterial cannulation, lumbar puncture, and myringotomy in children and adults. Pain during circumcision in neonates is attenuated by this topical anesthetic.¹¹³ Although 45 minutes have been suggested as the minimum effective onset time for decreasing the pain of IV cannulation, a significant decrease in pain scores may be noted after only 5 minutes. Low-frequency ultrasound pretreatment is effective in accelerating the onset of EMLA cream.¹¹⁴ The addition of nitroglycerin ointment to EMLA cream increases the ease of venous cannulation by promoting venodilation.¹¹⁵ If EMLA cream is used to anesthetize the skin before blood sampling, the results of the analyses of the blood are not distorted. However, the use of EMLA cream to prevent the pain of intradermal skin tests decreases the flare response and may lead to false-negative interpretation of weakly positive tests.

Skin blood flow, epidermal and dermal thickness, duration of application, and the presence of skin pathology are important factors affecting the onset, efficacy, and duration of EMLA analgesia. African Americans may be less responsive than whites, presumably because of increased density of the stratum corneum.¹¹⁶ Blanching of the skin may be seen after 30 to 60 minutes, probably due to vasoconstriction. Plasma levels of lidocaine and prilocaine are below toxic levels, although methemoglobin concentrations reflecting the metabolism of prilocaine may be increased in children younger than 3 months of age, reflecting immature reductase pathways. The enzyme capacity for red blood cell methemoglobin reductase in children

younger than 3 months of age can be overloaded when EMLA cream is administered concurrently with other methemoglobin-inducing drugs (sulfonamides, acetaminophen, phenytoin, nitroglycerin, nitroprusside).¹¹⁷ Likewise, EMLA cream should not be used in those rare patients with congenital or idiopathic methemoglobinemia. Local skin reactions, such as pallor, erythema, and alterations in temperature sensation; edema; pruritus; and rash are common after EMLA cream application.

The EMLA cream is not recommended for use on mucous membranes because of the faster absorption of lidocaine and prilocaine than through intact skin.¹¹² Similarly, EMLA cream is not recommended for skin wounds, and the risk of wound infection may be increased.¹¹⁸ Patients being treated with certain antidysrhythmic drugs (mexiletine) may experience additive and potentially synergistic effects when exposed to EMLA cream. The EMLA cream is contraindicated in patients with a known history of allergy to amide local anesthetics.

Other Topically Effective Local Anesthetics

Amethocaine, like EMLA cream, requires several minutes to become effective, and the cream must be covered with an occlusive dressing. A microemulsion of amethocaine increases skin penetration and shortens the time until cutaneous anesthesia is achieved.¹¹⁹ New commercial preparations for topical anesthesia are being developed. Ametop gel (4% tetracaine) is used to provide topical anesthesia for venous cannulation, and Rapydan patch (7% lidocaine and 7% tetracaine) has been developed to provide topical anesthesia by a different mechanism (heat assisted delivery). They provide comparable pain relief for venous cannulation in 90% of the patients.¹²⁰

Local Infiltration

Local infiltration anesthesia involves extravascular placement of local anesthetic in the area to be anesthetized. Subcutaneous injection of the local anesthetic in the area to be traversed for placement of an intravascular cannula is one example. Lidocaine is the local anesthetic most often selected for infiltration anesthesia. Infiltration of 0.25% ropivacaine or bupivacaine is equally effective in the management of pain at an inguinal operative site.¹²¹

The duration of infiltration anesthesia can be approximately doubled by adding 1:200,000 epinephrine to the local anesthetic solution. Epinephrine-containing solutions, however, should not be injected intracutaneously or into tissues supplied by end arteries (fingers, ears, and nose) because resulting vasoconstriction can produce ischemia and even gangrene.

Peripheral Nerve Block Anesthesia

Peripheral nerve block anesthesia is achieved by injection of local anesthetic solutions into tissues surrounding individual peripheral nerves or nerve plexuses such as the brachial plexus. When local anesthetic solutions are deposited in the vicinity of a peripheral nerve, they diffuse from the outer surface (mantle) toward the center (core) of the nerve along a concentration gradient.¹²² Consequently, nerve fibers located in the mantle of the mixed nerve are anesthetized first. These mantle fibers usually are distributed to more proximal anatomic structures in contrast to distal structures innervated by nerve fibers near the core of the nerve. This explains the initial development of anesthesia proximally, with subsequent distal spread as local anesthetic solution diffuses to reach more central core nerve fibers. Conversely, recovery of sensation occurs in a reverse direction; nerve fibers in the mantle that are exposed to extraneural fluid are the first to lose local anesthetic so that sensation returns initially to the proximal and last to the distal parts of the limb.

Skeletal muscle paralysis may precede the onset of sensory anesthesia if motor nerve fibers are distributed peripheral to sensory fibers in the mixed peripheral nerve.^{122,123} Indeed, the sequence of onset and recovery from blockade of sympathetic, sensory, and motor nerve fibers in a mixed peripheral nerve depends as much on anatomic location of the nerve fibers within the mixed nerve as on their sensitivity to local anesthetics. This differs from results of in vitro studies on single nerve fibers, in which diffusion distance does not play a role. In an in vitro model, nerve fiber size is most important, with the onset of conduction blockade being inversely proportional to fiber size. For example, the smallest sensory and autonomic nervous system fibers are anesthetized first, followed by larger motor and proprioceptive axons.

The rapidity of onset of sensory anesthesia after injection of a local anesthetic solution into tissues around a peripheral nerve depends on the pK of the drug. The pK determines the amount of local anesthetic that exists in the active nonionized form at the pH of the tissue (see [Table 10.1](#)). For example, the onset of action of lidocaine occurs in approximately 3 minutes, whereas onset after injection of bupivacaine, levobupivacaine, or ropivacaine requires approximately 15 minutes, reflecting the greater fraction of lidocaine that exists in the lipid-soluble nonionized form. The onset and duration of sensory anesthesia for brachial plexus block produced by 0.5% bupivacaine, levobupivacaine, or ropivacaine is similar. Tetracaine, with a slow onset of anesthesia and a high potential to cause systemic toxicity, is not recommended for local infiltration or peripheral nerve block anesthesia.

Duration of peripheral nerve block anesthesia depends on the dose of local anesthetic, its lipid solubility, its degree of protein binding, and concomitant use of a vasoconstrictor such as epinephrine. The duration of action is prolonged more safely by epinephrine than by increasing the dose of local anesthetic, which also increases the likelihood of systemic toxicity. Conversely, not all reports document a prolongation of the duration of action when epinephrine is added to bupivacaine or ropivacaine.^{[124](#)}

Continuous Peripheral Nerve Blocks

Modern regional anesthesia practice has moved toward ultrasound-guided peripheral nerve blocks and using catheter for continuous infusions. Use of ultrasound guidance increases the chances for successful block, takes less time to perform, hasten onset, and is longer duration when compared to those performed with peripheral nerve stimulation guidance.^{[125](#)} Ultrasound guidance also decreased the risk of vascular puncture during block performance. This provides more consistent nerve block and also analgesia for few days after the surgery, depending on type of local anesthetic medication used. Continuous nerve blocks have shown to be associated with improved pain control, decreased need for opioid analgesics, less nausea, and greater patient satisfaction, when compared to single shot blocks.^{[126](#)} Commonly used medication and dosages are shown in [Table 10.4](#). Midazolam, magnesium, dexmedetomidine, and ketamine have been used as additives to local anesthetic solutions for peripheral nerve blocks, but they cannot be routinely recommended due to a dearth of supportive data, modest efficacy, and (in the case of ketamine) significant adverse effects.^{[127](#)}

TABLE 10.4

Dosage chart for common continuous nerve blocks

Block type	Local anesthetic	Continuous rate (mL per hour)	Bolus dose (mL)	Lock out interval (minutes)	Number of doses per hour
Interscalene	0.25% bupivacaine or 0.2% ropivacaine	8	12	60	1
Supraclavicular	0.25% bupivacaine or 0.2% ropivacaine	8	12	60	1
Popliteal	0.25% bupivacaine or 0.2% ropivacaine	8	12	60	1
Femoral ^a	0.12% bupivacaine or 0.1% ropivacaine	8	0

^aLower concentration used for femoral block to reduce the chances of motor blockade and to prevent falls.

Intravenous Regional Anesthesia (Bier Block)

The IV injection of a local anesthetic solution into an extremity isolated from the rest of the systemic circulation by a tourniquet produces a rapid onset of anesthesia and skeletal muscle relaxation. The duration of anesthesia is independent of the specific local anesthetic and is determined by how long the tourniquet is kept inflated. The mechanism by which local anesthetics produce IV regional anesthesia is unknown but probably reflects action of the drug on nerve endings as well as nerve trunks. Normal sensation and skeletal

muscle tone return promptly on release of the tourniquet, which allows blood flow to dilute the concentration of local anesthetic.

Ester and amide local anesthetics produce satisfactory effects when used for IV regional anesthesia. Lidocaine is the most frequently selected amide local anesthetic for producing this type of regional anesthesia. Alternatives to lidocaine include prilocaine, mepivacaine, and ropivacaine. The onset, duration, and quality of IV regional anesthesia produced by 50 mL of a 0.5% solution of lidocaine or prilocaine are similar, but plasma concentrations of prilocaine are lower than those of lidocaine after tourniquet deflation ([Figure 10.12](#)).¹²⁸ The associated degree of methemoglobinemia (3% of hemoglobin as methemoglobin) seen with prilocaine is far below the level needed to produce cyanosis (10% hemoglobin as methemoglobin). The significantly lower plasma prilocaine concentrations after tourniquet deflation may indicate a greater margin of safety for prilocaine compared to lidocaine in terms of potential systemic toxicity. Mepivacaine 5 mg/kg provided superior analgesia to lidocaine 3 mg/kg when used for IV regional anesthesia.¹²⁹ Plasma concentrations of lidocaine decreased significantly in the first 60 minutes following tourniquet deflation, whereas blood concentrations of mepivacaine remained below toxic concentrations. Ropivacaine, 1.2 and 1.8 mg/kg, compared with lidocaine, 3 mg/kg, produced comparable IV regional anesthesia, but residual analgesia was longer lasting with ropivacaine.¹³⁰ Chloroprocaine is not selected for IV regional anesthesia because of a high incidence of thrombophlebitis. Bupivacaine is not recommended for IV regional anesthesia considering its greater likelihood than other local anesthetics for producing cardiotoxicity when the tourniquet is deflated at the conclusion of the anesthetic. Ropivacaine, although less likely to produce cardiotoxicity than bupivacaine, is not recommended for IV regional anesthesia.

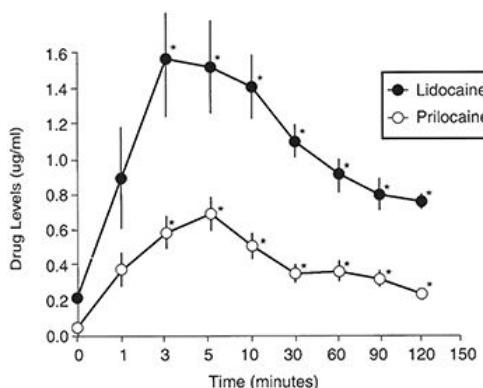

FIGURE 10.12 After tourniquet deflation, plasma concentrations of lidocaine exceed concentrations of prilocaine (mean \pm standard error; $*P < .05$). Epidural Anesthesia

Local anesthetic solutions placed in the epidural or sacral caudal space produce epidural anesthesia by two presumed mechanisms. First, local anesthetic diffuses across the dura to act on nerve roots and the spinal cord as it does when injected directly into the lumbar subarachnoid space to produce spinal anesthesia. Second, local anesthetic also diffuses into the paravertebral area through the intervertebral foramina, producing multiple paravertebral nerve blocks. These slow diffusion processes account for the 15- to 30-minute delay in onset of sensory anesthesia after placement of local anesthetic solutions in the epidural space. Lidocaine is commonly used for epidural anesthesia because of its good diffusion capabilities through tissues. Despite a reasonable safety profile of bupivacaine, many clinicians prefer to use the costly ropivacaine or levobupivacaine because ropivacaine or levobupivacaine are associated with less risk for cardiac and CNS toxicity and are also less likely to result in unwanted postoperative motor blockade.¹³¹ The delivery of local anesthetic in epidural space is achieved mostly by a continuous epidural infusion with an option of patient-

controlled epidural bolus option. For labor analgesia, novel programmed intermittent bolus is superior to continuous epidural infusion.¹³²

Bupivacaine and ropivacaine at similar concentrations (0.5% to 0.75%) produce similar prolonged sensory anesthesia (ropivacaine has a greater tendency to block A- δ and C fibers) when used for epidural anesthesia, but the motor anesthesia produced by ropivacaine is less intense and of shorter duration.^{133,134} These characteristics of ropivacaine may be advantageous for obstetric patients in labor and for those experiencing acute and chronic pain. The addition of epinephrine 1:200,000 to 0.5% or 0.75% bupivacaine or ropivacaine does not appear to offer an advantage in terms of duration of action.¹³⁵ Use of 1% ropivacaine may provide longer sensory anesthesia than 0.75% bupivacaine, whereas the motor block is similar.^{124,136} The lower systemic toxicity of ropivacaine compared with bupivacaine enables ropivacaine to be used for surgical anesthesia in concentrations up to 1%.⁵ For postoperative analgesia, the infusion of 0.2% ropivacaine at 6 to 10 mL per hour is effective.¹³⁷

In children, there is no difference with regard to postoperative analgesia provided by bupivacaine, levobupivacaine, or ropivacaine, but unwanted motor blockade was more frequent in patients receiving bupivacaine (**Figure 10.13**).¹³⁸

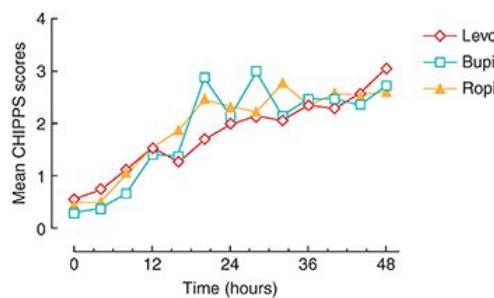

FIGURE 10.13 Mean postoperative pain scores (Children's and Infant's Postoperative Pain Score [CHIPPS]) were similar in patients receiving epidural levobupivacaine (levo), bupivacaine (bupi), and ropivacaine (ropi) infusions. Reprinted with permission from De Negri P, Ivani G, Tirri T, et al. A comparison of epidural bupivacaine, levobupivacaine, and ropivacaine on postoperative analgesia and motor blockade. Anesth Analg. 2004;99(1):45-48. Copyright © 2004 International Anesthesia Research Society.

In contrast to spinal anesthesia, during epidural anesthesia, there often is not a zone of differential sympathetic nervous system blockade, and the zone of differential motor blockade may average up to four rather than two segments below the sensory level. Another difference from spinal anesthesia is the larger dose required to produce epidural anesthesia, leading to substantial systemic absorption of the local anesthetic. For example, peak plasma concentrations of lidocaine are 3 to 4 μ g/mL after placement of 400 mg into the epidural space. Bupivacaine, 70 to 100 mg of 0.5% with 1:200,000 epinephrine placed in the epidural space, results in peak average plasma concentrations of 0.335 μ g/mL occurring about 30 minutes after instillation of the local anesthetic.¹³⁹ Peak plasma concentrations of bupivacaine near 1 μ g/mL occur when epinephrine is not added to the local anesthetic solution placed in the epidural space. In this regard, addition of epinephrine to the local anesthetic solution may decrease systemic absorption of the local anesthetic by approximately one-third. The peak venous plasma concentration of ropivacaine is 1.3 μ g/mL after epidural placement of 200 mg of the local anesthetic. Addition of 1:200,000 epinephrine solution decreases systemic absorption of ropivacaine by approximately one-third. Systemic absorption of epinephrine produces β -adrenergic stimulation characterized by peripheral vasodilation, with resultant decreases in systemic blood pressure, even though the inotropic and chronotropic effects of epinephrine increase cardiac output.

Addition of opioids to local anesthetic solutions placed in the epidural or intrathecal space results in synergistic analgesia.¹⁴⁰ An exception to this analgesic synergy is 2-chloroprocaine, which appears to decrease the effectiveness of epidural opioids when administered with local anesthetic solutions placed into the epidural space.¹⁴¹ Combining local anesthetics and opioids for peripheral nerve blocks appears to be ineffective in altering the characteristics or results of the block.

Spinal Anesthesia

Spinal anesthesia is produced by injection of local anesthetic solutions into the lumbar subarachnoid space. Local anesthetic solutions placed into lumbar cerebrospinal fluid act on superficial layers of the spinal cord, but the principal site of action is the preganglionic fibers as they leave the spinal cord in the anterior rami. Because the concentration of local anesthetics in cerebrospinal fluid decreases as a function of distance from the site of injection, and because different types of nerve fibers differ in their sensitivity to the effects of local anesthetics, zones of differential anesthesia develop. Because preganglionic sympathetic nervous system fibers are blocked by concentrations of local anesthetics that are insufficient to affect sensory or motor fibers, the level of sympathetic nervous system denervation during spinal anesthesia extends approximately two spinal segments cephalad to the level of sensory anesthesia. For the same reasons, the level of motor anesthesia averages two segments below sensory anesthesia.

Dosages of local anesthetics used for spinal anesthesia vary according to the (1) height of the patient, which determines the volume of the subarachnoid space; (2) segmental level of anesthesia desired; and (3) duration of anesthesia desired. The total dose of local anesthetic administered for spinal anesthesia is more important than the concentration of drug or the volume of the solution injected.

Spinal anesthesia with lidocaine has been reported to produce a higher incidence of transient neurologic symptoms than spinal anesthesia produced by bupivacaine (see “[Neural Tissue Toxicity \[Neurotoxicity\]](#)” section). For these reasons, bupivacaine has been proposed as an alternative local anesthetic to lidocaine for spinal anesthesia.^{142,143} If lidocaine is selected, it may be prudent to limit the dose to 60 mg.¹⁴³ Bupivacaine used for spinal anesthesia is more effective than tetracaine in preventing lower extremity tourniquet pain during orthopedic surgery.¹⁴⁴ This effectiveness may reflect the ability of bupivacaine to produce greater frequency-dependent conduction blockade of fibers than does tetracaine. In parturients, the intrathecal placement of bupivacaine, 2.5 mg, plus sufentanil, 10 µg, provided labor analgesia and allowed the patients to continue to ambulate.¹⁴⁵ The addition of intrathecal fentanyl 5 µg provides a bupivacaine dose-sparing effect similar to that provided by 15 or 25 µg of fentanyl, resulting in less pruritus but a shortening of the duration of action.¹⁴⁶

Ropivacaine, 3 mL of 0.5% or 0.75%, produces sensory anesthesia, although complete motor blockade was present in only about 50% of patients receiving the lower dose.¹⁴⁷ Ropivacaine is an acceptable local anesthetic to produce spinal anesthesia for cesarean section, and decreased lower extremity blockade compared with bupivacaine may be a desirable feature.^{148,149} Levobupivacaine has equivalent clinical efficacy to bupivacaine for spinal anesthesia ([Figure 10.14](#)).¹⁵⁰ Dibucaine is 1.5 to 2.0 times as potent as tetracaine when used for spinal anesthesia. In the past, chloroprocaine was not recommended for placement in the subarachnoid space because of potential neurotoxicity.^{151–153} However, preservative-free 2-chloroprocaine solutions (2% and 3%) are available for intrathecal injection and have been shown to produce reliable sensory and motor blockade with a short duration and little or no risk of transient neurologic symptoms, making this local anesthetic an attractive selection for outpatient surgical procedures performed under spinal anesthesia ([Figure 10.15](#)).^{154–156}

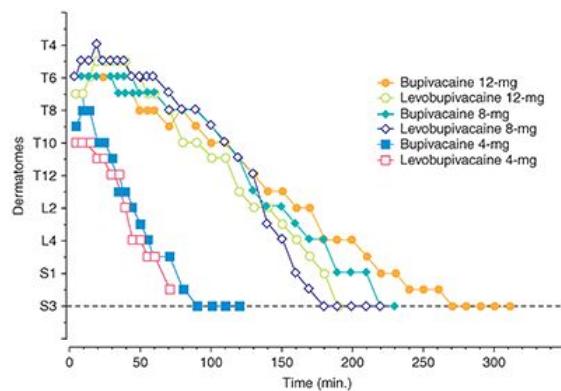

FIGURE 10.14 Recovery from sensory block occurs at a similar rate following spinal anesthesia produced with equipotent doses of bupivacaine and levobupivacaine. The specific gravity of local anesthetic solutions injected into the lumbar cerebrospinal fluid is important in determining spread of the drugs. Addition of glucose to local anesthetic solutions increases the specific gravity of local anesthetic solutions above that of cerebrospinal fluid (hyperbaric). Addition of distilled water lowers the specific gravity of local anesthetic solutions below that of cerebrospinal fluid (hypobaric). Cerebrospinal fluid does not contain significant amounts of cholinesterase enzyme; therefore, the duration of action of ester local anesthetics as well as amides placed in the subarachnoid space depends on systemic absorption of the drug.

Injected intrathecally, tetracaine produces a significant increase in spinal cord blood flow, an effect that can be prevented or reversed by epinephrine.¹⁵⁷ Vasodilation is less prominent with lidocaine, and bupivacaine produces vasoconstriction. Predictably, vasoconstrictors appear to be most effective in prolonging tetracaine-induced spinal anesthesia (up to 100%) and less effective at prolonging lidocaine spinal anesthesia, whereas the effect on bupivacaine spinal anesthesia remains controversial and is, at best, minimal.

Physiologic Effects

The goal of spinal anesthesia is to provide sensory anesthesia and skeletal muscle relaxation. It is the accompanying level of sympathetic nervous system blockade, however, that produces physiologic alterations.

Cardiac Arrest

Cardiac arrest may accompany hypotension and bradycardia associated with spinal anesthesia.^{85,158,159} Risk factors for hypotension include sensory anesthesia above T5 and baseline systolic blood pressure of <120 mm Hg. Risk factors for bradycardia include sensory anesthesia above T5, baseline heart rate <60 beats per minute, prolonged P-R interval on the electrocardiogram, and concomitant treatment with β-blocking drugs. Common features of cardiac arrest in patients receiving spinal anesthesia have included administration of sedation to produce a sleeplike state without spontaneous verbalization and lack of early administration of epinephrine. Even when therapy is promptly administered, patients may be refractory to treatment because local anesthetic-induced sympathetic nervous system blockade, which decreases circulating blood volume, may also cause a defective neuroendocrine response to stress. Even early administration of epinephrine in patients being previously monitored with pulse oximetry and capnography may not guarantee a good outcome following neuraxial cardiac arrest.⁸⁵

Sympathetic nervous system blockade results in arteriolar dilatation, but systemic blood pressure does not decrease proportionally because of compensatory vasoconstriction in areas with intact sympathetic nervous system innervation. Compensatory vasoconstriction occurs principally in the upper extremities and does not involve the cerebral vasculature. Even with total sympathetic nervous system blockade produced by spinal anesthesia, the decrease in systemic vascular resistance is <15%. This change is minimal because smooth muscles of arterioles retain intrinsic tone and do not dilate maximally.

The most important cardiovascular responses produced by spinal anesthesia are those that result from changes in the venous circulation. Unlike arterioles denervated by sympathetic nervous system blockade, venules do not maintain intrinsic tone and thus dilate maximally during spinal anesthesia. The resulting increased vascular capacitance decreases venous return to the heart, leading to decreases in cardiac output and systemic blood pressure. The physiologic effect of spinal anesthesia on venous return emphasizes the risk of extreme systemic hypotension if this technique is instituted in hypovolemic patients. Blockade of preganglionic cardiac accelerator fibers (T1-T4) results in heart rate slowing, particularly if decreased venous return and central venous pressure decrease the stimulation of intrinsic stretch receptors in the right atrium (Bezold-Jarisch reflex). For example, heart rate will increase with a head-down position that increases venous return and central venous pressure to stimulate these receptors. During spinal anesthesia, myocardial oxygen requirements are decreased as a result of decreased heart rate, venous return, and systemic blood pressure.

Apnea

Apnea that occurs with an excessive level of spinal anesthesia probably reflects ischemic paralysis of the medullary ventilatory centers due to profound hypotension and associated decreases in cerebral blood flow. Concentrations of local anesthetics in ventricular cerebrospinal fluid are usually too low to produce pharmacologic effects on the ventilatory centers. However, rarely phrenic nerve which originates from anterior rami of C3-C5 nerve roots, can be paralyzed.

Analgesia

Lidocaine and procaine have been demonstrated to produce intense analgesia when injected IV. Use of local anesthetics for this purpose, however, is limited by the small margin of safety between IV analgesic doses and those that produce systemic toxicity. Nevertheless, continuous low-dose infusion of lidocaine to maintain a plasma concentration of 1 to 2 µg/mL decreases the severity of postoperative pain and decreases requirements for opioids without producing systemic toxicity.¹⁶⁰ Lidocaine administered IV also decreases anesthetic requirements for volatile drugs.¹⁶¹ Lidocaine may also be administered IV in the perioperative period as a cough suppressant. In this regard, the cough reflex during intubation of the trachea is suppressed by plasma concentrations of lidocaine >2 µg/mL.¹⁶² Stump pain (neuromas) but not phantom pain (cortical reorganization) following amputation is diminished by IV administration of lidocaine.¹⁶³ Lidocaine infusion during surgery may be a useful analgesic adjunct for patients undergoing open and laparoscopic colorectal surgeries and has shown to improve pain scores, reduce opioid consumption, and reduce length of hospital stay. However, according to a recent Cochrane review, it is uncertain if lidocaine improves pain scores or gastrointestinal recovery, postoperative nausea, and opioid consumption in the early postoperative phase.¹⁶⁴

Suppression of Ventricular Cardiac Dysrhythmias

In addition to suppressing ventricular cardiac dysrhythmias, the IV administration of lidocaine may increase the defibrillation threshold. Failure to recognize this effect could lead to unnecessary revision of the lead system of an implantable cardioverter defibrillator.¹⁶⁵

Antiinflammatory Effects

Local anesthetics modulate inflammatory responses and may be useful in mitigating perioperative inflammatory injury.¹⁰⁷ For example, overreactive inflammatory responses that destroy rather than protect are critical in the development of several perioperative phenomena including postoperative pain, adult respiratory distress syndrome, systemic inflammatory response syndrome, and multiple organ failure. Beneficial effects attributed to epidural anesthesia (pain relief, decreased thrombosis from hypercoagulability) may reflect

antiinflammatory effects of local anesthetics. Adverse effects of local anesthetic-induced antiinflammatory effects include retardation of wound healing and increased risk of infection. Nevertheless, there is evidence that local anesthetics also possess significant antibacterial effects (tetracaine > bupivacaine > lidocaine).¹⁶⁶ The IV lidocaine is being postulated to decrease perioperative stress and improve anesthetic depth. Effect on depth of anesthesia, of IV lidocaine, as measured by bispectral index is studied in the presence or absence of midazolam. The IV lidocaine decreases bispectral index by modulating the effect of midazolam.¹⁶⁷

Mechanism

Antiinflammatory effects of local anesthetics are not dependent on the sodium ion channel blockade that is responsible for the anesthetic effects of these drugs. Local anesthetics may modulate inflammatory responses by inhibiting inflammatory mediator signaling. For example, local anesthetics inhibit platelet-activating factor (an inflammatory mediator), which is an established signaling mechanism in early acute respiratory distress syndrome, a typical postoperative inflammatory disorder.¹⁶⁸ Many of the mediators (thrombin, thromboxane, platelet-activating factor, and interleukins) of the inflammatory and hemostatic systems act through G protein-coupled receptors. Local anesthetics may inhibit G proteins, resulting in antiinflammatory effects.¹⁶⁹ In addition, local anesthetics inhibit neutrophil accumulation at sites of inflammation and impair free radical and mediator release.¹⁷⁰ Local anesthetics in clinically relevant concentrations inhibit superoxide anion production of platelet-activating factor-primed neutrophils.¹⁶⁸ Priming is the process whereby the response of neutrophils to a subsequent activating stimulus is potentiated. Levobupivacaine is more effective than bupivacaine and other local anesthetics in suppressing neutrophil priming.¹⁷¹ Decreased generation of reactive oxygen radicals is associated with decreases in ischemic damage after myocardial infarction.

Bronchodilation

Inhaled lidocaine and ropivacaine attenuate histamine-induced bronchospasm and induce airway anesthesia. This response most likely reflects topical airway anesthesia, as bronchial reactivity is inhibited at plasma concentrations that are lower than those needed to attenuate bronchial reactivity. Nevertheless, dyclonine, a longer lasting and more intense local anesthetic, does not reliably attenuate bronchial hyperreactivity, suggesting that other properties of local anesthetics may be important.¹⁷²

Liposomal Local Anesthetics

Various formulation and drug delivery system including liposomes, cyclodextrins, and biopolymers are intended to prolong the duration and to limit the toxicity of local anesthetics. The goal is to upload higher amount of local anesthetic into the molecule and to have a consistent release of local anesthetic in the tissues.¹⁷³ Liposomes, hydrophobic-based polymer particles such as poly(lactic-co-glycolic acid) microspheres, and solid polymers like poly(sebacic-co-ricinoleic acid) P(SA:RA) and their combination with synthetic and natural local anesthetic are examples of delivery systems currently in development or in clinical use.¹⁷⁴

Drugs such as lidocaine, tetracaine, and bupivacaine have been incorporated into liposomes to prolong the duration of action and decrease toxicity.¹⁷⁵ Currently, liposomal bupivacaine is indicated for single-dose infiltration in adults to produce postsurgical local analgesia and as an interscalene brachial plexus nerve block to produce postsurgical regional analgesia.¹⁷⁶⁻¹⁷⁸ Liposomal bupivacaine consists of microscopic, spherical, and multivesicular liposomes, and each liposome particle is composed of a honeycomb-like structure of numerous internal aqueous chambers. Lipid membranes separate these aqueous chambers that contain encapsulated bupivacaine. Bupivacaine is released from the liposome particles by a complex mechanism over an extended period (up to 96 hours). Mixing liposomal bupivacaine with nonbupivacaine-based local anesthetics, including lidocaine, is not recommended. It may cause an immediate release of bupivacaine from liposomes and may cause toxicity. Although the use of liposomal bupivacaine has exponentially increased in all surgery settings, the clear evidence of benefit when compared to much cheaper plain bupivacaine is lacking.

In a randomized, double-blind, placebo-controlled, parallel-group study, liposomal bupivacaine demonstrated a statistically significant reduction in pain through 72 hours, decreased opioid requirements, delayed time to first opioid use, and improved patient satisfaction compared with placebo after hemorrhoidectomy (Figure 10.16).¹⁷⁸ Liposomal bupivacaine is also been studied for use in nerve blocks,¹⁷⁹ intraoperative administration in ileostomy reversal,¹⁸⁰ but the results are inconclusive due to smaller sample size.

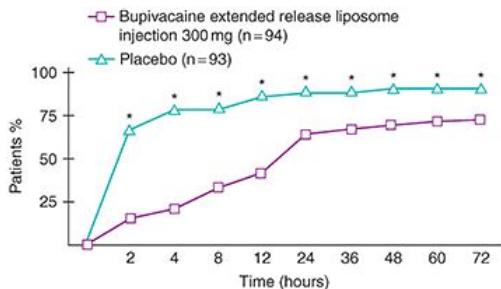

FIGURE 10.16 Time to first use of opioid rescue medication (percentage of patients) after surgery. Gorfine SR, Onel E, Patou G, Krivokapic ZV. *Bupivacaine extended-release liposome injection for prolonged postsurgical analgesia in patients undergoing hemorrhoidectomy: a multicenter, randomized, double-blind, placebo-controlled trial*. Dis Colon Rectum. 2011;54(12):1552-1559.

In a systematic review of 11 studies, periarticular liposomal bupivacaine infiltration resulted in similar pain control and functional recovery after total knee arthroplasty, compared to peripheral nerve blocks or periarticular blocks using traditional local anesthetic.¹⁸¹ However, appropriate use of liposomal bupivacaine for local infiltration analgesia compared to plain bupivacaine for total knee surgery improved postsurgical pain, opioid consumption, and time to first opioid rescue.¹⁸² When comparing all techniques, liposomal bupivacaine was not associated with a clinically relevant improvement in inpatient opioid prescription, resource utilization, or opioid-related complications in patients who received modern pain management including a peripheral nerve block.¹⁸³

In a prospective evaluation of hip arthroscopy patients, postoperative pain scores and opioid use was similar with either liposomal bupivacaine or plain bupivacaine fascia iliaca block.¹⁸⁴ Overall, a Cochrane review of 10 randomized trial summarized the current evidence as costly, “liposomal bupivacaine use at the surgical site does appear to reduce postoperative pain compared to placebo, however, at present the limited evidence does not demonstrate superiority to bupivacaine hydrochloride.”¹⁸⁵

Tumescent Liposuction

Tumescent technique for liposuction characterizes the subcutaneous infiltration of large volumes (5 L or more) of solution containing highly diluted lidocaine (0.05% to 0.10%) with epinephrine (1:100,000). The taut stretching of overlying blanched skin by the large volume of solution and epinephrine-induced vasoconstriction is the origin of the term **tumescent technique**.

The result is sufficient local anesthesia for the liposuction, virtually bloodless aspirates, and prolonged postoperative analgesia. Slow and sustained release of lidocaine into the circulation is associated with plasma concentrations <1.5 µg/mL that peak 12 to 14 hours after injection and then decline gradually over the next 6 to 14 hours.¹⁸⁶ Plasma concentrations of epinephrine peak at 3 to 5 times the upper normal limits approximately 3 hours following injection of the solution and return to normal after about 12 hours.¹⁸⁷ The recommended adult dose of lidocaine with epinephrine for regional anesthesia is about 7 mg/kg. When highly diluted lidocaine solutions are administered for tumescent liposuction, the dose of lidocaine may range from 35 to 55 mg/kg (“mega-dose lidocaine”).¹⁸⁸ It is estimated that 1 g of subcutaneous tissue can absorb up to 1 mg of lidocaine (“tissue buffering system”). The injection of additional undiluted lidocaine for concomitant cosmetic procedures must be considered in estimating the likely plasma concentrations of lidocaine that will occur.

Tumescent liposuction is commonly used in aesthetic contouring of thigh, abdomen, hip and buttocks, and its use is increasing in reconstructive plastic surgery procedures. Despite the popularity and presumed safety of tumescent liposuction, there are reports of increased mortality associated with this technique (greater than mortality associated with automobile accidents).¹⁸⁹ Causes of death may include lidocaine toxicity or local anesthetic-induced depression of cardiac conduction and contractility. Overall complication rate in a nationwide quality improvement study was 0.7%, in which 0.57% were minor complications and 0.14% were major complications.^{190,191}

Cocaine Toxicity

Cocaine abuse and intoxication is widespread across the globe. In the United States, 1.5 million (2010) adults use cocaine; in Europe, 4 million (2009) adults use cocaine.¹⁹² Cocaine produces sympathetic nervous system stimulation by blocking the presynaptic uptake of norepinephrine and dopamine, thus increasing their postsynaptic concentrations. Because of this blocking effect, dopamine remains at high concentrations in the synapse and continues to affect adjacent neurons, producing the characteristic cocaine “high.”^{193,194} Chronic exposure to cocaine is postulated to affect adversely dopaminergic function in the brain due to dopamine depletion.

Pharmacokinetics

Once cocaine is absorbed, the pharmacokinetics, regardless of the route of administration, are similar.¹⁹⁵ Conversely, the route of administration is important in the rate of onset as well as the intensity and duration of cocaine’s effects. For example, peak venous plasma concentrations of cocaine are achieved at approximately 30 to 40 minutes after intranasal administration and approximately 5 minutes after IV and smoked cocaine administration. The maximum physiologic effects of intranasal cocaine occur within 15 to 40 minutes, and the maximum subjective effects occur within 10 to 20 minutes. The duration of effects is approximately 60 minutes or longer after peak effects. The subjective effects occur within minutes of IV or smoked cocaine use, and the duration of effect is approximately 30 to 45 minutes. The elimination half-time of cocaine is 60 to 90 minutes, and metabolism is principally by plasma esterases (see “[Metabolism of Ester Local Anesthetics](#)” section). Urinary excretion of unchanged cocaine (<1% of the total dose) and metabolites (benzoylecgonine and ecgonine methyl ester representing about 65% of the dose) is similar regardless of the route of administration.

Adverse Physiologic Effects

Acute cocaine administration has local anesthetic, vasoconstrictive, and sympathomimetic effects. Cardiac function is adversely affected, and cocaine is known to cause coronary vasospasm, myocardial ischemia, myocardial infarction, and ventricular cardiac dysrhythmias, including ventricular fibrillation.¹⁹⁶ Associated hypertension and tachycardia further increase myocardial oxygen requirements at a time when coronary oxygen delivery is decreased by the effects of cocaine on coronary blood flow. Even remote cocaine use can result in myocardial ischemia and hypotension for as long as 6 weeks after discontinuing cocaine use.^{197,198} Presumably, delayed episodes of myocardial ischemia are due to cocaine-induced coronary artery vasospasm. Excessive sensitivity of the coronary vasculature to catecholamines after chronic exposure to cocaine may be due in part to cocaine-induced depletion of dopamine activity. Cocaine-abusing parturients are at higher risk for interim peripartum events such as hypertension, hypotension, and wheezing episodes.¹⁹⁹

Cocaine may produce hyperpyrexia, which can contribute to seizures. Unexpected patient agitation in the perioperative period may reflect the effects of cocaine ingestion.²⁰⁰ There is a temporal relationship between the recreational use of cocaine and cerebrovascular accidents.²⁰¹

Treatment

Nitroglycerin has been used to treat cocaine-induced myocardial ischemia.²⁰² β -Adrenergic blockade accentuates coronary artery vasospasm in the setting of acute cocaine overdose.^{203,204} Whether β -adrenergic blockade is harmful for coronary vasospasm in the setting of chronic cocaine use is not known. Furthermore,

administration of β -blocking drugs in the presence of catecholamine-induced hypertension and tachycardia has been associated with profound cardiovascular collapse and cardiac arrest that is unresponsive to aggressive cardiopulmonary resuscitation.²⁰⁵ Thus, β blockers should be used with caution. In this situation, administration of a vasodilating drug such as nitroprusside may be the safest intervention. α -Adrenergic blockade may be effective in treatment of coronary vasoconstriction due to cocaine, but in the presence of hypotension, this intervention is questionable.

In 2008, American Heart Association published a statement for management of cocaine-associated chest pain and myocardial infarction (Figure 10.17).²⁰⁶ In addition to their beneficial effect in seizure control, benzodiazepines also help in acute coronary syndromes by relieving chest pain and improving hemodynamic profile. Nitroglycerin and phentolamine is useful in reversing coronary vasoconstriction.

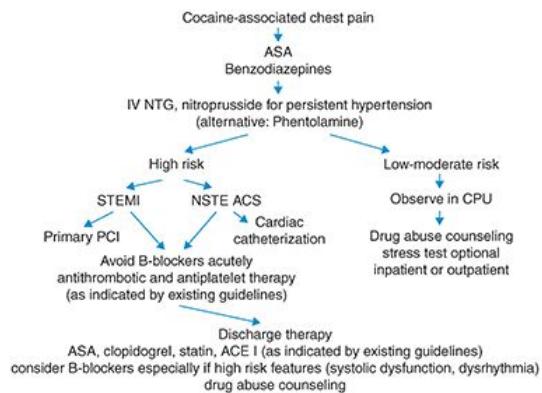

FIGURE 10.17 Therapeutic and diagnostic recommendations in cocaine-associated chest pain.²⁰⁶ ACE I, angiotensin-converting enzyme inhibitor; ASA, acetylsalicylic acid; CPU, chest pain unit; IV NTG, intravenous nitroglycerin; NSTE ACS, non-ST-segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction.

Neuromuscular Physiology

Mohamed A. Naguib[†]

The mammalian neuromuscular junction (NMJ) is one of the most studied and best understood synapses.¹ The NMJ is a synapse that develops between a motor neuron and a muscle fiber and is made up of several components: the presynaptic nerve terminal, the postsynaptic muscle membrane on the muscle membrane, and the intervening cleft (or gap). In the 19th century and early years of the 20th century, there was broad support for the concept that impulses in the nerves acted directly on muscle, resulting in muscular contraction—the “electrical theory.” This theory was eventually refuted with the discovery of the role of acetylcholine in neuromuscular transmission,^{2,3} and in 1936, the Nobel Prize in Physiology or Medicine was awarded to Sir Henry Hallett Dale and Otto Loewi “for their discoveries relating to chemical transmission of nerve impulses.” This was followed by the discovery that a muscle membrane-bound allosteric protein, the nicotinic acetylcholine receptor (nAChR).⁴

Muscle Types

Muscle is generally classified as skeletal, smooth, or cardiac. Both skeletal and cardiac muscles are striated muscles sharing a common basic organization of the contractile filaments. There are, however, distinct histologic and functional differences between these two muscles. Skeletal muscle cells are multinucleated and tubular in shape, whereas cardiac muscle cells may be mono- or binucleated, are branched, and contain intercalated discs. Skeletal muscle is responsible for voluntary actions, whereas smooth and cardiac muscles subserve functions related to the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Muscle composes 45% to 50% of total body mass, with skeletal muscles accounting for approximately 40% of body mass. An estimated 250 million cells are present in more than 400 skeletal muscles of humans. Muscle cells are highly specialized cells for the conversion of chemical energy into mechanical energy. Inappropriate activity of smooth muscle is involved in many illnesses including hypertension, atherosclerosis, asthma, and disorders of the gastrointestinal tract.

Motor Units

Vertebrate skeletal muscles are innervated by large myelinated α motor neurons that originate from cell bodies located in the brainstem or ventral (anterior) horns of the spinal cord ([Figure 11.1](#)).⁵ The myelinated nerve axon reaches the muscle through mixed peripheral nerves. Motor nerves branch in the skeletal muscle with each nerve terminal innervating a single muscle cell.

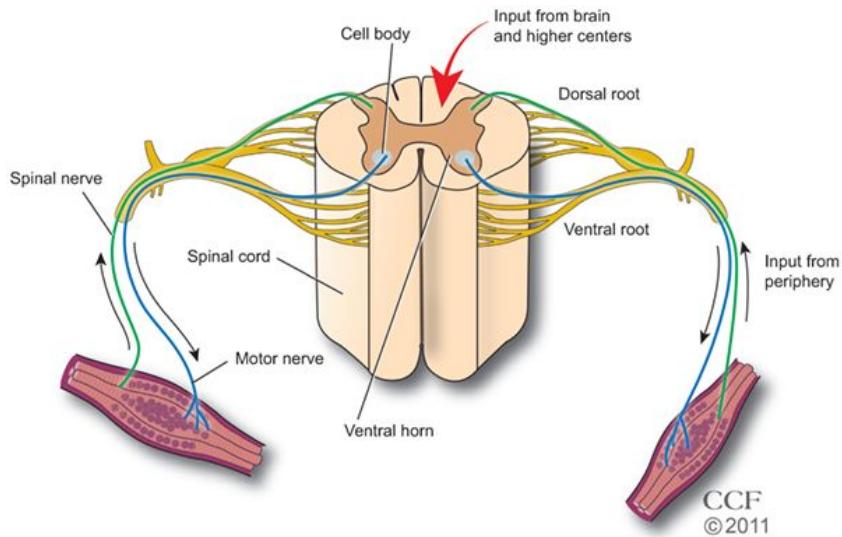

FIGURE 11.1 Schematic depiction of skeletal muscle innervation. Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography. Copyright © 2011-2020. All Rights Reserved.

The motor unit is the functional contractile unit and is composed of a single myelinated α motor neuron and all muscle fibers that receive innervation from this single neuron. Motor units vary in size. A large motor nerve innervates more muscle fibers than a smaller motor nerve does. In general, small motor units innervate the “red slow” muscle fibers, whereas large motor units innervate the “white or pale fast” muscle fibers. The slow muscle fibers appear red (eg, masseters) as a result of high contents of myoglobin, mitochondria, and capillaries compared with white muscle fibers (eg, psoas muscle). Unlike the white muscle fibers, the red fibers are resistant to fatigue.⁶ Muscles contain a varying mixture of motor units depending on their function.

The Neuromuscular Junction

The NMJ comprises portions of three structures—motor neuron, muscle fiber, and glial cells known as Schwann cell. The NMJ is a highly specialized synapse at which presynaptic motor nerve endings meet the postsynaptic membranes of skeletal muscles (motor end plates) ([Figure 11.2](#)). The formation, differentiation, and function of the NMJ require a proper interaction (cross talk) between the nerve terminal and muscle cell (for a review, see Naguib et al¹). Failure of this cross talk will result in a wide spectrum of neuromuscular disorders. It should be noted that in early postnatal period, muscle fibers are innervated by multiple motor nerves. It has been shown in mice that on the second postnatal day, approximately 75% of muscle fibers are multiply innervated (>95% by two axons).⁷ However, the transition from multiple to single innervation at the NMJ occurs within few days.⁷ The motor nerve ending branches to form a complex of nerve terminals that invaginate into the skeletal muscle fiber but lie outside the sarcolemma. As each motor neuron approaches its target muscle fiber, it loses its myelin sheath and makes a contact with a single muscle fiber to form an NMJ. The naked motor nerve terminal that is not in contact with the muscle fiber is capped by Schwann cells, providing it with physical integrity by insulating it from the environment and supplying it with nutrients and removing waste products. The importance of glial (Schwann) cells for development, survival, and repair of several aspects of NMJ is addressed elsewhere.^{1,8}

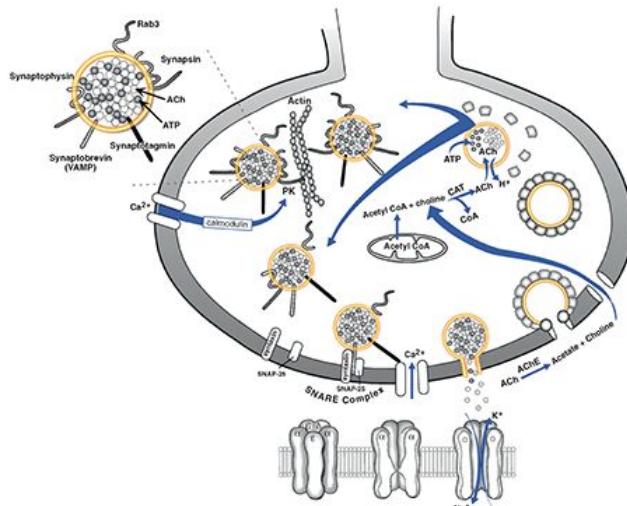

FIGURE 11.2 The synaptic vesicle (SV) exocytosis-endocytosis cycle. After an action potential and calcium ion (Ca^{2+}) influx, phosphorylation of synapsin is activated by calcium-calmodulin activated protein kinases I and II. This results in the mobilization of SVs from the cytomatrix toward the plasma membrane. The formation of the soluble N-ethylmaleimide sensitive factor (NSF) attachment **protein** receptor (SNARE) complex is an essential step for the docking process. After fusion of SVs with the presynaptic plasma membrane, acetylcholine (ACh) is released into the synaptic cleft. Some of the released ACh molecules bind to the nicotinic acetylcholine receptors on the postsynaptic membrane, whereas the rest is rapidly hydrolyzed by the acetylcholinesterase (AChE) present in the synaptic cleft to choline and acetate. Choline is recycled into the terminal by a high-affinity uptake system, making it available for the resynthesis of ACh. Exocytosis is followed by endocytosis in a process dependent on the formation of a clathrin coat and of action of dynamin. After recovering of SV membrane, the coated vesicle uncoats and another cycle starts again. See text for details. Abbreviations: ATP, adenosine triphosphate; CAT, choline acetyltransferase; CoA, coenzyme A; H^+ , hydrogen ion; K^+ , potassium ion; Na^+ , sodium ion; PK, protein kinase; SNAP-25, synaptosomal nerve-associated protein 25 kDa; VAMP, vesicle-associated membrane protein. The NMJ is designed to transmit electrical impulses from the nerve terminal to the skeletal muscle via the chemical transmitter, acetylcholine. Structurally, the NMJ is consisted of a three components: (1) the *presynaptic* (or prejunctional) nerve terminal containing synaptic vesicles (SVs) (filled with acetylcholine) and mitochondria; (2) the *synaptic cleft* that contains basal lamina to which acetylcholinesterase enzyme responsible for hydrolysis of free acetylcholine is attached; and (3) the *postsynaptic* (or postjunctional) muscle membrane that opposes the nerve terminal is highly infolded and these folds are called secondary folds (or secondary postsynaptic cleft). Membrane infoldings increase the surface area of the muscle plasma membrane in the postsynaptic region (see [Figure 11.6](#)). The nAChRs are concentrated at the crests of these folds (directly opposing the *active zones* of the presynaptic membrane in which SVs are clustered), and voltage-gated sodium channels are present in the troughs of the folds.

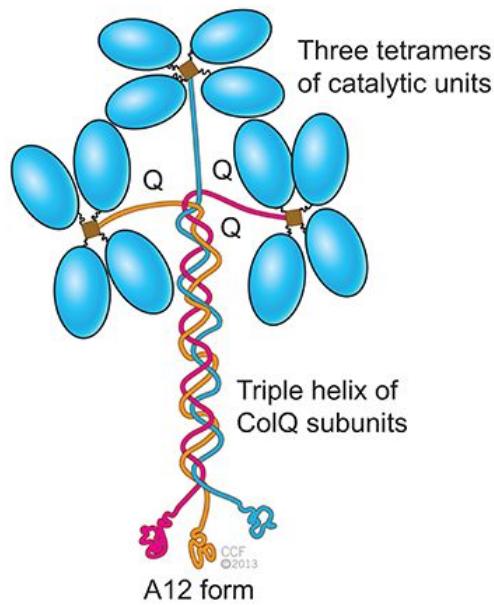

FIGURE 11.3 Structure of acetylcholinesterase.

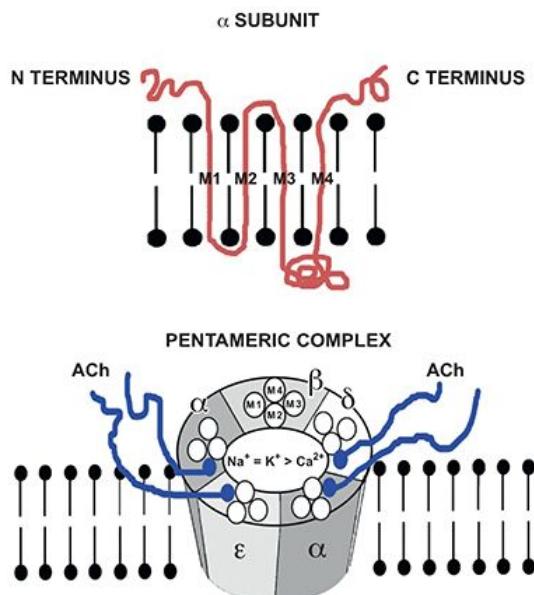

FIGURE 11.4 Subunit composition of the nicotinic acetylcholine receptor (nAChR) in the endplate surface of adult mammalian muscle. The adult AChR is an intrinsic membrane protein with five distinct subunits ($\alpha\beta\delta\epsilon$). Each subunit contains four helical domains labeled M1 to M4. The M2 domain forms the channel pore. The upper panel shows a single α subunit with its N and C termini on the extracellular surface of the membrane lipid bilayer. Between the N and C termini, the α subunit forms four helices (M1, M2, M3, and M4), which span the membrane bilayer. The lower panel shows the pentameric structure of the nAChR of adult mammalian muscle. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine (ACh). These pockets occur at the ϵ - α and the δ - α subunit interface. The M2 membrane spanning domain of each subunit lines the ion channel. The doubly liganded ion channel has equal permeability to sodium ion (Na^+) and potassium ion (K^+); calcium ion (Ca^{2+}) contributes approximately 2.5% to the total permeability. The plasticity of neuromuscular transmission is dependent on a highly orchestrated mechanism involving (1) synthesis, storage, and release of acetylcholine from the presynaptic region at the NMJ; (2) binding of acetylcholine to nicotinic receptors on the muscle membrane (postsynaptic region) and generation of action potentials; (3) rapid hydrolysis of acetylcholine by the enzyme acetylcholinesterase, which is

present in the synaptic cleft; and (4) adaptation of the muscle contractile proteins to functional demands.¹ Synaptic plasticity is the “ability of individual synaptic junctions to respond [ie, to change in strength in response] to either use or disuse.”⁹

Presynaptic Region

Synaptic Vesicles

The SVs are specialized secretory organelles (see [Figure 11.2](#)). The SVs are synthesized in the neuronal cell body in the endoplasmic reticulum and transported to the nerve terminal via the microtubule system. The SVs are then loaded with acetylcholine in the motor nerve endings. Acetylcholine is first synthesized in the cytoplasm of the nerve terminal from acetyl coenzyme A and choline in a reaction catalyzed by the soluble enzyme choline acetyltransferase. An energy-dependent “transporter” then accumulates acetylcholine within vesicles. Each vesicle contains 5,000 to 10,000 molecules of acetylcholine. The acetylcholine contained in a single vesicle is often referred to as a “quantum” of transmitter. The SVs possess a diverse set of specialized proteins that can be divided into two functional classes: proteins involved in the uptake of neurotransmitters (transport proteins) and proteins that mediate SV membrane traffic such as docking, fusion, and budding (for review, see Naguib et al¹). Calcium ion signaling plays a pivotal role in the process of acetylcholine vesicles exocytosis (see [Figure 11.2](#)). There are two pools of vesicles that differ in the probability of mobilization to the active site: a readily releasable store (active pool) and a reserve store. The active pool is aligned near the active zones.

The miniature endplate potential amplitude represents the depolarization of the postsynaptic membrane produced by the contents of a single vesicle. The endplate potential results from summation of miniature endplate potential produced by acetylcholine contents of ~50 to 300 SVs. Nearly 50% of the released acetylcholine is rapidly hydrolyzed by the acetylcholinesterase during diffusion across the synaptic cleft before reaching the postsynaptic receptors. The products of this hydrolysis are choline and acetate. Choline is recycled into the terminal by a high-affinity uptake system, making it available for the resynthesis of acetylcholine. After exocytosis, the membrane components of the SVs are recovered by endocytosis and recycled for future use.

Synaptic Cleft

The synaptic cleft is ~20 to 50 nm wide. It separates nerve and muscle fiber plasma membranes and is encompasses the synaptic basal lamina and is filled with extracellular fluid. Acetylcholinesterase enzyme is bound to the basal lamina at the cleft ([Figure 11.3](#)).

Acetylcholinesterase ranks as one of the most efficient catalytic processes known. The efficiency of acetylcholinesterase depends on its fast activity. It can catalyze acetylcholine hydrolysis (4,000 molecules of acetylcholine hydrolyzed per active site per second) at near diffusion-limited rates.¹⁰ Acetylcholinesterase is highly concentrated at the NMJ but present in a lower concentration throughout the length of muscle fibers.¹¹ Acetylcholinesterase is regulated, in part, by muscle activity and by the spontaneous or nerve-evoked depolarization of the plasma membrane.¹² After denervation, there is a large decrease in the density of acetylcholinesterase molecules. In addition to hydrolysis of acetylcholine, acetylcholinesterase has other functions such as nerve growth-promoting activities¹³ and modulation of nAChRs.

The Nicotinic Acetylcholine Receptor at the Neuromuscular Junction

In the adult mammalian skeletal muscle, the nAChRs are highly concentrated (~10,000/ μm^2) at the crests of junctional folds and in close proximity to acetylcholine-releasing sites. The AChR expression and clusters are both regulated by positive and negative signals from the nerve and muscle. The nAChR is a pentameric complex of two α subunits in association with a single β , δ , and ϵ subunit ([Figure 11.4](#)). These subunits are organized to form a transmembrane pore (a channel) as well as the extracellular binding pockets for acetylcholine and other agonists or antagonists.¹ Each of the two α subunits has an acetylcholine-binding site. These sites are proteins located in pockets approximately 3.0 nm above the surface membrane at the interfaces of the α - ϵ and α - δ subunits.¹⁴ The fetal nAChRs are different from postnatal ones in composition

and electric properties. It contains a γ subunit instead of an ϵ adult subunit. The mature nAChR has shorter burst duration and a higher conductance to sodium ion, potassium ion (K^+), and calcium ion than the fetal nAChR.^{1,15}

The fetal nAChR is a low-conductance channel in contrast to the high-conductance channel of the adult nAChR ([Figure 11.5](#)). Thus, acetylcholine release causes brief activation and reduced probability of channel opening.¹ Upregulation of nAChRs, found in states of functional or surgical denervation, is characterized by the spreading of predominantly fetal type nAChRs. These receptors are resistant to nondepolarizing neuromuscular blockers and more sensitive to succinylcholine (SCh).¹⁶ When depolarized, the immature isoform has a prolonged open channel time that exaggerates the K^+ efflux.¹⁷

Simultaneous binding of two acetylcholine molecules to the extracellular N-terminal domain of the two α subunits of nAChRs initiates conformational changes that open a channel through the center of the receptor, allowing sodium and calcium ions to move into the skeletal muscle and K^+ to leave. Each NMJ contains several million postjunctional receptors, and a burst of acetylcholine from the nerve ending opens at least 400,000 receptors. As a result, sufficient current flows through these open receptors to depolarize the endplate and create the action potential that triggers contraction of the skeletal muscle. It is the flow of ions that is the basis of normal neuromuscular transmission.

The two α subunits, in addition to being the binding sites for acetylcholine, are occupied by neuromuscular-blocking drugs. Nondepolarizing neuromuscular-blocking drugs bind to one or both α subunits but, unlike acetylcholine, lack agonist activity (competitive blockade). As a result, conformational changes do not occur, and the receptor channel remains closed. Therefore, ions do not flow through these channels, and depolarization cannot occur at these sites. If enough channels remain closed, there is blockade of neuromuscular transmission. A nondepolarizing neuromuscular-blocking drug may show preference for one of the two α subunits. This may result in synergism if two nondepolarizing neuromuscular-blocking drugs with different selective preferences for each α subunit are administered simultaneously.^{18,19} The probability of binding is dependent on the concentration of acetylcholine and nondepolarizing neuromuscular-blocking drug at the receptor and the affinity of the receptor for the neurotransmitter or drug. When the neuromuscular-blocking drug diffuses from the nAChRs, the probability of receptor binding of acetylcholine increases, and the effect of the nondepolarizing neuromuscular-blocking drug decreases.

The SCh, which is structurally two molecules of acetylcholine bound together, is a partial agonist at nAChRs and depolarizes (opens) the ion channels. This opening requires the binding of only one molecule of SCh to the α subunit. The other α subunit can be occupied by either acetylcholine or SCh. Because SCh is not hydrolyzed by acetylcholinesterase, the channel remains open for a longer period of time than would be produced by acetylcholine, resulting in a depolarizing block (sustained depolarization prevents propagation of an action potential). Furthermore, SCh can diffuse from nAChRs and repeatedly bind to other nAChRs until it is cleared from the area of the NMJ and is exposed to hydrolysis by plasma cholinesterase. Plasma cholinesterase has a distinct molecular structure and function from acetylcholinesterase.

Large doses of nondepolarizing neuromuscular-blocking drugs may also prevent normal flow of ions by entering the channels formed by nAChRs to produce blockade within the channel. Similar blockade of sodium ion channels is produced by local anesthetics.

Neuromuscular Transmission and Excitation-Contraction Coupling

- 1. Motor nerve**
 - a.** Depolarization of the motor nerve will open the voltage-gated calcium ion channels that trigger both mobilization of SVs and the fusion machinery in the nerve terminal to release acetylcholine.
 - b.** Several forms of K^+ channel present in the nerve terminal serve to limit the extent of calcium ion entry and transmitter release (ie, initiate repolarization of nerve terminal).²⁰
- 2. Muscle**
 - a.** The released acetylcholine binds to α subunits of the nAChRs. These ligand-gated cation channels open almost instantaneously when two acetylcholine molecules bind cooperatively to sites on the

extracellular surface of the protein, causing a conformational shift in the subunits. When the channel opens, sodium ions flow down their electrochemical gradient and into the muscle cell and depolarize the muscle cell membrane at the NMJ, whereas potassium simultaneously exits the cytosol of the fiber.^{20,21}

- b.** This depolarization activates voltage-gated sodium channels that present in the muscle membrane, which mediate the initiation and propagation of action potentials across the surface of the muscle membrane and into the transverse tubules (T tubules) resulting in the upstroke of the action potential.^{20,21,22}
- c.** There are two types of calcium channels, dihydropyridine receptor (DHPR) in the T tubules and the ryanodine receptor 1 (RyR1) in the sarcoplasmic reticulum (SR) (**Figure 11.6**). The DHPRs act as “voltage sensors”^{23,24} and are activated by membrane depolarization, which in turn activate RyR1 receptors.
- d.** DHPR-RyR1 interaction²⁵ releases large amounts of calcium ion from the SR that result in a transient increase in myoplasmic free calcium ion, which binds to troponin C. This initiates movement of tropomyosin on the thin filament (actin) and allows cross-bridges between the myosin with the binding sites on actin, which eventually result in force development. This process is known as excitation-contraction coupling (**Figure 11.7**).²⁶ Shortly after releasing calcium, the SR begins to reaccumulate this ion by an active transport process (calcium pump). This transport mechanism can concentrate calcium up to 2,000-fold inside the SR. Adenosine triphosphate provides the energy for calcium ion transport. Once the calcium concentration in the sarcoplasm has been lowered sufficiently, cross-bridging between myosin and actin ceases and the skeletal muscle relaxes. Failure of the calcium ion pump results in sustained skeletal muscle contraction and marked increases in heat production, leading to malignant hyperthermia. The gene for this calcium ion channel (RyR1) is on chromosome 19. Mutations in this gene are associated with malignant hyperthermia susceptibility in some patients.
- e.** Repolarization of the muscle membrane is initiated by the closing of the sodium channels and by the opening of K⁺ channel that conduct an outward K⁺ current.²⁷
- f.** The return of the muscle membrane potential to its resting level (approximately –70 to –90 mV) is achieved by allowing chloride (Cl[–]) to enter the cell through voltage-sensitive chloride channels.²⁰

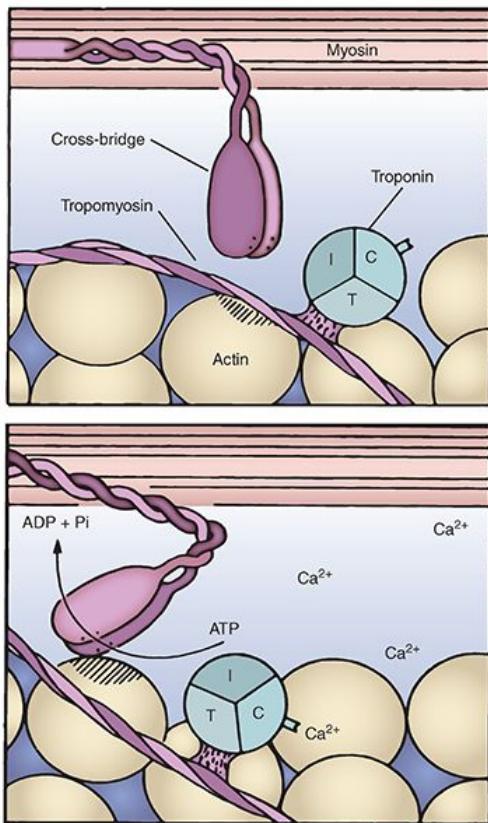

FIGURE 11.7 Contraction of skeletal muscle is initiated by attachment of calcium ions (Ca^{2+}) to troponin, leading to hydrolysis of adenosine triphosphate (ATP) and cross-bridging between actin and myosin. Abbreviation: ADP, adenosine diphosphate; Pi, inorganic phosphate. Republished with permission of McGraw Hill LLC from Ganong WF. Review of Medical Physiology, 21st ed. Blood Flow

Skeletal muscle blood flow can increase more than 20 times (a greater increase than in any other tissue of the body) during strenuous exercise.²⁸ At rest, only 20% to 25% of the capillaries are open, and skeletal muscle blood flow is 3 to 4 mL/100 g/min. During strenuous exercise, almost all skeletal muscle capillaries become patent. Opening of previously collapsed capillaries diminishes the distance that oxygen and other nutrients must diffuse from capillaries to skeletal muscle fibers and contributes an increased surface area through which nutrients can diffuse from blood. Presumably, exercise lowers the local concentration of oxygen, which in turn causes vasodilation because the vessel walls cannot maintain contraction in the absence of adequate amounts of oxygen. Alternatively, oxygen deficiency may cause release of vasodilator substances such as K^+ and adenosine. The increase in cardiac output that occurs during exercise results principally from local vasodilation in active skeletal muscles and subsequent increased venous return to the heart.

Exercise is associated with a centrally mediated stimulation of the sympathetic nervous system manifesting as vasoconstriction in nonmuscular tissues and increases in systemic blood pressure. Excessive increases in systemic blood pressure, however, are prevented by vascular vasodilation that occurs in the large tissue mass represented by skeletal muscles. Exceptions to nonmuscular tissue vasoconstriction induced by exercise are the coronary and cerebral circulations. This is teleologically understandable because the heart and brain are essential to the response to exercise, as are the skeletal muscles.

Smooth Muscle

Smooth muscle is distinguished anatomically from skeletal and cardiac muscle because it lacks visible cross-striations (actin and myosin are not arranged in regular arrays). Smooth muscle is categorized as *multiunit* or *visceral* smooth muscle. Multiunit smooth muscle contraction is controlled almost exclusively by nerve signals, and spontaneous contractions rarely occur. Examples of multiunit smooth muscles are the ciliary muscles of the eye, iris of the eye, and smooth muscles of many large blood vessels. Smooth muscle must develop force or shorten to provide motility or to alter the dimensions of an organ.

Smooth muscle cells lack T tubules that provide electrical links to SR. However, the sarcolemma of smooth muscle contains saclike invaginations (caveoli) that may be sites where calcium ions enter the cells through voltage-gated calcium ion channels. Calcium ions are released from the SR into the myoplasm when stimulatory neurotransmitters, hormones, or drugs bind to receptors on the sarcolemma. Calcium ion channels on the SR of smooth muscles include RyR1 (similar to those present in skeletal muscles) and inositol 1,4,5-triphosphate (IP_3)-gated calcium ion channels. Neurotransmitters or hormones that act via receptors in the sarcolemma can activate phospholipase C followed by the generation of the second messenger IP_3 . The IP_3 channels are activated when hormones bind to calcium-mobilizing receptors in the SR in smooth muscle cells.

Visceral smooth muscle is characterized by cell membranes that contact adjacent cell membranes, forming a functional syncytium that often undergoes spontaneous contractions as a single unit in the absence of nerve stimulation. These spontaneous action potentials are particularly prominent in tubular structures, accounting for peristaltic motion in sites such as the bile ducts, ureters, and gastrointestinal tract, especially when they are distended. Plateaus in the action potentials of visceral smooth muscle lasting up to 30 seconds may occur in the ureters and uterus. The normal resting transmembrane potential is approximately -60 mV , which is approximately 30 mV less negative than in skeletal muscles.

In addition to stimulation in the absence of extrinsic innervation, smooth muscles are unique in their sensitivity to hormones or local tissue factors. For example, smooth muscle spasm may persist for hours in response to norepinephrine or antidiuretic hormone, whereas local factors such as lack of oxygen or accumulation of hydrogen ions cause vasodilation. It is believed that local factors and hormones cause smooth muscle contraction by activating the calcium ion transport mechanism. Drugs relax smooth muscle by increasing the intracellular concentration of cyclic adenosine monophosphate or cyclic guanosine monophosphate.

Mechanism of Contraction

Smooth muscles contain both actin and myosin. Smooth muscles are different from skeletal muscles: They are innervated by autonomic neurons and they lack troponin. In contrast to skeletal muscles, in which calcium binds to troponin to initiate cross-bridging, in smooth muscle, the calcium-calmodulin complex activates the enzyme necessary for phosphorylation of myosin. This myosin has ATPase activity, and actin then slides on myosin to produce contraction.

The source of calcium in smooth muscle differs from that in skeletal muscle because the SR of smooth muscle is poorly developed. Most of the calcium that causes contraction of smooth muscles enters from extracellular fluid at the time of the action potential. The time required for this diffusion is 200 to 300 milliseconds, which is approximately 50 times longer than for skeletal muscles. Subsequent relaxation of smooth muscles is achieved by a calcium ion transport system that pumps these ions back into extracellular fluid or into the SR. This calcium ion pump is slow compared with the SR pump in skeletal muscles. As a result, the duration of smooth muscle contraction is often seconds rather than milliseconds as is characteristic of skeletal muscles.

Smooth muscles, unlike skeletal muscles, do not atrophy when denervated, but they do become hyperresponsive to the normal neurotransmitter. This denervation hypersensitivity is a general phenomenon that is largely due to synthesis or activation of more receptors.²⁹

An NMJ that is similar to that present on skeletal muscles does not occur in smooth muscles. Instead, nerve fibers branch diffusely on top of a sheet of smooth muscle fibers without making actual contact. These nerve fibers secrete their neurotransmitter into an interstitial fluid space a few microns from the smooth muscle cells. Two different neurotransmitters, acetylcholine and norepinephrine, are secreted by the

autonomic nervous system nerves that innervate smooth muscles. Acetylcholine is an excitatory neurotransmitter for smooth muscles at some sites and functions as an inhibitory neurotransmitter at other sites. Norepinephrine exerts the reverse effect of acetylcholine.

Uterine Smooth Muscle

Uterine smooth muscle is characterized by a high degree of spontaneous electrical and contractile activity. Unlike the heart, there is no pacemaker, and the contraction process spreads from one cell to another at a rate of 1 to 3 cm/s. Contractions of labor result in peak intrauterine pressures of 60 to 80 mm Hg in the second stage. Resting uterine pressure during labor is approximately 10 mm Hg. Movement of sodium ions appears to be the primary determinant in depolarization, whereas calcium ions are necessary for excitation-contraction coupling. Availability of calcium ions greatly influences the response of uterine smooth muscle to physiologic and pharmacologic stimulation or inhibition. α Excitatory and β inhibitory receptors are also present in the myometrium.

Neuromuscular-Blocking Drugs and Reversal Agents

Mohamed A. Naguib[†]

The first successful administration of curare, a neuromuscular-blocking drug (NMBD) to produce surgical relaxation in an anesthetized patient, was reported in 1912, when Arthur Läwen, a German surgeon from Leipzig, used a partially purified preparation of the substance.¹ Läwen's findings were subsequently ignored for nearly three decades until January 23, 1942, when Enid Johnson, following Harold Griffith's instructions, administered 5 mL of curare intravenously to a 20-year-old man who had been anesthetized with cyclopropane via a facemask for an appendectomy. The use of NMBDs in clinical anesthesia has increased exponentially since that time.

The NMBDs that are currently available for clinical use are classified as (1) **depolarizing** NMBDs or (2) **nondepolarizing** NMBDs (**Table 12.1**). Nondepolarizing NMBDs compete with acetylcholine for the active binding sites at the postsynaptic nicotinic acetylcholine receptor and are also called competitive antagonists. Depolarizing NMBDs act as agonists (ie, they are similar in structure to acetylcholine) at postsynaptic nicotinic acetylcholine receptors and cause prolonged membrane depolarization resulting in neuromuscular blockade. Succinylcholine is the only depolarizing NMBD currently in clinical use.

TABLE 12.1

Classification of commonly used and new nondepolarizing neuromuscular-blocking drugs according to duration of action (time to T₁ = 25% of control) after administration of 2 times ED₉₅^{a,b}

	Duration of action		
	Long (>50 min)	Intermediate (20-50 min)	Short (10-20 min)
Steroidal compounds	Pancuronium	Vecuronium Rocuronium	—
Benzylisoquinolinium compounds	Tubocurarine	Atracurium Cisatracurium	Mivacurium

^aED₉₅ is the dose that results in 95% depression of twitch height.

^bThe majority of nondepolarizing neuromuscular-blocking drugs are bisquaternary ammonium compounds. Tubocurarine, vecuronium, and rocuronium are monoquaternary compounds.

Principles of Action of Neuromuscular-Blocking Drugs at the Neuromuscular Junction

In the resting state, the ion channel of the acetylcholine receptor is closed. Simultaneous binding of two acetylcholine molecules to the α subunits initiates conformational changes that open the channel. On the other hand, binding of a single molecule of a nondepolarizing NMBD (a competitive antagonist) to one α subunit is sufficient to produce neuromuscular block (see [Chapter 11](#)).

Succinylcholine produces prolonged depolarization of the endplate region that results in desensitization of nicotinic acetylcholine receptors, inactivation of voltage-gated sodium channels at the neuromuscular junction, and increases in potassium permeability in the surrounding membrane. These electrophysiologic changes will result in membrane hyperpolarization, inhibition of action potential generation, and neuromuscular transmission blockade.

With respect to neuromuscular pharmacology, two enzymes of importance are known to hydrolyze choline esters: acetylcholinesterase and butyrylcholinesterase. Acetylcholinesterase (similar to red cell cholinesterase and also known as "true" cholinesterase) is present at the neuromuscular junction and is

responsible for the rapid hydrolysis of released acetylcholine to acetic acid and choline. Butyrylcholinesterase (also known as plasma cholinesterase or pseudocholinesterase) is synthesized in the liver. Butyrylcholinesterase catalyzes the hydrolysis of succinylcholine, which occurs mainly in the plasma. Plasma cholinesterase also metabolizes mivacurium, cocaine, procaine, and chloroprocaine.

Pharmacology of Succinylcholine

Succinylcholine is the only depolarizing NMBD in clinical use. This compound is also called suxamethonium. Depolarizing block (also called phase I block) is often preceded by muscle fasciculation. The clinical presentation of fasciculations noted after succinylcholine administration is variable (in location and severity) among patients.² The most plausible explanation of succinylcholine-induced fasciculations is that it results from antidromic (retrograde) conduction of action potentials that can activate unparalyzed parts of the motor unit.³ The administration of a small dose of nondepolarizing neuromuscular blocker (precurarization) to prevent a succinylcholine-induced side effects, such as an increase in intraocular pressure, has not been consistently proven in different studies.

Structure-Activity Relationships for Succinylcholine

Succinylcholine is a long, thin, flexible molecule composed of two molecules of acetylcholine linked through the acetate methyl groups. Like acetylcholine, succinylcholine stimulates cholinergic receptors at the neuromuscular junction and at nicotinic (ganglionic) and muscarinic autonomic sites (resulting in side effects that include increased intraocular pressure and intragastric pressure), opening the ionic channel in the acetylcholine receptor, resulting, for example, in cardiac arrhythmias.

Pharmacokinetics, Pharmacodynamics, and Pharmacogenomics of Succinylcholine

Succinylcholine has an elimination half-life of 47 seconds.⁴ The elimination of succinylcholine appears to follow first-order kinetics.^{4,5} The $t_{1/2}$, k_{e0} and Hill coefficient (after fitting two doses of 1 mg/kg succinylcholine) were 244 seconds (standard deviation 157) and 7.9 (standard deviation 3.3), respectively.⁴ The dose of succinylcholine causing on average 95% suppression of twitch height (the ED₉₅) is approximately 0.3 mg/kg.^{6,7}

The usual dose of succinylcholine required for tracheal intubation in adults is 1.0 mg/kg. Administration of succinylcholine 1 mg/kg (3 times the ED₉₅) results in complete suppression of response to neuromuscular stimulation in approximately 60 seconds. In patients with genotypically normal butyrylcholinesterase activity, time to recovery to 90% muscle strength following administration of 1 mg/kg succinylcholine ranges from 9 to 13 minutes.^{8,9} In one study, administration of 0.6 mg/kg of succinylcholine resulted in acceptable intubating conditions at 60 seconds in 95% of patients.¹⁰ The reported proportions of patients with acceptable intubating conditions after administration of 1.0 mg/kg succinylcholine vary from 91.8% to 97%.^{11–13} It also appears that there are no advantages to using succinylcholine doses larger than 1.5 mg/kg in a rapid sequence induction of anesthesia. Paradoxically, succinylcholine doses as large as 2.0 mg/kg (6 times the ED₉₅) guaranteed excellent intubating conditions at 60 seconds in only 86.7% of patients.¹⁴ There is no dose of succinylcholine that can assure 90% excellent conditions in 60 seconds. It should be noted that the adequacy of intubating conditions is related not only to the use of an NMBD but also to the depth of anesthesia, airway anatomy, and the experience of the anesthesiologist.

The short duration of action of succinylcholine is due to its rapid hydrolysis by butyrylcholinesterase (plasma cholinesterase) to succinylmonocholine and choline, such that only 10% of the administered drug reaches the neuromuscular junction. Succinylmonocholine, a metabolite of succinylcholine, is a much weaker neuromuscular-blocking agent than succinylcholine and is metabolized much more slowly to succinic acid and choline.

There is little or no butyrylcholinesterase at the neuromuscular junction. Butyrylcholinesterase influences the onset and duration of action of succinylcholine by controlling the rate at which the drug is hydrolyzed in the plasma before it reaches, and after it leaves, the neuromuscular junction. Recovery from

succinylcholine-induced blockade occurs as succinylcholine diffuses away from the neuromuscular junction, down a concentration gradient as the plasma concentration decreases.

Factors Affecting Butyrylcholinesterase Activity

Butyrylcholinesterase is synthesized by the liver and found in the plasma. The elimination half-time of plasma cholinesterase is 8 to 16 hours, and levels of <75% are necessary for prolongation of succinylcholine effect. Butyrylcholinesterase is responsible for metabolism of succinylcholine, mivacurium, procaine, chloroprocaine, tetracaine, cocaine, and heroin. Neuromuscular block induced by succinylcholine or mivacurium is prolonged when there is a significant reduction in the concentration or activity of butyrylcholinesterase. The activity of the enzyme refers to the number of substrate molecules (μmol) hydrolyzed per unit of time, often expressed in international units.

Factors that have been described as lowering butyrylcholinesterase activity are advanced liver disease, advanced age, malnutrition, pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, anticholinesterase drugs, metoclopramide, and bambuterol. The β -blocker esmolol inhibits butyrylcholinesterase but causes only a minor prolongation of succinylcholine block. In severe liver disease, plasma cholinesterase activity is reduced to 20% of normal resulting in an increase of duration of apnea after the administration of succinylcholine from a normal duration of 3 minutes to only 9 minutes. When glaucoma is treated with echothiophate, plasma cholinesterase activity was noted to decrease from 49% of control to no activity. The increase in duration of succinylcholine-induced neuromuscular blockade was noted but in no patient did the total duration exceed to 23 minutes.¹⁵

Neostigmine (and to a lesser degree edrophonium) causes a profound decrease in butyrylcholinesterase activity. Even 30 minutes after administration of neostigmine, the butyrylcholinesterase activity remains about 50% of control values. Potent anticholinesterase drugs used in insecticides and occasionally in the treatment of glaucoma and myasthenia gravis, as well as chemotherapeutic drugs (nitrogen mustard and cyclophosphamide), may decrease butyrylcholinesterase activity so that prolonged neuromuscular blockade follows administration of succinylcholine. High estrogen levels, as observed in parturients at term, are associated with up to 40% decreases in butyrylcholinesterase activity. Paradoxically, the duration of action of succinylcholine-induced skeletal muscle paralysis is not prolonged, presumably reflecting an increased volume of distribution of the drug at term.

Genetic Variants of Butyrylcholinesterase

Neuromuscular block induced by succinylcholine or mivacurium can be significantly prolonged if the patient has an abnormal genetic variant of butyrylcholinesterase. Analysis of butyrylcholinesterase involves the determination of both enzyme activity and biochemical phenotypes. Phenotype is determined by the use of specific enzyme inhibitors (such as dibucaine or fluoride) that produce phenotype-specific patterns of dibucaine or fluoride numbers (**Table 12.2**). Molecular genetic analyses can determine the true genotypes.

TABLE 12.2 Relationship between dibucaine number and duration of succinylcholine or mivacurium neuromuscular block				
Type of butyrylcholinesterase	Genotype	Incidence	Dibucaine number ^a	Response to succinylcholine or mivacurium
Homozygous typical	$E_1^uE_1^u$	Normal	70-80	Normal
Heterozygous atypical	$E_1^uE_1^a$	1/480	50-60	Lengthened by 50%-100%
Homozygous atypical	$E_1^aE_1^a$	1/3,200	20-30	Prolonged to 4-8 hours

^aThe dibucaine number indicates the percentage of enzyme inhibited.

Dibucaine, a local anesthetic with an amide linkage, inhibits the activity of normal butyrylcholinesterase by more than 70%, compared with only approximately 20% inhibition of the activity of atypical enzyme. It is important to recognize that the dibucaine number reflects quality of cholinesterase enzyme (ability to

hydrolyze succinylcholine) and not the quantity of the enzyme that is circulating in the plasma. In case of the usual butyrylcholinesterase genotype ($E_1^uE_1^u$), the dibucaine number is 70 or higher, whereas in individuals homozygous for the atypical gene ($E_1^aE_1^a$) (frequency in general population of 1 in 3,500), the dibucaine number is less than 30. In individuals with the heterozygous atypical variant ($E_1^uE_1^a$) (frequency in general population of 1 in 480), the dibucaine number is in the range of 40 to 60.^{16,17} In individuals with the homozygous atypical genotype ($E_1^aE_1^a$), the neuromuscular block induced by succinylcholine or mivacurium is prolonged to 4 to 8 hours, and in individuals with the heterozygous atypical genotype ($E_1^uE_1^a$), the period of neuromuscular block induced by succinylcholine or mivacurium is about 1.5 to 2 times that seen in individuals with the usual genotype ($E_1^uE_1^u$). For a recent review, please see Delacour et al.¹⁸ The longest period of apnea after the administration of succinylcholine was found in patients homozygous for the silent gene ($E_1^sE_1^s$). In those patients, train-of-four (TOF) stimulation will help in detecting the development of phase II block. The decision whether to attempt antagonism of a phase II block has always been controversial, and the use edrophonium or neostigmine do not consistently result in adequate antagonism of neuromuscular blockade.¹⁹ The alternative is to keep the patient adequately sedated and maintain artificial ventilation until the train-of-four ratio (TOFR) has recovered to 0.9 or more.

Fluoride-resistant butyrylcholinesterase variants have also been described. In case of the usual butyrylcholinesterase genotype ($E_1^uE_1^u$), the fluoride number is 60, whereas in individuals with the homozygous atypical genotype ($E_1^fE_1^f$), the fluoride number is 36.²⁰ Individuals with homozygous fluoride-resistant genotype exhibit mild to moderate prolongation of succinylcholine-induced paralysis. The heterozygous fluoride-resistant genotype usually produces clinically insignificant prolongation of succinylcholine block, unless accompanied by a second abnormal allele or by a coexisting acquired cause of butyrylcholinesterase deficiency.

Although the dibucaine or fluoride number indicates the genetic makeup of an individual with respect to butyrylcholinesterase, it does not measure the concentration of the enzyme in the plasma, nor does it indicate the efficiency of the enzyme in hydrolyzing succinylcholine or mivacurium. Both of these latter factors are determined by measuring butyrylcholinesterase activity—which may be influenced by genotype.

Some rare butyrylcholinesterase variants are associated with increased enzyme activity (2-3 times normal).²¹ Resistance to succinylcholine²² and mivacurium²³ as a result of increased butyrylcholinesterase activity has been described.

Side Effects of Succinylcholine

Cardiovascular Effects

Sinus bradycardia, junctional rhythm, and even sinus arrest may follow administration of succinylcholine. These cardiac effects reflect the actions of succinylcholine at cardiac muscarinic cholinergic receptors where the drug mimics the physiologic effects of acetylcholine. Cardiac dysrhythmias are most likely to occur when a second dose of succinylcholine is administered approximately 5 minutes after the first dose. Sinus bradycardia (resulting from stimulation of cardiac muscarinic receptors) is frequently seen in children²⁴ and in adults after a repeated dose of succinylcholine.²⁵ Atropine is effective in treating or preventing bradycardia.

In contrast to actions at cardiac muscarinic cholinergic receptors, the effects of succinylcholine at autonomic nervous system ganglia may produce ganglionic stimulation and associated increases in heart rate and systemic blood pressure. The ganglionic stimulation reflects an effect of succinylcholine on autonomic ganglia that resembles the physiologic effect of acetylcholine at these sites. Ventricular dysrhythmias after succinylcholine administration have been attributed to autonomic stimuli associated with laryngoscopy and tracheal intubation.²⁶

Hyperkalemia

The administration of succinylcholine is associated with approximately 0.5 mEq/dL increase in the plasma potassium concentration in healthy individuals, which is well tolerated and generally does not cause dysrhythmias. Patients with renal failure are no more susceptible to an exaggerated hyperkalemic response to succinylcholine than patients with normal renal function.^{27,28}

Succinylcholine has been associated with severe hyperkalemia in patients with burn, severe abdominal infections,²⁹ severe metabolic acidosis,³⁰ closed head injury,³¹ or conditions associated with upregulation of extrajunctional acetylcholine receptors (eg, hemiplegia or paraplegia, muscular dystrophies, Guillain-Barré syndrome, and burn). For reviews, see Naguib et al³² and Martyn and Richtsfeld.³³ Because of the risk of massive rhabdomyolysis, hyperkalemia, and death in children with undiagnosed muscle disease, succinylcholine is not recommended for use in children except for emergency tracheal intubation.³⁴⁻³⁶

Myoglobinuria

Damage to skeletal muscles is suggested by the occurrence of myoglobinuria after administration of succinylcholine, especially to pediatric patients.³⁷ It is unlikely that succinylcholine-induced fasciculations could produce muscle damage resulting in myoglobinuria.

Most of the patients with rhabdomyolysis and myoglobinuria were subsequently found to have malignant hyperthermia or occult muscular dystrophy.

Increased Intraocular Pressure

Succinylcholine usually causes an increase in intraocular pressure. The intraocular pressure peaks at 2 to 4 minutes after administration and returns to normal by 6 minutes.³⁸ This increase is likely the result of contraction of tonic myofibrils and/or transient dilatation of choroidal blood vessels. The use of succinylcholine is not widely accepted in open eye injury (when the anterior chamber is open) even though succinylcholine was shown to cause no adverse events in a series of 73 patients with penetrating eye injuries.³⁹ The efficacy of precurarization in attenuating increases in intraocular pressure following succinylcholine administration is controversial.⁴⁰⁻⁴²

Increased Intragastric Pressure

Administration of succinylcholine is associated with a variable increase in intragastric and lower esophageal sphincter pressures. The increase in intragastric pressure appears to be related to (1) the intensity of fasciculations of the abdominal skeletal muscles,⁴³ which could be prevented by prior administration of a nondepolarizing NMBD and (2) a direct increase in vagal tone. Administration of succinylcholine does not predispose to regurgitation in patients with an intact lower esophageal sphincter because the increase in intragastric pressure does not exceed the “barrier pressure.”⁴⁴

Increased Intracranial Pressure

Succinylcholine has the potential to increase intracranial pressure. This increase can be attenuated or prevented by pretreatment with a nondepolarizing NMBD.

Myalgias

Postoperative skeletal muscle myalgia, which is particularly prominent in the skeletal muscles of the neck, back, and abdomen, can occur after administration of succinylcholine, especially to young adults undergoing minor surgical procedures that permit early ambulation. Myalgia localized to neck muscles may be perceived as a pharyngitis (“sore throat”) by the patient and attributed to tracheal intubation by the anesthesiologist. Muscle pain occurs more frequently in patients undergoing ambulatory surgery, especially in women, than in bedridden patients.⁴⁵ The incidence of muscle pain following administration of succinylcholine varies from 0.2% to 89%.⁴⁶ The mechanism of succinylcholine-induced myalgia appears to be complex and is not fully understood. One hypothesis proposes that myalgia is secondary to muscle damage by succinylcholine-induced fasciculations.⁴⁵ This hypothesis is supported by findings of myoglobinemia and increases in serum creatine kinase level following succinylcholine administration.^{37,47,48} However, although prior administration

of a small dose of a nondepolarizing NMBD prevents fasciculations due to succinylcholine, this approach is not always effective in preventing succinylcholine-induced myalgia.⁴⁶⁻⁴⁹ Another hypothesis suggests a possible role for prostaglandins and cyclooxygenases in succinylcholine-induced myalgias.^{2,50} Pretreatment with a prostaglandin inhibitor (lysine acetyl salicylate or diclofenac) has been shown to be effective in decreasing the incidence of muscle pain after succinylcholine administration.^{2,51} A meta-analysis showed that myalgia may best be prevented with muscle relaxants, lidocaine, or nonsteroidal antiinflammatory drugs.⁵² It should be noted, however, that myalgias following outpatient surgery occur even in the absence of succinylcholine.^{53,54}

Masseter Spasm

Succinylcholine is a known trigger agent for malignant hyperthermia. Although an increase in tone of the masseter muscle may be an early indicator of malignant hyperthermia,⁵⁵ it is not consistently associated with malignant hyperthermia.⁵⁶⁻⁵⁸ It has been suggested that the high incidence of masseter spasm in children given succinylcholine may be due to inadequate succinylcholine dosage.⁵⁹

Pharmacology of Nondepolarizing Neuromuscular-Blocking Drugs

Nondepolarizing NMBDs act as competitive antagonists by binding to the α subunits of the nicotinic acetylcholine receptor. The NMBDs have been classically classified either based on their chemical class (the steroid, benzylisoquinolinium, and other NMBDs) or based on the duration of action (long acting, intermediate acting, or short acting) of equipotent doses (see **Table 12.1**). Nondepolarizing NMBDs are positively charged, relatively large molecules. In general, a dose of 2 to 3 times ED₉₅ is used to facilitate tracheal intubation, whereas a dose of 10% of the ED₉₅ is used to maintain neuromuscular blockade.

Benzylisoquinolinium Compounds

The South American Indians' arrow poisons, known as curare, served as the basis for the development of the benzylisoquinoline-type relaxants. Tubocurarine was introduced as an NMBD for use during surgical anesthesia, but it is not currently in use anymore because of its side effects.^{1,60}

Atracurium

Atracurium consists of a racemic mixture of 10 stereoisomers.^{61,62} These isomers have been separated into three geometrical isomer groups that are designated *cis-cis*, *cis-trans*, and *trans-trans* based on their configuration about the tetrahydroisoquinoline ring system.^{61,62} The ratio of the *cis-cis*, *cis-trans*, and *trans-trans* isomers is approximately 10:6:1.⁶³

Atracurium has been designed to undergo spontaneous degradation at physiologic temperature and pH by a mechanism called Hofmann elimination, yielding laudanosine (a tertiary amine) and a monoquaternary acrylate as metabolites.^{61,64} Furthermore, atracurium can undergo ester hydrolysis. Hofmann elimination is a purely chemical process that results in loss of the positive charges by molecular fragmentation to laudanosine and a monoquaternary acrylate.^{65,66} Laudanosine depends on the liver for clearance, with approximately 70% excreted in the bile and the remainder in urine.⁶⁷ Hepatic cirrhosis in humans does not alter clearance of laudanosine, whereas excretion of this metabolite is impaired in patients with biliary obstruction.⁶⁸ Laudanosine easily crosses the blood–brain barrier, and it has central nervous system stimulating properties. The seizure threshold is not known in humans. In patients in the intensive care unit, blood levels of laudanosine can be as high as 5.0 to 6.0 $\mu\text{g}/\text{mL}$.⁶⁹ There is no evidence to suggest that prolonged administration of atracurium in the operating room or in the intensive care unit in patients with normal or impaired renal function is likely to result in concentrations of laudanosine capable of producing convulsions. The plasma elimination half-life of laudanosine is similar in patients with normal and impaired renal function — 197 \pm 38 and 234 \pm 81 minutes, respectively.^{70,71}

Cisatracurium

Cisatracurium is the 1R *cis*-1'R *cis* isomer of atracurium and represents about 15% of the marketed atracurium mixture by weight but more than 50% of the mixture in terms of potency or neuromuscular-blocking activity. Like atracurium, cisatracurium is metabolized by Hofmann elimination to laudanosine and a monoquaternary alcohol metabolite.⁷²⁻⁷⁴ There is no ester hydrolysis of the parent molecule.⁷² Hofmann elimination accounts for 77% of the total clearance of 5 to 6 mL/kg/min.⁷⁵ Twenty-three percent of the drug is cleared through organ-dependent means, with renal elimination accounting for 16% of this.⁷⁴ Because cisatracurium is about 4 to 5 times as potent as atracurium, about 5 times less laudanosine is produced, and accumulation of this metabolite is not thought to be of any consequence in clinical practice. Unlike atracurium, cisatracurium in the clinical dose range does not cause histamine release.^{76,77} This indicates that the phenomenon of histamine release may be stereospecific.^{76,78}

Mivacurium

Mivacurium consists of a mixture of three stereoisomers. Mivacurium is metabolized by butyrylcholinesterase at about 70% to 88% rate of succinylcholine to a monoester, a dicarboxylic acid.^{79,80} Mivacurium may produce histamine release, especially if administered rapidly.⁸¹

Steroidal Compounds

The steroid skeleton possesses onium centers at different positions. In the steroidal compounds, it is probably essential that one of two nitrogen atoms in the molecule be quaternized.⁸² The presence of acetyl ester (acetylcholine-like moiety) is thought to facilitate interaction of steroidal compounds with nicotinic acetylcholine receptors at the postsynaptic muscle membrane.^{83,84}

Pancuronium

Pancuronium is a potent long-acting NMBD with vagolytic, direct sympathomimetic stimulation because it blocks the reuptake of norepinephrine and butyrylcholinesterase-inhibiting properties.⁸⁵ About 40% to 60% of pancuronium is cleared by the kidney,⁸⁶ and 11% is excreted in the bile. A small amount (15%-20%) is metabolized, mainly by deacetylation in the liver. The metabolites (3-OH, 17-OH, and 3,7-di-OH) are considerably less potent as NMBDs and are excreted in the urine.⁸⁷ Accumulation of the 3-OH metabolite is responsible for prolongation of the duration of block induced by pancuronium. Given its prolonged effect and the concern for postoperative residual paralysis and associated morbidity, many clinicians elect to use other NMBD when trying to achieve neuromuscular blockade in their patients.

Vecuronium

Vecuronium is a monoquaternary NMBD with an intermediate duration of action. Vecuronium is simply pancuronium without the quaternizing methyl group in the 2-piperidino substitution. The minor molecular difference between vecuronium and pancuronium means that vecuronium is characterized by (1) a slight decrease in potency; (2) virtual loss of the vagolytic properties of pancuronium; (3) molecular instability in solution (this explains in part the shorter duration of action of vecuronium compared with pancuronium); and (4) increased lipid solubility, which results in a greater biliary elimination of vecuronium than pancuronium.

The liver is the principal organ of elimination for vecuronium, and renal excretion accounts for excretion of approximately 30% of the administered dose. Approximately 30% to 40% of vecuronium is cleared in the bile as parent compound.⁸⁸ The duration of the vecuronium-induced neuromuscular block is therefore dependent primarily on hepatic function and, to a lesser extent, on renal function.^{89,90} Vecuronium is metabolized in the liver by deacetylation into three possible metabolites: 3-OH, 17-OH, and 3,17-di-OH vecuronium. The 3-OH metabolite has 80% the neuromuscular-blocking potency of vecuronium. Therefore, during prolonged administration of vecuronium, this metabolite may contribute to prolonged neuromuscular blockade.⁹¹

Vecuronium is prepared as a lyophilized powder because it is less stable in solution. Vecuronium cannot be prepared as a ready-to-use solution with a sufficient shelf life, even as a buffered solution.⁹² In

pancuronium, the 2-piperidine is quaternized and no longer basic (charged). Thus, it does not participate in catalysis of the 3-acetate hydrolysis.

Rocuronium

Rocuronium is an intermediate-acting monoquaternary NMBD with a faster onset of action than either pancuronium or vecuronium. Rocuronium is about 6 times less potent than vecuronium.^{93,94} Rocuronium is primarily eliminated by the liver and excreted in bile. It is taken up into the liver by a carrier-mediated active transport system. The putative metabolite, 17-desacetylrocuronium, has not been detected in significant quantities. Approximately 30% of rocuronium is excreted unchanged in the urine. At room temperature, rocuronium is stable for 60 days, whereas pancuronium is stable for 6 months.

Potency of Nondepolarizing Neuromuscular-Blocking Drugs

Drug potency is commonly expressed in terms of the dose-response relationship. The potency of nondepolarizing NMBDs can be expressed as the dose of drug required to produce an effect—for example, 50% or 95% depression of twitch height, commonly expressed as ED₅₀ and ED₉₅, respectively.

Effect of Drug Potency on Speed of Onset

The speed of onset of action is inversely proportional to the potency of nondepolarizing NMBDs. Low potency is predictive of rapid onset, and high potency is predictive of slow onset. Except for atracurium,⁹⁵ molar potency (the ED₅₀ or ED₉₅ expressed in μM/kg) is highly predictive of a drug's time to onset of effect (at the adductor pollicis muscle).⁹⁶ Rocuronium has a molar potency (ED₉₅ ≈ 0.54 μM/kg), which is about 13% that of vecuronium and only 9% that of cisatracurium. Thus, rapid onset of rocuronium is to be expected.

The influence of potency on speed of onset could be simply explained by the fact that, for an equipotent dose (eg, a dose that results in 50% receptor occupancy), a low-potency drug (such as rocuronium) will have a higher number of molecules than a high-potency drug (such as tubocurarine). The higher number of drug molecules will result in a greater diffusion gradient of the low-potency drug from capillary to the neuromuscular junction (faster rate of drug transfer from plasma to biophase) and a greater biophase concentration of low-potency drug resulting in a fast onset.

The concept of “buffered diffusion” must be invoked to explain the slow recovery of long-acting NMBDs and to understand biophase kinetics.⁹⁷ Buffered diffusion is the process in which diffusion of a drug (eg, diffusion of an NMBD from the neuromuscular junction) is impeded because it binds to extremely high-density receptors within a restricted space (neuromuscular junction). This process is seen with high-potency but not low-potency drugs. Buffered diffusion causes repetitive binding to and unbinding from receptors, keeping potent drugs such as tubocurarine in the neighborhood of effector sites and potentially lengthening the duration of effect.

Factors That Increase the Potency of Nondepolarizing Neuromuscular-Blocking Drugs

Inhalational anesthetics potentiate the neuromuscular-blocking effect of nondepolarizing NMBDs. This potentiation results mainly in a decrease in the required dosage of nondepolarizing NMBD and prolongation of both the duration of action of the relaxant and recovery from neuromuscular block. The magnitude of this potentiation depends on several factors, including the duration of inhalational anesthesia, the specific inhalational anesthetic used,⁹⁸ and the concentration of inhalational agent used. The rank order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide–barbiturate–opioid or propofol anesthesia. The mechanisms proposed for this potentiation include (1) a central effect on α motoneurons and interneuronal synapses, (2) inhibition of postsynaptic nicotinic acetylcholine receptors, and (3) augmentation of the antagonist’s affinity at the receptor site.

Some antibiotics can also potentiate neuromuscular blockade. The aminoglycoside antibiotics, the polymyxins, and lincomycin and clindamycin primarily inhibit the prejunctional release of acetylcholine and

also depress postjunctional nicotinic acetylcholine receptor sensitivity to acetylcholine. The tetracyclines, on the other hand, exhibit postjunctional activity only.

Hypothermia or magnesium sulfate potentiates the neuromuscular blockade induced by nondepolarizing NMBDs. The recovery to 10% twitch height with 0.1 mg/kg of vecuronium increases from 28 minutes at a mean central temperature of 36.4°C to 64 minutes at 34.4°C.⁹⁹ If the skin temperature is dropped to 27°C, the interpretation of response in that arm is unreliable.¹⁰⁰ The mechanism(s) underlying this potentiation may be pharmacodynamic, pharmacokinetic, or both. High magnesium concentrations inhibit calcium channels at the presynaptic nerve terminals that trigger the release of acetylcholine.

Most local anesthetics when given in large doses potentiate neuromuscular block; in smaller doses, no clinically significant potentiation occurs. Antidysrhythmic drugs, such as quinidine, also potentiate neuromuscular block.

Factors That Decrease the Potency of Nondepolarizing Neuromuscular-Blocking Drugs

Resistance to nondepolarizing NMBDs (except for mivacurium¹⁰¹ and probably atracurium¹⁰²) has been demonstrated in patients receiving chronic anticonvulsant therapy, as evidenced by accelerated recovery from neuromuscular blockade and the need for increased doses to achieve complete neuromuscular blockade.^{102,103} This resistance has been attributed to increased clearance, increased binding of the nondepolarizing NMBDs to α_1 -acid glycoproteins, and/or upregulation of neuromuscular acetylcholine receptors.

In hyperparathyroidism, hypercalcemia is associated with decreased sensitivity to atracurium and thus a shortened duration of neuromuscular blockade. Increasing calcium concentrations also decreased the sensitivity to tubocurarine and pancuronium in a muscle-nerve model.¹⁰⁴

Adverse Effects of Nondepolarizing Neuromuscular-Blocking Drugs

Neuromuscular-blocking agents seem to play a prominent role in adverse reactions that occur during anesthesia. The Committee on Safety of Medicines in the United Kingdom reported that 10.8% (218 of 2,014) of adverse drug reactions and 7.3% of deaths (21 of 286) were attributable to NMBDs.¹⁰⁵

Autonomic Effects

Neuromuscular-blocking agents interact with nicotinic and muscarinic cholinergic receptors within the sympathetic and parasympathetic nervous systems and at the nicotinic receptors of the neuromuscular junction. Administration of tubocurarine was associated with marked ganglion blockade resulting in hypotension; in susceptible patients, manifestations of histamine release such as flushing, hypotension, reflex tachycardia, and bronchospasm can be seen. Pancuronium has a direct vagolytic effect. Pancuronium can block muscarinic receptors on sympathetic postganglionic nerve terminals,¹⁰⁶ resulting in inhibition of a negative-feedback mechanism whereby excessive catecholamine release is modulated or prevented.¹⁰⁷ Pancuronium may also stimulate catecholamine release from adrenergic nerve terminals.¹⁰⁸

Histamine Release

Histamine release by benzylisoquinolinium compounds such as mivacurium, atracurium, and tubocurarine can cause skin flushing, decreases in blood pressure and systemic vascular resistance, and increases in pulse rate.^{81,109–112} In contrast, steroid NMBDs are not associated with histamine release in typical clinical doses.^{113–115} The clinical effects of histamine are seen when plasma concentrations increase to 200% to 300% of baseline values, especially if such concentrations are achieved quickly by rapid drug administration. The effect is usually of short duration (1–5 minutes), is dose related, and is clinically insignificant in healthy patients. Histamine has positive inotropic and chronotropic effects on the myocardial H₂ receptors, and there is some evidence that its chronotropic effect may result in part from the liberation of catecholamines.¹¹⁶ Although ganglionic block secondary to the administration of tubocurarine has been demonstrated to occur in various species,¹¹⁷ the peripheral venous and arteriolar dilatation via stimulation of vascular H₁ and H₂ receptors can result in a significant degree of hypotension as well as carotid-sinus-mediated reflex response to histamine-induced peripheral vasodilatation.¹¹¹ Other substances liberated by mast cell degranulation, such

as tryptase or prostaglandins, may also play a role.¹¹⁸ The serosal mast cell, located in the skin and connective tissue and near blood vessels and nerves, is principally involved in the degranulation process.¹¹⁸

For patients who may be compromised hemodynamically, selecting a drug with less or no histamine release (cisatracurium, vecuronium, or rocuronium) may be appropriate. Another strategy for maintaining cardiovascular stability involves slow administration of benzylisoquinolinium NMBDs (over 60 seconds) or the prophylactic use of the combined histamine H₁- and H₂-receptor antagonists.

The administration of benzylisoquinolinium NMBDs (with the exception of cisatracurium) is associated with histamine release, which may result in increased airway resistance and bronchospasm in patients with hyperactive airway disease.

Allergic Reactions

Life-threatening anaphylactic (immune-mediated) or anaphylactoid reactions during anesthesia have been estimated to occur in 1 in 1,000 to 1 in 25,000 administrations and are associated with a mortality rate of about 5%.^{119,120} In France, the most common causes of anaphylaxis in patients who experienced allergic reactions were reported to be NMBDs (58.2%), latex (16.7%), and antibiotics (15.1%).¹²¹ Anaphylactic reactions are mediated through immune responses involving immunoglobulin E antibodies fixed to mast cells. Anaphylactoid reactions are not immune mediated and represent exaggerated pharmacologic responses in very sensitive individuals, who represent a very small proportion of the population. Cross-reactivity has been reported between NMBDs and food, cosmetics, disinfectants, and industrial materials.

Steroidal compounds (eg, rocuronium, vecuronium, or pancuronium) result in no significant histamine release. Nevertheless, in the aforementioned series from France, among cases of anaphylaxis due to NMBDs, 43.1% were due to rocuronium and 22.6% to succinylcholine.¹²¹ There are currently no standards regarding which diagnostic tests (skin prick test, interdermal test, or immunoglobulin E testing) should be performed to identify patients at risk.¹²²

Treatment of anaphylactic reactions include immediate administration of oxygen (100%) and intravenous epinephrine (10-20 µg/kg). Early tracheal intubation with a cuffed endotracheal tube should be considered in patients with rapidly developing angioedema. Fluids (crystalloid and/or colloid solutions) must be administered concurrently. Norepinephrine or a sympathomimetic drug (eg, phenylephrine) may also be necessary to maintain perfusion pressure until the intravascular fluid volume can be restored. Dysrhythmias should be treated. The use of antihistamines and/or steroids is controversial.

Drugs for Reversal of Nondepolarizing Neuromuscular Blockade

Acetylcholinesterase at the Neuromuscular Junction

At the neuromuscular junction, acetylcholinesterase is enzyme responsible for rapid hydrolysis of released acetylcholine.¹²³ Approximately 50% of the released acetylcholine is hydrolyzed during its diffusion across the synaptic cleft, before reaching nicotinic acetylcholine receptors. Acetylcholinesterase has one of the highest catalytic efficiencies known. It can catalyze acetylcholine hydrolysis at a rate of 4,000 molecules of acetylcholine hydrolyzed per active site per second, which is nearly the rate of diffusion.¹²³

Acetylcholinesterase is highly concentrated at the neuromuscular junction but is present in a lower concentration throughout the length of muscle fibers (see [Chapter 10](#)).¹²⁴

Mechanisms of Action of Acetylcholinesterase Inhibitors

Acetylcholinesterase inhibitors (eg, neostigmine, edrophonium, and less commonly, pyridostigmine) are used clinically to antagonize the residual effects of nondepolarizing NMBDs and to accelerate recovery from nondepolarizing neuromuscular blockade. Acetylcholine accumulates at the neuromuscular junction after administration of neostigmine and competes with the residual molecules of the nondepolarizing NMBD drug for the available unoccupied nicotinic acetylcholine receptors at the neuromuscular junction. The clinical implication is that neostigmine has a ceiling effect on acetylcholinesterase. Once the inhibition of acetylcholinesterase is complete, administering additional doses of neostigmine will serve no useful purpose

because the concentration of acetylcholine that can be produced at the neuromuscular junction is finite. “In practical terms, the maximum depth of block that can be antagonized approximately corresponds to the reappearance of the fourth response to TOF stimulation.”¹²⁵ Because of their ceiling effect, the anticholinesterases cannot effectively antagonize profound or deep levels of neuromuscular blockade.

For neostigmine, the maximum effective dose is in the 60 to 80 µg/kg range, and for edrophonium, it is in the 1.0 to 1.5 mg/kg range. Antagonism of residual neuromuscular blockade induced by the various nondepolarizing NMBDs is similar (or possibly greater) in children and adults.¹²⁶ Neostigmine is still the anticholinesterase agent most widely used by anesthesiologists worldwide.¹²⁷

The notion that neostigmine administration at a time when spontaneous clinical recovery from nondepolarizing block is almost complete may have adverse clinical consequences has been disputed.^{128–132} The effect of an anticholinesterase on neuromuscular transmission seems to be dependent whether or not a nondepolarizing NMBD is present at the neuromuscular junction.^{133,134} When the fade cannot be detected on TOF stimulation at the adductor pollicis muscle using a conventional peripheral nerve stimulator (PNS) following spontaneous recovery from a nondepolarizing NMBD, available evidence suggests that the prudent course of action is to administer a small (≤ 30 µg/kg) dose of neostigmine.

Clinical Pharmacology

Pharmacokinetics of Acetylcholinesterase Inhibitors

The elimination half-life of edrophonium is similar to those of neostigmine and pyridostigmine, although that of pyridostigmine is somewhat longer. Renal excretion accounts for about 50% of the excretion of neostigmine and about 75% of that of pyridostigmine and edrophonium. Renal failure decreases the plasma clearance of neostigmine, pyridostigmine, and edrophonium as much as, if not more than, that of the long-acting nondepolarizing NMBDs.

Side Effects of Acetylcholinesterase Inhibitors

Inhibition of acetylcholinesterase increases the concentration of acetylcholine not only at the neuromuscular junction (nicotinic site) but also at all other synapses that use acetylcholine as a transmitter.

Cardiovascular Side Effects

Because only the nicotinic effects of acetylcholinesterase inhibitors are desired, the muscarinic effects must be blocked by atropine or glycopyrrolate.⁸⁴ To minimize the muscarinic cardiovascular side effects of acetylcholinesterase inhibitors, an anticholinergic agent should be coadministered with the acetylcholinesterase inhibitor. Atropine (7-10 µg/kg) matches the onset of action and pharmacodynamic profile of the rapid-acting edrophonium (0.5-1.0 mg/kg),⁸⁴ and glycopyrrolate (7-15 µg/kg) matches the slower acting neostigmine (40-70 µg/kg) and pyridostigmine.^{135,136} In patients with preexisting cardiac disease, glycopyrrolate may be preferable to atropine,¹³⁷ and the acetylcholinesterase inhibitor and anticholinergic should be administered slowly (eg, over 2-5 minutes). The hemodynamic effects of tracheal extubation are significantly greater than that following the coadministration of neostigmine and glycopyrrolate.

Pulmonary and Alimentary Side Effects

Administration of acetylcholinesterase inhibitors is associated with bronchoconstriction, increased airway resistance, increased salivation, and increased bowel motility (muscarinic effects). Anticholinergics tend to reduce this effect. There is no evidence to indicate that neostigmine increases the incidence of postoperative nausea and vomiting.¹³⁸ Neostigmine has been described as having antiemetic properties and as having no effect on the incidence of postoperative nausea and vomiting.

Limitations of Acetylcholinesterase Inhibitors

As indicated in the previous sections, postanesthetic morbidity in the form of incomplete reversal and residual postoperative weakness is a frequent occurrence.^{139–144} In 2003, for example, Debaene and

colleagues¹⁴⁰ reported a 45% incidence of postoperative residual neuromuscular blockade in patients arriving in the postanesthesia care unit. Moreover, surveys indicated that most practitioners demonstrated overconfidence in their knowledge and ability to manage the use of NMBDs¹⁴⁵ and do not know what constitutes adequate recovery from neuromuscular blockade.¹⁴⁶ Although an argument can be made that these problems could be attributed to (1) lack of routine use of PNSs (and more importantly, the quantitative ones) or (2) the ceiling effect of the reversal agents when administered at a deep level of neuromuscular blockade,^{147,148} one study found that, despite both the use of nerve stimulators by clinicians with knowledge and expertise and administration of neostigmine, the incidence of critical respiratory events in the postoperative care unit remained a significant 0.8%.¹⁴² Clearly, avoidance of critical respiratory events requires changes in clinical care (see [Quantitative vs Qualitative Measurement](#) in the discussion section that follows).¹⁴⁹

Sugammadex: A Selective Relaxant Binding Agent

Chemistry

Cyclodextrins are cyclic dextrose units joined through one to four glycosyl bonds that are produced from starch or starch derivatives using cyclodextrin glycosyltransferase. The three natural unmodified cyclodextrins consist of 6-, 7-, or 8-cyclic oligosaccharides and are called α -, β -, or γ -cyclodextrin, respectively. Their three-dimensional structures, which resemble a hollow, truncated cone or a doughnut, have a hydrophobic cavity and a hydrophilic exterior because of the presence of polar hydroxyl groups.

Sugammadex is a modified γ -cyclodextrin compound composed of an eight-membered ring with a central cavity that encapsulates steroid NMBDs.^{150–153} This modification entails (1) the addition of eight side chains to extend the cavity of γ -cyclodextrin in order to better accommodate the four hydrophobic steroid rings of rocuronium and (2) the inclusion of negatively charged carboxyl groups at the end of the side chains in order to enhance electrostatic binding to the positively charged quaternary nitrogen of rocuronium. Sugammadex exerts its effect by forming very tight complexes at a 1:1 ratio with steroid neuromuscular-blocking agents (rocuronium > vecuronium >> pancuronium) ([Figure 12.1](#)). The intermolecular (van der Waals) forces, thermodynamic (hydrogen) bonds, and hydrophobic interactions of the sugammadex-rocuronium complex make it very tight.¹⁵⁰ The sugammadex-rocuronium complex has a very high association rate and a very low dissociation rate. It is estimated that for every 30 million sugammadex-rocuronium complexes, only one complex dissociates.

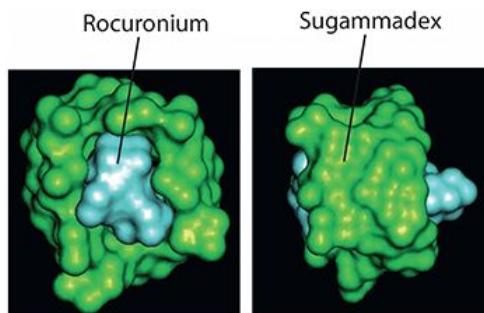

FIGURE 12.1 Encapsulation of rocuronium molecule (blue) by a sugammadex molecule (green) at 1:1 ratio. Reprinted with permission from Naguib M. Sugammadex: another milestone in clinical neuromuscular pharmacology. Anesth Analg. 2007;104(3):575-581. Copyright © 2007 International Anesthesia Research Society.

Sugammadex is the first selective relaxant-binding agent. It exerts no effect on acetylcholinesterases or on any receptor system in the body, thus eliminating the need for anticholinergic drugs and their undesirable adverse effects. Moreover, the unique mechanism of reversal by encapsulation is independent of the depth of neuromuscular block; thus, reversal can be accomplished even during profound neuromuscular block.

Pharmacokinetics

Sugammadex is biologically inactive and does not bind to plasma proteins. Metabolism of sugammadex is at most very limited, and approximately 75% of the dose was eliminated through the urine. The mean percentage of the dose excreted in urine up to 24 hours after administration varied between 59% and 80%. In patients with substantial renal impairment, clearances of sugammadex and rocuronium were decreased by a factor of 16 and 3.7, respectively, relative to that in healthy subjects, and the elimination half-lives were increased by a factor of 15 and 2.5, respectively. The effectiveness of dialysis in removing sugammadex and rocuronium from plasma was not demonstrated consistently. Therefore, sugammadex should be avoided in patients with a creatinine clearance of <30 mL/min. The main reason for not recommending sugammadex in this population because of the lack of safety data on the ultimate disposition of this complex in humans with end-stage renal disease. It is likely that sugammadex-rocuronium complex will be deposited in the reticuloendothelial system in the body.

In the absence of sugammadex, rocuronium is eliminated mainly by biliary excretion (>75%) and to a lesser degree by renal excretion (10%-25%). The plasma clearance of sugammadex alone is approximately 3 times lower than that of rocuronium alone. In volunteers, the plasma clearance of rocuronium was decreased by a factor of >2 after administration of a ≥ 2.0 mg/kg dose of sugammadex. This is because the biliary route of excretion becomes unavailable for the rocuronium-sugammadex complex, and rocuronium clearance decreases to a value approaching the glomerular filtration rate (120 mL/minute). As noted earlier, after administration of sugammadex, the plasma concentration of free rocuronium decreases rapidly, but the total plasma concentration of rocuronium (both free and that bound to sugammadex) increases.

Pharmacodynamics

Sugammadex, used in appropriate doses, is capable of reversing any depth of neuromuscular blockade (profound or shallow) induced by rocuronium or vecuronium to a TOFR of ≥ 0.9 within 3 minutes.^{144,154} During rocuronium- or vecuronium-induced neuromuscular blockade, intravenous administration of sugammadex results in rapid removal of free rocuronium or vecuronium molecules from the plasma. This creates a concentration gradient favoring movement of the remaining rocuronium or vecuronium molecules from the neuromuscular junction back into the plasma, where they are encapsulated by free sugammadex molecules. The latter molecules also enter the tissues and form a complex with the rocuronium or vecuronium. Therefore, the neuromuscular blockade of these agents is terminated rapidly by their diffusion away from the neuromuscular junction back into the plasma. This results in an increase in the total plasma concentration of rocuronium (both free and bound to sugammadex)¹⁵⁵ or vecuronium.

At doses of 2 mg/kg, sugammadex reverses rocuronium and vecuronium when the TOF count is at least 2 in about 3 minutes. A dose of 4 mg/kg is recommended for antagonism of deeper levels of blockade (such as when only posttetanic twitches are present). A dose of 16 mg/kg can be used to rapidly and emergently reverse the effects of 1.2 mg/kg rocuronium. This dose of sugammadex restores muscle function faster than the spontaneous recovery from succinylcholine administration ([Figure 12.2](#)). However, pharmacologic intervention with sugammadex should not be relied on to rescue patients in the setting of “cannot intubate, cannot ventilate” (CICV) situation ([Figure 12.3](#)). Following induction of anesthesia, rescue reversal of 1.2 mg/kg rocuronium with 16 mg/kg sugammadex in the setting of CICV may still not result in reliable, immediate return of spontaneous ventilation. In a simulation study, it was reported that, in obese and morbidly obese patients, even after adequate preoxygenation, neuromuscular reversal may not be sufficiently rapid to prevent significant hemoglobin desaturation. The clinical management of CICV should primarily focus on restoration of airway patency, oxygenation, and ventilation consistent with the American Society of Anesthesiologist’s Practice guidelines for management of the difficult airway.¹⁵⁶

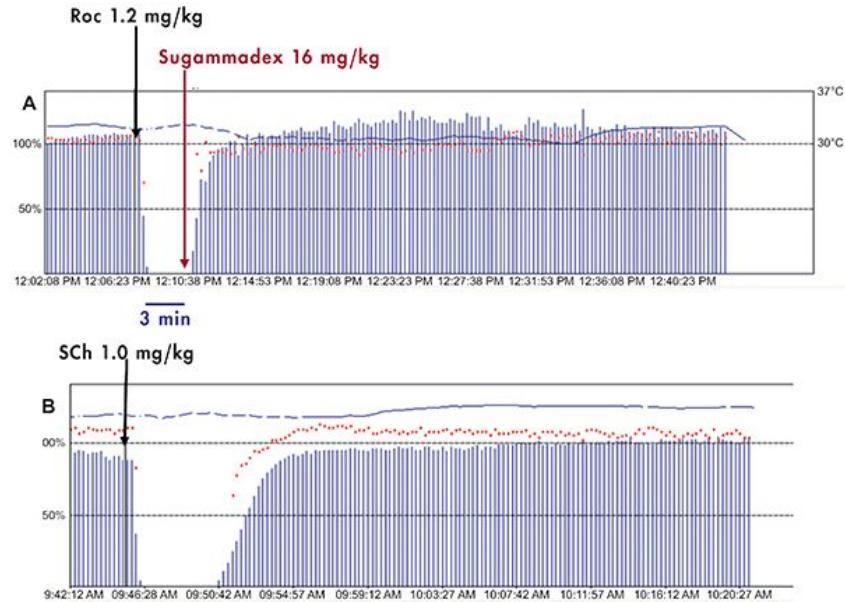

FIGURE 12.2 Panel A shows the recovery of the twitch height and train-of-four (TOF) ratio after administration of 1.2 mg/kg rocuronium (Roc) followed 3 minutes later by 16 mg/kg sugammadex, both given intravenously. Recovery to a first twitch height (T1) of 90% and a TOF ratio of 0.94 occurred 110 second later. The onset-offset time with this sequence (ie, the time from the end of the injection of rocuronium to a T1 recovery to 90%) was 4 min 47 s. Panel B shows the effects of administering 1.0 mg/kg succinylcholine (SCh) with spontaneous recovery to a T1 of 90% occurring after 9 minutes and 23 seconds. *Reprinted with permission from Naguib M. Sugammadex: another milestone in clinical neuromuscular pharmacology. Anesth Analg. 2007;104(3):575-581. Copyright © 2007 International Anesthesia Research Society.*

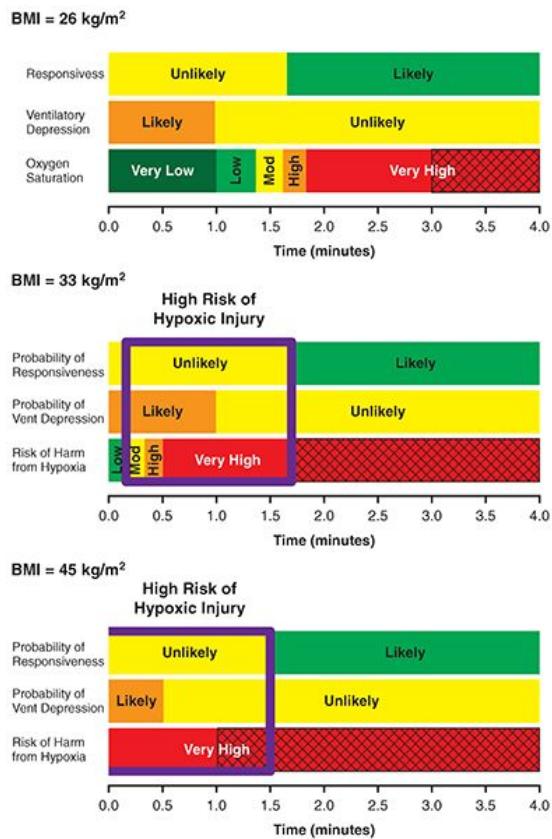

FIGURE 12.3 Comparison of responsiveness, intolerable ventilatory depression (a respiratory rate of ≤ 4 breaths/min), and hypoxia to estimate periods of *high risk of hypoxic injury* after induction with failure to ventilate or secure the airway. For discussion purposes, the duration of effects presented in this table is presented as the time from reversal of rocuronium neuromuscular blockade with sugammadex until selected endpoints in drug effects. See methods for criteria used to estimate a high risk of hypoxic injury. [Figure 12.2](#), upper and middle panels present the definitions of the scales used to characterize the probability of effects. Time segments that met criteria are identified with a blue rectangle. The purple rectangle for the body mass index (BMI) of 45 kg/m^2 is truncated at time = 0 min because criteria were met for a high risk of injury 1.5 minute before reversal with sugammadex. *Reprinted with permission from Naguib M, Brewer L, LaPierre C, et al. The Myth of Rescue Reversal in “Can’t Intubate, Can’t Ventilate” Scenarios. Anesth Analg. 2016;123(1):82-92. Copyright © 2016 International Anesthesia Research Society.*

Sugammadex is ineffective against succinylcholine and benzylisoquinolinium NMBDs such as mivacurium, atracurium, and cisatracurium because it cannot form inclusion complexes with these drugs.¹⁵⁷ For example, the association rate constant, which reflects the binding affinity for sugammadex, is 1.79×10^7 for rocuronium and 3.79×10^3 for atracurium.¹⁵⁸ This means that sugammadex affinity for rocuronium is 4,723 times that of atracurium. In fact, in anesthetized rhesus monkey, the speed of recovery following 1 mg/kg of sugammadex was not different from spontaneous recovery during atracurium-induced neuromuscular block.¹⁵⁷ Therefore, if neuromuscular blockade must be reestablished after using sugammadex, one of the benzylisoquinolinium NMBDs should be considered.

Drug Interactions

Sugammadex can bind and inhibit oral contraceptives. Patients should use alternative contraceptive techniques for 7 days after exposure to sugammadex.¹⁵⁸

Adverse Effects

The use of sugammadex may cause anaphylactic reaction. A recent retrospective analysis from Japan suggested that the incidence of anaphylaxis to sugammadex is approximately 0.04% of administrations, which would be comparable with that encountered with rocuronium.¹⁵⁹ Tryptase plasma concentrations must be estimated during the acute event and repeated about 2 to 6 hours later to have an accurate indication of an anaphylactic response. Ideally, a third sample should be taken at 24 hours when the plasma tryptase levels would be expected to have returned to normal values.¹⁶⁰

Cardiac arrhythmias, including marked bradycardia and asystole, may occur after administration of sugammadex.¹⁶⁰ Thus, full electrocardiogram monitoring should be continued during and after administration of sugammadex, and atropine and other vasoactive drugs should be immediately available.¹⁶⁰ From 2009 to 2017, 138 cases of serious cardiac adverse events with nine deaths after administration of sugammadex were reported to the US Food and Drug Administration adverse events reporting system, including bradycardia ($n = 66$), cardiac arrest ($n = 39$), ventricular fibrillation ($n = 10$), and ventricular tachycardia ($n = 8$).¹⁶¹ Although sugammadex-induced bradycardia is typically transient, it has precipitated cardiac arrest and hemodynamic collapse in some cases.¹⁶²

Small increases in activated partial thromboplastin time and prothrombin time have been reported after sugammadex administration, but clinically significant bleeding has not been reported.¹⁶³

Monitoring of Neuromuscular Function

Monitoring of neuromuscular function after administration of an NMBD serves at least two purposes in clinical settings. First, it allows the anesthesiologist to administer these agents with appropriate dosing; second, it ensures that the patient recovers adequately from residual effects of the NMBD (ie, TOFR ≥ 0.90), thus guaranteeing patient safety. Residual postoperative paralysis has numerous associated complications such as upper airway obstruction, aspiration, and hypoxemia.

A recent “Consensus Statement on Perioperative Use of Neuromuscular Monitoring”¹⁴⁹ emphasized that clinical bedside criteria for tracheal extubation (such as a 5-second head lift or ability to generate a peak negative inspiratory force of minus 25–30 cm H₂O) are insensitive indicators of the adequacy of neuromuscular recovery,^{164,165} and that subjective (qualitative) evaluation of the responses to TOF stimulation (when using a PNS) should be abandoned in favor of objective monitoring. Subjective evaluation of the evoked muscular response to TOF and tetanic stimulation are notoriously inaccurate as estimates of fade or postoperative residual neuromuscular blockade.^{166,167} Quantitative monitoring is defined as an objective real-time measurement of the TOFR. The difference between quantitative and qualitative assessments of neuromuscular blockade is in their ability to objectively measure the TOFR. Therefore, the term *monitor* will be restricted to those devices that measure, analyze, and display the TOFR in real time.

Subjective (Qualitative) Evaluation of Neuromuscular Blockade

Visual and/or tactile (subjective) evaluation of evoked responses with the use of a PNS is unreliable at determining recovery from neuromuscular blockade and exposes patients to unnecessary risks associated with residual neuromuscular weakness.¹⁴⁹ Although subjective assessment may help clinicians assess complete block (when posttetanic count = 0), deep block (when posttetanic count ≥ 1 and train-of-four count [TOFC] = 0), and moderate block (TOFC = 1–3), readiness for tracheal extubation (TOFR ≥ 0.90) cannot be assured by subjective evaluation because absence of subjective fade does not consistently identify complete recovery. This modality uses stimulating skin electrodes placed on the skin overlying a superficial motor nerve that innervates the muscle of interest. The negative (typically black) electrode is placed distally to the positive (typically red) electrode (Figures 12.4 and 12.5).¹⁶⁸ Subjective evaluation of TOF stimulation with the use of a PNS requires the observer to determine (1) the number of twitches (TOFC) and (2) the strength of the first response in the train and compare it to the fourth evoked response by tactile or visual means. The TOFC of 1, 2, 3, and 4 corresponds approximately to 10%, 20%, 30%, and 40%, respectively, of single twitch control twitch height.^{169,170} The limitation of TOFR is that once it approaches 0.40, most clinicians cannot detect the presence of fade by subjective assessments and may therefore not administer a reversal drug to ensure adequate recovery of neuromuscular function before tracheal extubation.

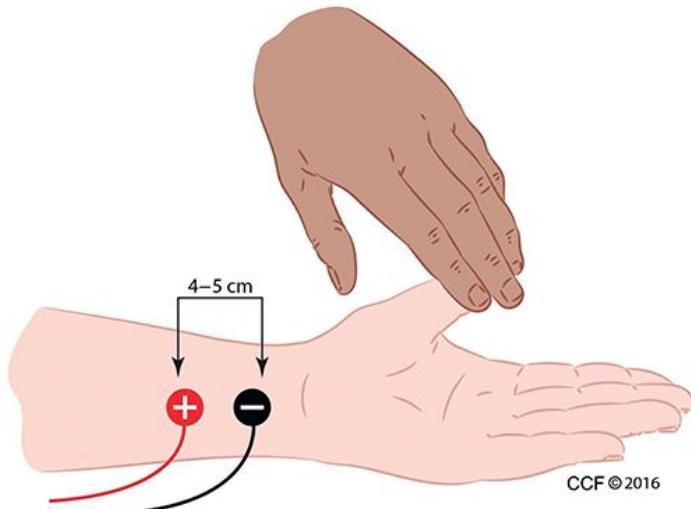

FIGURE 12.4 Subjective (tactile) evaluation of neuromuscular responses at the adductor pollicis (thumb) muscle in response to ulnar nerve stimulation. Note that the black (negative) electrode is distal to the proximal red (positive) electrode. *From Naguib M, Brull SJ, Johnson KB. Conceptual and technical insights into the basis of neuromuscular monitoring. Anaesthesia. 2017;72(Suppl 1):16-37. Objective (Quantitative) Evaluation of Neuromuscular Blockade

Objective evaluation involves the quantification of the TOFR through the measurement of electrical or mechanical response to nerve stimulation. There are numerous modalities that have been employed to provide such measurements, and the most clinically relevant techniques are discussed here.

Electromyography (EMG) is the oldest form of neuromuscular monitoring; it involves stimulation of a peripheral nerve and measurement of the muscle action potential that is generated by the contraction of the innervated muscle ([Figure 12.6](#)). Active (recording) electrodes are placed over the muscle body, whereas a neutral electrode is placed at a remote site, usually near the muscle insertion site. The EMG signals are subject to electrical interference, direct muscle stimulation, and hypothermia. An EMG is different from other techniques in that there is no muscle movement being analyzed.

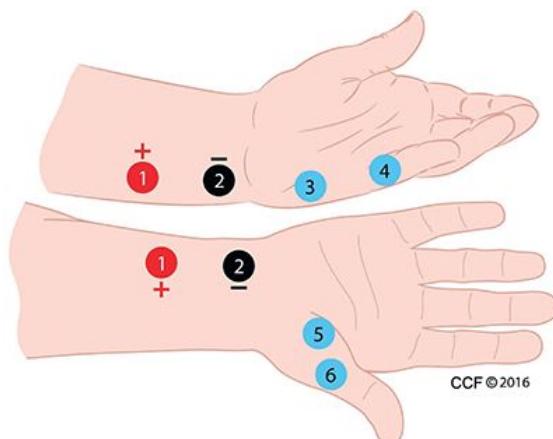

FIGURE 12.6 Placement of the stimulating electrodes (1 and 2) along the ulnar nerve and of the recording electrodes for monitoring the abductor digiti minimi (3 and 4) or the adductor pollicis (5 and 6) muscles by electromyography. *From Naguib M, Brull SJ, Johnson KB. Conceptual and technical insights into the basis of neuromuscular monitoring. Anaesthesia. 2017;72(Suppl 1):16-37. Mechanomyography (MMG) measures the force created by muscle contraction in response to electrical stimuli applied to peripheral nerves ([Figure 12.7](#)). It is regarded as the gold standard of neuromuscular blockade monitoring, and a mechanomyographic adductor pollicis muscle TOFR of 0.9 or more is widely accepted as the threshold for exclusion of residual paralysis. However, its use in clinical settings is limited by stringent preparation and maintenance of a constant preload. An MMG is primarily used for research purposes.

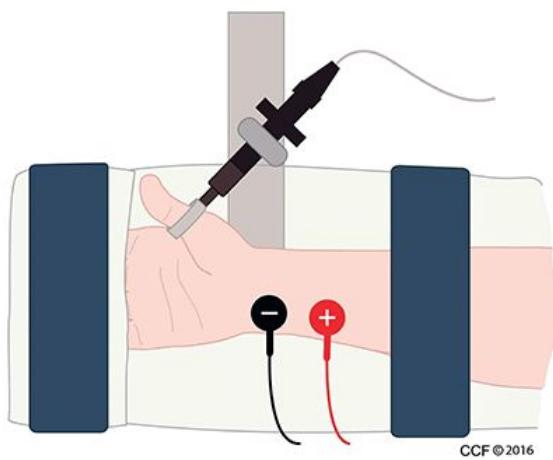

FIGURE 12.7 Apparatus for objective monitoring of the adductor pollicis (thumb) muscle using mechanomyography. A force transducer ring is attached to the thumb, and the fingers are secured to prevent

movement during nerve stimulation. Ulnar nerve stimulation (note that the negative electrode is distal to the positive electrode) will result in contraction of the adductor pollicis muscle, and the force of contraction is measured by the force transducer. The results are displayed on an interfaced screen. *From Naguib M, Brull SJ, Johnson KB. Conceptual and technical insights into the basis of neuromuscular monitoring. Anaesthesia. 2017;72(Suppl 1):16-37. Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography. Copyright © 2016-2020. All Rights Reserved.*

Acceleromyography is based on Newton's second law (force = mass × acceleration) and utilizes a piezoelectric transducer attached to a muscle ([Figure 12.8](#)). An acceleromyography involves measurement of the acceleration of a muscle (usually the adductor pollicis) in response to nerve (usually the ulnar) stimulation. As this technique relies on the free movement of the thumb and requires access to the hand for monitoring, surgical positioning may limit its clinical use.

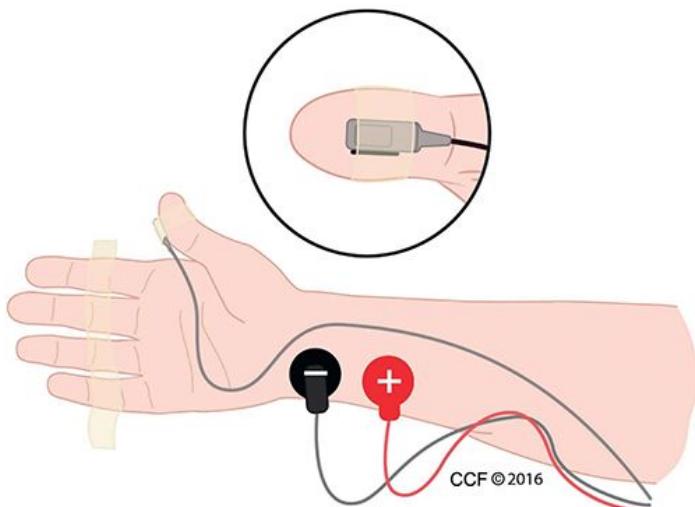

FIGURE 12.8 Apparatus for objective monitoring of the adductor pollicis (thumb) muscle contraction using acceleromyography. An accelerometer is attached to the thumb and the fingers and secured to prevent movement during nerve stimulation. Ulnar nerve stimulation (note that the negative electrode is distal to the positive electrode) will result in contraction of the adductor pollicis muscle, and the thumb acceleration is measured. The results are displayed on the monitor's screen. *From Naguib M, Brull SJ, Johnson KB. Conceptual and technical insights into the basis of neuromuscular monitoring. Anaesthesia. 2017;72(Suppl 1):16-37. Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography. Copyright © 2016-2020. All Rights Reserved.*

Kinemyographic device is based on a mechanosensor strip that contains a piezoelectric polymer ([Figure 12.9](#)). The strip is placed between the base of the thumb and the base of the index finger. When the sensor is bent and exposed to motion, it generates an electrical signal that is proportional to the magnitude of bending; the results are then analyzed. Commercially available devices are versatile and mobile and can be integrated into anesthesia workstations. However, the resulting measurements have been shown not to correlate with the MMG gold standard, limiting its clinical application.

FIGURE 12.9 Apparatus for objective monitoring of the adductor pollicis (thumb) muscle contraction using kinemyography. A mechanosensor (metallic strip) is placed in the groove between the thumb and index finger; ulnar nerve stimulation produces adductor pollicis muscle contraction that bends the strip, generating a current, which is proportional to the strength of muscle contraction. The results are displayed on the monitor's screen. *From Naguib M, Brull SJ, Johnson KB. Conceptual and technical insights into the basis of neuromuscular monitoring. Anaesthesia. 2017;72(Suppl 1):16-37. Reprinted with permission from Cleveland Clinic Center for Medical Art & Photography. Copyright © 2016-2020. All Rights Reserved.*

Clinical Considerations

The blockades produced by depolarizing and nondepolarizing NMBDs are distinct and can be distinguished by their response to peripheral nerve stimulation ([Figure 12.10](#)). During partial blockade, the depolarizing block induced by succinylcholine is characterized by the absence of both fade (to TOF or tetanic stimulation) and posttetanic potentiation in response to nerve stimulation. During partial blockade, the block produced by nondepolarizing NMBDs is characterized by fade after repeated stimulation as well as the ability to cause posttetanic potentiation in which a 5-second tetanic stimulation produces an amplified subsequent response to stimulation. This tetanic stimulus mobilizes prejunctional calcium and allows for the positive feedback on presynaptic acetylcholine receptors, and previously unavailable acetylcholine is released into the synaptic cleft, producing a transiently exaggerated response. It should be noted that succinylcholine can produce fade or posttetanic potentiation when used in large doses (>10 times ED₉₅), after prolonged exposure (>30 min), or in patients with butyrylcholinesterase deficiency.

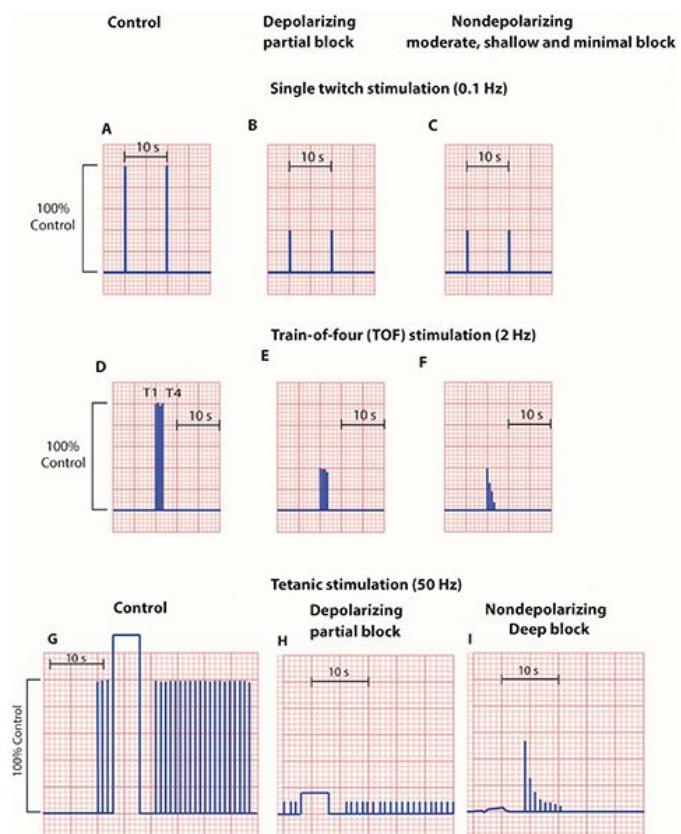

FIGURE 12.10 Depiction of muscle contractions in response to single twitch (ST) stimuli delivered at a frequency of 0.1 Hz during normal conduction (Control, A); partial depolarizing block (B); and moderate, shallow or minimal nondepolarizing block (C). Note the lack of fade between the first ST and subsequent ST evoked responses during both depolarizing and nondepolarizing block when stimuli are delivered at this slow, 0.1-Hz frequency. Train-of-four (TOF) stimulation. The TOF pattern in the absence of neuromuscular block (D, Control). The TOF ratio (TOFR) is calculated as the ratio between the fourth twitch of the TOF sequence (T4) and the first (T1). In the unblocked muscle, the TOF ratio is 1.0. During a partial depolarizing block (E), there is minimal, if any, fade such that the TOF ratio remains close to 1.0. The TOF fade is noted during moderate, shallow, or minimal nondepolarizing block (F). Tetanic stimulation and posttetanic count (PTC). (G) In the unblocked muscle, the mechanical response to a 50-Hz tetanic stimulation is characterized by a sustained contraction with virtually no fade in tetanic response or posttetanic potentiation of twitch response. During partial depolarizing block (H), there is a reduction in the amplitude of tetanic stimulation, but there is no tetanic fade or posttetanic potentiation (I). Application of tetanus during deep block resulted in a faint contraction for 5 seconds, and posttetanic potentiation that results in eight progressively weaker contractions (PTC = 8). Note that when measuring the PTC, one always uses 1-Hz stimulation. From Naguib M, Brull SJ, Johnson KB. *Conceptual and technical insights into the basis of neuromuscular monitoring*. Different muscle groups respond differently to the neuromuscular-blocking effects of NMBDs. Vessel-rich, large, central muscle groups, such as the diaphragm, are more susceptible to NMBD effects than peripheral muscle groups. Thus, these central muscles become paralyzed before peripheral muscles following administration of NMBDs, and they recover faster. Understanding this relationship is essential to monitoring the level of neuromuscular blockade, regardless of which muscles are being monitored. Whether subjective or objective techniques are being used, monitoring the adductor pollicis muscle in response to ulnar nerve

stimulation has been advocated to exclude residual weakness because the adductor pollicis is one of the last muscles to recover from NMBD-induced paralysis.

Compared to peripheral muscles, the laryngeal and diaphragmatic muscles are more resistant to the effects of NMBDs. Neuromuscular blockade develops faster, lasts a shorter time, and recovers faster at the laryngeal and diaphragm muscles compared to the adductor pollicis muscle. The diaphragm and larynx have greater total blood flow than the adductor pollicis muscle, resulting in faster delivery of NMBDs to these muscles. Conversely, washout of NMBDs also occur faster at the central muscles, so recovery occurs here before it does peripherally. Stimulation of the facial nerve will evoke contraction of the orbicularis oculi muscle (the eyelid) as well as the corrugator supercilii muscle (the eyebrow). The corrugator supercilii muscles have the same time course of paralysis and recovery as the laryngeal adductor muscles, whereas the orbicularis oculi muscles time course follows peripheral muscles such as the adductor pollicis.¹⁷¹ Monitoring of facial muscles is a poor substitute for monitoring the adductor pollicis muscle. A recent report showed a 52% incidence of residual paralysis in the recovery room using subjectively assessed eyebrow responses, compared with 22% incidence of residual paralysis during hand muscle monitoring.

Neurologically Active Drugs

Mark Alexander Burbridge • Pamela Flood

Antiepileptic Drugs

Epilepsy is one of the most common neurologic conditions. While 10% of people will report at least one seizure in their lifetime, it is estimated that 1% to 2% of the population worldwide meets the diagnostic criteria for epilepsy ([Table 13.1](#)).¹ Epilepsy is a collective term used to designate a group of chronic central nervous system (CNS) disorders characterized by the onset of sudden disturbances of sensory, motor, autonomic, or psychic origin. These disturbances are usually transient with the exception of status epilepticus and are almost always associated with abnormal discharges on the electroencephalogram. Only 30% of patients with seizures have an identifiable neurologic or systemic disorder.²

TABLE 13.1

Classification of epileptic seizures

Partial seizures (beginning locally)
Simple partial seizures (consciousness not impaired)
Complex partial seizures (consciousness impaired)
Partial seizures evolving into secondary generalized seizures
Generalized seizures (convulsive or nonconvulsive)
Absence seizures (petit mal)
Myoclonic seizures
Clonic seizures
Tonic seizures
Tonic-clonic seizures

Unclassified seizures

Adapted from Brodie MJ, Dichter MA. Antiepileptic drugs. *N Engl J Med.* 1996;334:168-175.

The goal of pharmacologic treatment of epilepsy is to control seizures with minimal medication-related adverse effects. Approximately 70% of patients with epilepsy will become seizure-free using a single antiepileptic drug. For the remaining 30% of patients, further treatment options may include transitioning to another drug; combining the primary drug with an additional drug; or, upon failure of medical therapy, progression to surgical procedures such as a vagal nerve stimulator, laser ablation, implantation of a responsive neurostimulation device, or neurosurgical resection.³ The antiepileptic drug selected to treat epilepsy is highly individualized and tailored to the patient, explaining the high interpatient variability in drug regimens. Criteria that must be considered in choosing an antiepileptic drug include efficacy for the characteristic seizures experienced by the patient, tolerability, safety, ease of use and frequency of administration, and pharmacokinetics ([Table 13.2](#)).³ Over the last several decades, there has been a dramatic increase in drug choices which offer markedly fewer side effects with often comparable efficacy to older drugs improving compliance.^{4,5} However, dose-related side effects can limit the use of any of the antiepileptic drugs ([Table 13.3](#)). Although side effects are normally associated with higher plasma concentrations of the drug, the specific concentration at which a patient develops toxicity varies considerably ([Table 13.4](#)).⁶

TABLE 13.2

Antiepileptic drugs used to treat epilepsy

Drug	Principal mechanism of action	Targeted seizure	Dosage type
Carbamazepine	Sodium ion channel blockade	Partial seizures	10-40 mg/kg per day in 2-3 divided doses

Eslicarbazepine	Sodium ion channel blockade	Partial seizures	800-1,200 mg in 3 divided doses
Ethosuximide	T-type calcium ion change	Generalized seizures	15-40 mg/kg per day in 2-3 divided doses
Felbamate	Sodium ion channel blockade Glutamate antagonism Calcium ion channel blockade	Partial seizures Generalized seizures	15-45 mg/kg per day in 2-3 divided doses
Gabapentin	Unknown	Partial seizures Generalized seizures	10-60 mg/kg per day
Lacosamide	Sodium ion channel blockade	Partial-onset seizures	100-400 mg per day in 3 divided doses
Lamotrigine	Sodium ion channel blockade Calcium ion channel blockade	Partial seizures Generalized seizures	200-500 mg per day in 2 divided doses
Levetiracetam	Unknown (? potassium and calcium ion channel blockade)	Partial seizures Generalized seizures	1,000-3,000 mg per day in 2 divided doses
Oxcarbazepine	Sodium ion channel blockade	Partial seizures Generalized seizures	900-2,400 mg per day in 2 divided doses
Perampanel	AMPA receptor antagonist	Partial seizures Generalized tonic-clonic seizures	24-36 mg per day in 3 divided doses
Phenobarbital	Chloride ion channels	Partial seizures Generalized seizures	2-5 mg/kg per day every day or in 2 divided doses
Phenytoin	Sodium ion channel blockade Calcium ion channels NMDA receptors	Partial seizures Generalized seizures	3-7 mg/kg per day in 3 divided doses
Primidone	Chloride ion channels GABA uptake	Partial seizures Generalized seizures	500-1,500 mg per day in 2-3 divided doses
Rufinamide	Unknown (? sodium channel blockade	Lennox-Gastaut syndrome	400-800 mg per day in 2 divided doses
Stiripentol	Unknown	Dravet syndrome	50 mg/kg per day in 3 divided doses
Tiagabine	Enhanced GABA activity Carbonic anhydrase inhibition	Partial seizures Generalized seizures	32-56 mg/kg per day in 2-4 divided doses
Topiramate	Sodium ion channel blockade Enhanced GABA activity Glutamate antagonism Calcium ion channel blockade	Partial seizures Generalized seizures	500-3,000 mg per day in 2-4 divided doses
Valproate	Sodium ion channel blockade Calcium ion channels	Partial seizures Generalized seizures	500-3,000 mg per day in 2-4 divided doses
Vigabatrin	GABA transaminase inhibition	Complex partial Infantile spasms	3,000 mg per day in 2 divided doses
Zonisamide	Sodium ion channel blockade	Partial seizures	200-600 mg per day in 2-4

	Calcium ion channel blockade	Generalized seizures	divided doses
--	------------------------------	----------------------	---------------

Abbreviations: AMPA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GABA, γ -aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

TABLE 13.3

Side effects of antiepileptic drugs

	Dose-related	Idiosyncratic
Carbamazepine	Diplopia Vertigo Neutropenia Nausea Drowsiness Hyponatremia	Agranulocytosis Aplastic anemia Allergic dermatitis (rash) Stevens-Johnson syndrome Hepatotoxic effects Pancreatitis Teratogenicity
Eslicarbazepine	Fatigue Dizziness Diarrhea Nausea Vomiting Suicidal thoughts	Allergic dermatitis (rash) Heart block Hyponatremia
Ethosuximide	Nausea Anorexia Vomiting Agitation Headache Drowsiness	Agranulocytosis Aplastic anemia Allergic dermatitis (rash) Stevens-Johnson syndrome Lupus-like syndrome
Clonazepam	Sedation Vertigo Hyperactivity (children)	Allergic dermatitis (rash) Thrombocytopenia
Felbamate	Insomnia Anorexia Nausea Headache Irritability	Aplastic anemia Hepatotoxic effects
Gabapentin	Sedation Ataxia Vertigo Gastrointestinal disturbances	
Lacosamide	Nausea Vomiting Diarrhea Dizziness Irritability Headache Rash	Postural hypotension Cardiac arrhythmias
Lamotrigine	Tremor Vertigo Diplopia Ataxia	Stevens-Johnson syndrome

	Headache Gastrointestinal disturbances	
Levetiracetam	Sedation Anxiety Headache	Allergic dermatitis (rash)
Oxcarbazepine		Allergic dermatitis (rash)
Perampanel	Mood change Dizziness Fatigue Vertigo Slurred speech Euphoria	
Phenobarbital	Sedation Depression Hyperactivity (children)	Agranulocytosis Allergic dermatitis (rash) Stevens-Johnson syndrome Arthritic changes Hepatotoxic effects Teratogenicity
Phenytoin	Nystagmus Ataxia Nausea and vomiting Gingival hyperplasia Depression Megaloblastic anemia Drowsiness	Agranulocytosis Aplastic anemia Allergic dermatitis (rash) Stevens-Johnson syndrome Hepatotoxic effects Pancreatitis Acne Coarse facies Hirsutism Teratogenicity Dupuytren contracture
Primidone	Sedation	Rash Thrombocytopenia Agranulocytosis Lupus-like syndrome Teratogenicity
Rufinamide	Drowsiness Loss of coordination Headache Vomiting	Allergic dermatitis (rash)
Stiripentol	Drowsiness Ataxia Weight loss Fatigue	Elevated γ -glutamyltransferase Neutropenia
Tiagabine	Dizziness Aphasia Tremor	Allergic dermatitis (rash)
Topiramate	Sedation Ataxia Dizziness	Allergic dermatitis (rash)

TABLE 13.4

Pharmacokinetics of antiepileptic drugs

	Plasma therapeutic concentration ($\mu\text{g}/\text{mL}$)	Protein binding (%)	Elimination half-time (hours)	Route of elimination
Carbamazepine	6-12	70-80	8-24	Hepatic metabolism (active metabolite)
Clonazepam	0.02-0.08	80-90	30-40	Hepatic metabolism
Diazepam		95	20-35	Hepatic metabolism (active metabolites)
Eslicarbazepine		40	10-20	Renal excretion
Ethosuximide	40-100	0	20-60	Hepatic metabolism (25% excreted unchanged)
Felbamate		22-25	20-23	Renal excretion
Gabapentin	2-20	0	6	Renal excretion
Lacosamide		20	10-14	Renal excretion
Lamotrigine		54	25	Hepatic metabolism
Lorazepam		80	14	Hepatic metabolism
Oxcarbazepine		40	8-10	Renal excretion
Perampanel		95	100-110	Hepatic metabolism
Phenobarbital	10-40	48-54	72-144	Hepatic metabolism (25% excreted unchanged)
Phenytoin	10-20	90-93	9-40	Saturable hepatic metabolism
Primidone	5-12	20-30	4-12	Hepatic metabolism to active metabolites of which 40% are excreted unchanged
Rufinamide		30-40	10	Hepatic metabolism
Stiripentol		99	10-15	Hepatic metabolism
Tiagabine		95	5-8	Hepatic metabolism
Topiramate		10	8-15	Renal excretion and hepatic metabolism
Valproic acid	50-100	88-92	7-17	Hepatic metabolism (active metabolites)
Zonisamide		50	50-70	Hepatic metabolism

Adapted in part from Brodie MJ, Dichter MA. Antiepileptic drugs. *N Engl J Med*. 1996;334:168-175 and Dichter MA, Brodie MJ. New antiepileptic drugs. *N Engl J Med*. 1996;334:1583-1590.

Pharmacokinetics

All antiepileptic drugs are administered once daily or more frequently. Sustained release, as well as combination, preparations are becoming increasingly available and preferred by patients because of their ease of use and side effect profile. Absorption of these drugs from the gastrointestinal tract occurs slowly over a period of hours and may be incomplete, especially for gabapentin. Protein binding varies greatly (0% for gabapentin to 90% or greater for phenytoin). Hepatic and renal disease may necessitate dose adjustment. Medications that rely on renal excretion include gabapentin, pregabalin, levetiracetam, vigabatrin, and zonisamide and should be dosed according to renal function. The remainder of medications is hepatically metabolized and should be dosed according to the patient's degree of liver dysfunction.

Antiepileptic drug clearance and elimination half-time range from hours (carbamazepine, valproate, primidone, gabapentin) to days (phenytoin, lamotrigine, phenobarbital, zonisamide) (see [Table 13.4](#)). Because of their ability to induce or inhibit drug metabolism, all antiepileptic drugs, except gabapentin, levetiracetam, and vigabatrin, may be associated with pharmacokinetic drug interactions in which plasma drug concentrations and resulting pharmacologic effects of concomitantly administered drugs may be altered. Such drug interactions should be anticipated in all patients receiving antiepileptic drugs and subsequently receiving drugs for other purposes.

Drug Interactions Related to Protein Binding

Medications that compete for protein binding sites of highly bound antiepileptic drugs (phenytoin, valproate, carbamazepine) can displace the bound drug and lead to increases in the plasma concentration of pharmacologically active antiepileptic drug. Commonly used medications that are highly protein bound include thyroxine and salicylates. Albumin is the principal binding protein for antiepileptic drugs. Hypoalbuminemia, as may accompany renal or hepatic disease or malnutrition, can result in increased plasma concentrations of unbound antiepileptic drug, resulting in toxicity despite therapeutic plasma concentrations. In pregnancy, hypoalbuminemia due to a progressive increase in central volume offsets the dilutional effect.

Drug Interactions Related to Accelerated Metabolism

Enzyme-inducing antiepileptic drugs that accelerate metabolism (carbamazepine, lamotrigine oxcarbazepine, phenobarbital, phenytoin, topiramate, primidone) may accelerate the metabolism of estrogen and progesterone and thus render oral contraceptives ineffective at usual doses. Patients being treated with antiepileptic drugs have increased dose requirements for thiopental, propofol, midazolam, opioids, and nondepolarizing neuromuscular-blocking drug. Possible explanations for altered dose requirements for drugs administered during anesthesia include increased hepatic P450 enzyme activity as a result of stimulating effects of antiepileptic drugs, alterations in the number and/or responsiveness of receptors, and interactions with endogenous neurotransmitters.

Principles of Dosing

The initial dose is that which is high enough to expect clinical effect but low enough to avoid significant side effects (see [Table 13.3](#)). Gradual dose titration is recommended in all but emergency situations. The clinical response guides dose adjustment over time, as there is significant variability in clinical response over a wide range of dosages. A common cause of medication ineffectiveness is failure to achieve a sufficiently high plasma concentration. Noncompliance is a particular concern in specific patient populations including adolescents and the elderly.^{13.6}

To maintain plasma drug concentrations in a therapeutic range, equal doses of the antiepileptic drug are often administered at intervals equivalent to less than one elimination half-time of the drug (see [Table 13.4](#)). Dosing at one-half the drug's elimination half-time ensures that a single missed dose will not result in the plasma concentration decreasing below a therapeutic level.

Plasma Concentrations and Laboratory Testing

Phenytoin is the only agent for which monitoring is routinely recommended due to its nonlinear saturation dose kinetics. Routine laboratory monitoring of plasma concentrations for all other agents is not recommended.³ For this reason, titration to clinical efficacy is recommended for guiding the dosages of antiepileptic drugs. Some patients may respond at low plasma concentrations, and some patients will not respond until high plasma concentrations are obtained. If a patient does not respond to a particular drug as expected, investigating the plasma drug concentration may aid in determining compliance and identifying potential pharmacokinetic interactions.^{1,6}

Mechanism of Seizure Activity

Seizure activity in most patients with epilepsy has a localized or focal origin. Magnetic resonance imaging is the imaging modality of choice, and up to half of newly diagnosed patients with epilepsy exhibit an epileptogenic focus. The reason for the high frequency and synchronous firing in a seizure focus is usually unknown. Possible explanations include local biochemical changes, ischemia, loss of cellular inhibitory systems, infections, and head trauma.

Neurons in a chronic seizure focus exhibit a type of denervation hypersensitivity with regard to excitatory stimuli. The spread of seizure activity to neighboring normal cells is presumably restrained by normal inhibitory mechanisms. Factors such as changes in blood glucose concentrations, PaO_2 , Paco_2 , pH, electrolyte balance, endocrine function, stress, and fatigue may facilitate the spread of a seizure focus into areas of the normal brain. If the spread is sufficiently extensive, the entire brain is activated and a tonic-clonic seizure with unconsciousness ensues. Conversely, if the spread is localized, the seizure produces signs and symptoms characteristic of the anatomic focus. Once initiated, a seizure is most likely maintained by reentry of excitatory impulses in a closed feedback pathway that may not even include the original seizure focus.

Mechanism of Drug Action

The mechanism of action of antiepileptic drug activity is incompletely understood. It is commonly presumed that antiepileptic drugs control seizures by decreasing neuronal excitability or enhancing inhibition of neurotransmission. This is achieved by altering intrinsic membrane ion currents (sodium, potassium, and calcium conductance) or by affecting activity of inhibitory neurotransmitters. Ion currents affected by antiepileptic drugs are primarily those involving the voltage-gated sodium and calcium ion channels. Drugs that delay reactivation of sodium channels (phenytoin, carbamazepine, primidone, valproate, lamotrigine) during high-frequency neuronal firing produce an inhibitory effect on creation of action potentials until neuronal discharge is blocked. Some drugs (phenytoin, carbamazepine, valproate, lamotrigine, zonisamide) act at both sodium and calcium ion channels. Other drugs (ethosuximide, phenobarbital) act selectively at calcium ion channels. Ethosuximide selectively blocks the T-type calcium ion current, which is thought to act as a pacemaker for thalamic neurons and may be important in absence seizures. Drugs (phenobarbital, benzodiazepines) that alter synaptic function act primarily by enhancing γ -aminobutyric acid (GABA)-mediated neuronal inhibition. Benzodiazepines increase the frequency of GABA-mediated ion channel openings, whereas barbiturates increase the duration of ion channel openings. Tiagabine delays the reuptake of GABA from synaptic clefts, effectively enhancing GABA-mediated neuronal inhibition after synaptic release of the neurotransmitter.

Major Antiepileptic Drugs

The principal antiepileptic drugs used to treat patients with epilepsy are carbamazepine, clobazam, eslicarbazepine, ethosuximide, felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, phenobarbital, phenytoin, pregabalin, primidone, rufinamide, stiripentol, tiagabine, topiramate, valproate, vigabatrin, and zonisamide (see [Table 13.2](#)). Since 2005, the number of agents has more than doubled, thereby offering broader therapeutic with fewer drug interactions, broader spectrums of activity, and unique mechanisms of action (see [Table 13.3](#)).^{2,7}

Benzodiazepines such as diazepam, lorazepam, and midazolam are used for short-term treatment of acute seizures or status epilepticus and are usually administered parenterally. Clonazepam can be used to treat

epilepsy, but most patients develop tolerance to its antiepileptic effects and sedation is a common side effect. Felbamate is reserved for use in selected patients with uncontrolled seizures due to its side effect profile. Clobazam is a more recent addition to this class and is unique among other members of the class in that it does not induce significant levels of sedation and can be used for long-term therapy because tolerance is relatively uncommon.⁸

Drugs used in the treatment of partial seizures are carbamazepine, lamotrigine, oxcarbazepine, topiramate, zonisamide, and phenytoin, which are highly effective and associated with an acceptable side effect profile (see [Table 13.2](#)). Valproate, lamotrigine, and topiramate are the antiepileptic drugs useful for treatment of patients with generalized seizures. Ethosuximide, lamotrigine, or valproate are effective in treatment of patients with generalized nonconvulsive seizures, especially absence seizures.

Adverse Side Effects

Antiepileptic drugs may potentially produce numerous and varied adverse side effects related to their mechanism of action and off target effects. Newer agents have a significantly more favorable side effect profile. Some adverse side effects are dose related (sedation, lethargy, neurotoxicity), whereas others are idiosyncratic (hypersensitivity, hepatotoxicity, aplastic anemia) (see [Table 13.3](#)).

Maternal Epilepsy

Unintended pregnancy can result from enzyme inducing antiepileptic drugs that render oral contraceptive pills less effective. Seizures during pregnancy can result in significant morbidity and mortality to both mother and fetus, making seizure control during this period imperative.³ Monotherapy with the lowest dose possible is the guiding principle. Fetal organogenesis is largely complete by 8 weeks. Significant teratogenicity may occur during this period if pregnancy is not detected early enough to permit discontinuation of potentially teratogenic medications. Drug regimens in women of childbearing age should therefore be given special attention. In particular, parturients who take valproate have more than double the risk of giving birth to a fetus with congenital malformations including neural tube defects such as spina bifida, atrial septal defects, cleft palate, hypospadias, polydactyly, and craniosynostosis. Other antiepileptics that should be avoided during pregnancy because of risk of malformation rates include phenytoin and phenobarbital. Patients on less than 300 mg per day of lamotrigine or less than 400 mg per day of carbamazepine have rates of congenital malformation comparable to the general population. Clobazam may be added as needed especially during labor. Conclusive data regarding other antiepileptic drugs during pregnancy is lacking, in part due to the ethical and regulatory difficulty of conducting randomized trials during pregnancy.¹ Folate supplementation during pregnancy lowers the risk of teratogenicity in babies born to women who are taking antiepileptic medications.⁹

Carbamazepine

Carbamazepine is an iminostilbene derivative that is effective for suppression of nonconvulsive and convulsive partial and generalized seizures. In addition, this drug may be useful in the management of patients with trigeminal neuralgia and glossopharyngeal neuralgia. Structurally, carbamazepine is related to the tricyclic antidepressant imipramine. Like phenytoin, carbamazepine maintains sodium channels in their inactive conformation, which prevents repetitive and sustained firing of an action potential.

Pharmacokinetics

This drug is available only as an oral preparation (see [Table 13.4](#)). Oral absorption is rapid, with peak plasma concentrations occurring 2 to 6 hours after ingestion. Plasma protein binding is 70% to 80%. The plasma elimination half-time is 8 to 24 hours. The principal metabolite of carbamazepine is an epoxide derivative that has antiseizure effects that may also be responsible for many of the dose-limiting side effects of this drug. Because this drug induces its own metabolism, many patients require a dosage increase in 2 to 4 weeks after initiation of therapy. The usual therapeutic plasma concentration of carbamazepine is 6 to 12 µg/mL.

Side Effects

The toxicity of carbamazepine is similar to that produced by phenytoin (see [Table 13.3](#)). Sedation, vertigo, diplopia, nausea, and vomiting are the most frequent side effects of this drug. Chronic diarrhea develops in some patients, whereas others experience the syndrome of inappropriate antidiuretic hormone secretion. Aplastic anemia, thrombocytopenia, hepatocellular and cholestatic jaundice, oliguria, hypertension, and cardiac dysrhythmias are rare but potentially life-threatening complications. Chronic suppression of white blood cell counts can occur. For these reasons, it may be prudent to monitor bone marrow, cardiac, hepatic, and renal function in patients being treated with carbamazepine. At high plasma concentrations, carbamazepine has an arginine vasopressin hormone-like action that may result in hyponatremia. Skin rash, often with other manifestations of drug allergy, occurs in approximately 10% of chronically treated patients.

In addition to inducing its own metabolism, carbamazepine can accelerate the hepatic oxidation and conjugation of other lipid-soluble drugs. The most common interaction is with oral contraceptive pills, and most women require an increase in the daily dose of estrogen. Carbamazepine also accelerates the metabolism of valproic acid, ethosuximide, corticosteroids, anticoagulants, and antipsychotic drugs. Drugs that inhibit the metabolism of carbamazepine sufficiently to cause toxic effects include cimetidine, propoxyphene, diltiazem, verapamil, isoniazid, and erythromycin.

Eslcarbazepine

Eslcarbazepine is approved for use for partial-onset seizures. Its mechanisms of action also involve stabilization of the inactive state of voltage-gated sodium channels. This allows less sodium to enter the neuron, which reduces excitability. Upon oral administration, it is absorbed greater than 90% and is metabolized to eslicarbazepine, and peak plasma concentration occurs in 2 to 4 hours. It is 40% plasma protein bound. Excretion is 90% by the kidneys. The most common side effects are dizziness and fatigue, diarrhea, nausea, vomiting, rash, and hyponatremia. Eslcarbazepine is contraindicated in patients with second- or third-degree atrioventricular heart block as it may cause lethal cardiac arrhythmias. Carbamazepine and phenytoin reduce the plasma concentration of eslicarbazepine because of the induction of hepatic glucuronidation.[10,11](#)

Ethosuximide

Ethosuximide is the drug of choice for suppression of absence (petit mal) epilepsy in patients who do not also have tonic-clonic seizures. This drug acts by decreasing voltage-dependent calcium conductance in thalamic neurons. This is consistent with the speculated importance of the thalamocortical system in the etiology of absence seizures.

Pharmacokinetics

This drug is available only as an oral preparation (see [Table 13.4](#)). Peak plasma concentrations occur in 1 to 7 hours after oral administration. Ethosuximide is not significantly bound to albumin. Approximately 25% of the drug is excreted unchanged in urine, and the remainder is metabolized to inactive metabolites by hepatic microsomal enzymes. The elimination half-time is 20 to 60 hours. The usual maintenance dose of ethosuximide is 20 to 30 mg/kg. A plasma concentration of 40 to 100 µg/mL is required for satisfactory suppression of absence epilepsy.

Side Effects

Toxicity of ethosuximide is low, manifesting most often as gastrointestinal intolerance (nausea, vomiting) and CNS effects (lethargy, dizziness, ataxia, photophobia). There have been rare reports of bone marrow suppression. Hyponatremia is also a possible side effect.[9](#)

Felbamate

Because of its potential to produce life-threatening side effects, felbamate is not used as a first-line drug for treatment of seizures but rather is reserved for patients with intractable epilepsy. Felbamate is used principally for poorly controlled partial and secondarily generalized seizures. It also decreases the frequency of seizures associated with the Lennox-Gastaut syndrome and myotonic and atonic forms of epilepsy.[12](#) The mechanism

of action of felbamate is unknown but may involve action at voltage-gated sodium channels, *N*-methyl-D-aspartate and non-*N*-methyl-D-aspartate glutamate receptors, voltage-gated calcium currents, and GABA receptor modulation.⁸

Pharmacokinetics

Oral absorption is prompt and the elimination half-time is prolonged (see [Table 13.4](#)). Felbamate undergoes minimal metabolism with most of the drug being excreted unchanged by the kidneys.

Side Effects

Serious side effects include aplastic anemia and hepatotoxicity (see [Table 13.3](#)). Monitoring of treated patients with complete blood counts and liver function tests is indicated. Because felbamate is metabolized by hepatic cytochrome P450 enzymes, its metabolism is affected by concurrent administration of other drugs that are also metabolized by this system. In particular, concomitant administration of carbamazepine or phenytoin may decrease plasma concentrations of felbamate. Likewise, because felbamate is a potent inhibitor of P450 enzymes, it can slow the metabolism of phenytoin, phenobarbital, and valproic acid. In this regard, if a patient is receiving phenytoin, carbamazepine, or valproic acid and receives felbamate, the dose of these drugs should be decreased by 20% to 30% to prevent toxic effects.

Gabapentin

The pharmacokinetic considerations for gabapentin are discussed in detail in Chapter 2. Gabapentin is an analogue of GABA but does not bind to GABA receptors. Its mechanism of action is largely unknown but likely involves inhibition of voltage-gated calcium channels. Gabapentin induces dose-related sedation, and it has efficacy in the treatment of anxiety, panic, and major depression.¹³ Despite its multiple other uses, gabapentin has limited efficacy in the treatment of epilepsy.

Lacosamide

Lacosamide is indicated for partial-onset seizures. Its mechanism of action is through voltage-gated sodium channels. Specifically, it enhances the slow inactivation of voltage-gated sodium channels, thereby preventing the action potential from occurring. Because it prevents the sodium channel from opening on neurons, which are firing action potentials, it is able to effectively stabilize hyperexcitable neurons. Lacosamide is rapidly absorbed from the gastrointestinal tract and reaches peak plasma concentrations 2 to 5 hours after administration. It has a bioavailability of almost 100%. It has few drug interactions due to low plasma protein binding of less than 20%. It is excreted 95% in the urine. The most common side effects are nausea, vomiting, diarrhea, dizziness, headaches, drowsiness, postural hypotension, arrhythmias, itching, and rash.^{14,15}

Lamotrigine

Lamotrigine is a chemically novel anticonvulsant drug of the phenyltriazine class that most likely acts by stabilizing voltage-sensitive sodium ion channels, thus preventing release of aspartate and glutamate. This drug has a broad spectrum of activity and is effective when used alone or in combination in adults who have partial seizures or generalized seizures and in children with Lennox-Gastaut syndrome. When administered orally, lamotrigine is well absorbed, and its plasma elimination half-time is about 25 hours (see [Table 13.4](#)). Drugs that induce hepatic microsomal enzymes (phenobarbital, phenytoin, and carbamazepine) decrease the elimination half-time of lamotrigine by about 50%, necessitating a higher dose. Conversely, valproic acid slows the metabolism of lamotrigine and extends its elimination half-time to about 60 hours. The most common side effects of lamotrigine are headache, nausea, vomiting, dizziness, diplopia, and ataxia (see [Table 13.3](#)). Tremor can be troublesome at higher doses. In approximately 5% of adults, a rash develops, which subsequently disappears in some patients, despite continued therapy. In a few patients, however, the rash is more serious, and fever, arthralgias, and eosinophilia occur. In rare cases, Stevens-Johnson syndrome has been reported.

Levetiracetam

Levetiracetam is available in both oral and intravenous (IV) preparations. It is effective in the management of juvenile myoclonic epilepsy, partial and generalized convulsive seizures, generalized tonic-clonic seizures, and partial seizures. Its mechanism of action is not fully known; however, it binds to certain presynaptic calcium channels, acting to reduce synaptic neurotransmitter release.¹⁶ Side effects are considered minor and include sedation, asthenia, anxiety, and headache. The pharmacokinetic profile of levetiracetam is favorable, with the absence of hepatic metabolism and minimal protein binding. No significant drug interactions have been described with coadministration of other antiepileptic drugs.

Oxcarbazepine

Oxcarbazepine is a keto analogue of carbamazepine that provides equivalent seizure control but with fewer adverse side effects. After administration, oxcarbazepine acts as a prodrug that is converted to an active metabolite, 10-hydroxycarbazepine. Oxcarbazepine and its active metabolite do not induce hepatic microsomal enzymes nor does it displace other drugs from plasma protein binding sites. As such, they are safer drugs to be used in combination therapy.

Perampanel

Perampanel is indicated for patients with partial seizures and generalized tonic-clonic seizures. It has a unique mechanism of action that involves the selective noncompetitive antagonism of α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors. Perampanel is 95% plasma protein bound and has an elimination half-life of 110 hours. It is primarily metabolized by the liver and is excreted in the feces (70%) and urine (30%). A black box warning exists that some patients may experience suicidal or homicidal thoughts. Other side effects include dizziness, fatigue, vertigo, slurred speech, irritability, and aggression. In high doses, it can produce a euphoric sensation; therefore, it can be potentially abused.^{17,18}

Phenobarbital

Phenobarbital is a long-acting barbiturate that is effective against all seizure types except nonconvulsive primary generalized seizures. Cognitive and behavioral side effects limit this drug's usefulness in the treatment of epilepsy. Because of these side effects, phenobarbital is considered a second-line drug in the treatment of epilepsy.

Phenobarbital appears to exert its antiepileptic properties partly through potentiation of the postsynaptic actions of the inhibitory neurotransmitter GABA and inhibition of the excitatory postsynaptic actions of glutamate. These drug-induced effects prolong the duration of chloride channel opening and thus limit the spread of seizure activity and increase the seizure threshold.

Pharmacokinetics

Oral absorption of phenobarbital is slow but nearly complete, with peak concentrations occurring 12 to 18 hours after a single dose (see [Table 13.4](#)). Plasma protein binding is 48% to 54%. Approximately 25% of phenobarbital is eliminated by pH-dependent renal excretion, with the remainder inactivated by hepatic microsomal enzymes. The principal metabolite is an inactive parahydroxyphenyl derivative that is excreted in urine as a sulfate conjugate. The elimination half-time of phenobarbital is prolonged.

The usual daily oral dose of phenobarbital is 60 mg in adults or 4 mg/kg in children. Plasma phenobarbital concentrations of 10 to 40 μ g/mL are usually necessary for control of seizures. The value of measuring plasma phenobarbital concentrations is limited because the concentration associated with optimal control is highly variable among patients. In addition, the development of tolerance to the drug's CNS effects makes the toxic threshold imprecise.

Side Effects

Sedation in adults and children and irritability and hyperactivity in children are the most troublesome side effects when this drug is used to treat epilepsy (see [Table 13.3](#)). Tolerance to the sedative effects of phenobarbital may develop with chronic therapy. Depression develops in many adults taking phenobarbital,

and confusion may occur in elderly patients. Cognitive effects include slowing of task processing. Scarlatiniform or morbilliform rash occurs in up to 2% of patients. Megaloblastic anemia that responds to folic acid administration and osteomalacia that responds to vitamin D therapy may occur during chronic phenobarbital therapy as well as during treatment with phenytoin. Nystagmus and ataxia are likely if the plasma phenobarbital concentration is >40 $\mu\text{g}/\text{mL}$. Abnormal collagen deposition manifesting as Dupuytren contracture may occur. Congenital malformations may occur when phenobarbital is administered chronically during pregnancy. Coagulation defects and hemorrhage in the neonate must be considered in the setting of fetal exposure. Interactions between phenobarbital and other drugs usually involve induction of hepatic microsomal enzymes. In this regard, phenobarbital is the classic example of a hepatic microsomal enzyme inducer that can accelerate the metabolism of many lipid-soluble drugs.

Phenytoin

Phenytoin is the prototype of the hydantoins and is effective for the treatment of partial and generalized seizures. Available in oral and IV preparations, phenytoin may be administered acutely to achieve effective plasma concentrations within 20 minutes. This drug has a high therapeutic index, and its administration is not accompanied by excessive sedation.

Mechanism of Action

Phenytoin regulates neuronal excitability and thus the spread of seizure activity from a seizure focus by regulating sodium and possibly calcium ion transport across neuronal membranes. This stabilizing effect on cell membranes is relatively selective for the cerebral cortex, although the effect also extends to peripheral nerves. In addition to the effect on ion fluxes, phenytoin acts on second messengers such as calmodulin and the cyclic nucleotides.

Pharmacokinetics

Phenytoin is a weak acid ($\text{pK } 8.3$) that is maintained in aqueous solutions as a sodium salt (see [Table 13.4](#)). The drug precipitates in solutions with a pH of <7.8 . Its poor water solubility may result in slow and sometimes variable absorption from the gastrointestinal tract (30%-97%). The initial daily adult oral dosage is 3 to 4 mg/kg . Doses of >500 mg daily are rarely tolerated. The long duration of action of phenytoin allows a single daily dosage, but gastric intolerance may necessitate divided dosage. After intramuscular (IM) injection, the drug precipitates at the injection site and is slowly absorbed. For this reason, IM administration is not recommended. Infusion of phenytoin should probably not exceed 5 mg per minute.

Plasma Concentrations

Control of seizures is usually obtained when plasma concentrations of phenytoin are 10 to 20 $\mu\text{g}/\text{mL}$. In the control of digitalis-induced cardiac dysrhythmias, phenytoin, 0.5 to 1.0 mg/kg IV, is administered every 15 to 30 minutes until a satisfactory response is achieved or a maximum dose of 15 mg/kg is administered. A plasma phenytoin concentration of 8 to 16 $\mu\text{g}/\text{mL}$ is usually sufficient to suppress cardiac dysrhythmias. Adverse side effects of phenytoin such as nystagmus and ataxia are likely when the plasma concentration of drug >20 $\mu\text{g}/\text{mL}$. Nevertheless, the diagnosis of phenytoin toxicity should be made on the basis of clinical symptoms.

Protein Binding

Phenytoin is bound approximately 90% to plasma albumin. A greater fraction of phenytoin remains unbound in neonates, in patients with hypoalbuminemia, and in uremic patients.

Metabolism

Metabolism of phenytoin to inactive metabolites is by hepatic microsomal enzymes that are susceptible to stimulation or inhibition by other drugs. An estimated 98% of phenytoin is metabolized to the inactive derivative parahydroxyphenyl, which appears in urine as a glucuronide. Approximately 2% of phenytoin is recovered unchanged in urine.

When the plasma concentration of phenytoin is <10 µg/mL, metabolism follows first-order kinetics, and the elimination half-time averages 24 hours. At plasma concentrations of >10 µg/mL, the enzymes necessary for metabolism of phenytoin become saturated, and the elimination half-time becomes dose-dependent (zero-order kinetics). At this stage, relatively small increases in dose may result in dramatic increases in the plasma concentration of phenytoin. Zero-order kinetics in phenytoin metabolism resembles the metabolism of alcohol.

Side Effects

The side effects of phenytoin include CNS toxicity that manifests clinically as nystagmus, ataxia, diplopia, and vertigo (cerebellar-vestibular dysfunction) and is likely when the plasma phenytoin concentration is >20 µg/mL. Peripheral neuropathy has been observed in up to 30% of chronically treated patients. Gingival hyperplasia occurs in approximately 20% of chronically treated patients and is probably the most common manifestation of phenytoin toxicity in children and adolescents. This complication is minimized by improved oral hygiene and does not necessarily require discontinuation of phenytoin therapy. Other reversible cosmetic side effects include acne, hirsutism, and facial coarsening. Administration of phenytoin during pregnancy may result in the fetal hydantoin syndrome, which manifests as wide-set eyes, broad mandible, and finger deformities.

Allergic reactions include morbilliform rash in 2% to 5% of patients. Hyperglycemia and glycosuria may reflect phenytoin-induced inhibition of insulin secretion. Megaloblastic anemia is rare and has been attributed to altered folic acid absorption but probably also involves altered folic acid metabolism. Phenytoin-induced hepatotoxicity, although rare, may occur in genetically susceptible persons who lack the enzyme phenytoin epoxide. This enzyme is necessary to convert an electrophilic intermediate formed after the oxidative metabolism of phenytoin to an inert and nontoxic product. Gastrointestinal irritation is due to alkalinity of the drug; this may be minimized by taking phenytoin after meals.

Phenytoin can induce the oxidative metabolism of many lipid-soluble drugs, including carbamazepine, valproic acid, ethosuximide, anticoagulants, and corticosteroids. Because its metabolism is saturable, inhibitory interactions are particularly likely to have neurotoxic effects. Interactions involving protein binding displacement are not likely to be clinically significant.

Patients receiving phenytoin chronically have higher dose requirements for nondepolarizing neuromuscular-blocking drugs such as vecuronium compared with untreated patients. Phenytoin induces hepatic enzymes and it is likely that metabolism and elimination of nondepolarizing neuromuscular-blocking drugs is increased. Phenytoin may also produce mild blocking effects at the neuromuscular junction leading to upregulation of acetylcholine receptors.

Primidone

Primidone is metabolized to phenobarbital and another active metabolite, phenylethylmalonamide. The efficacy of this drug resembles that of phenobarbital, but it is less well tolerated. There is little to recommend this drug over phenobarbital for patients in whom treatment with a barbiturate is contemplated. Possible side effects include Dupuytren contracture, shortening of the QT segment, and coagulation defects. For this reason, it is seldom prescribed.

Rufinamide

Rufinamide is used as combination therapy in the treatment of Lennox-Gastaut syndrome in children and adults. It has an unknown mechanism of action, owing to its unique chemical structure that is different from all other antiepileptics. It is 30% to 40% protein bound and has an elimination half-life of 10 hours. It is metabolized by the liver via carboxylesterase-mediated hydrolysis and is 90% excreted in the urine. Common side effects include headaches, fatigue, dizziness, and nausea.[19,20](#)

Stiripentol

Stiripentol is approved for the treatment of Dravet syndrome and is typically used as an add-on therapy with valproate or clobazam. It has a unique chemical structure, belonging to the group of aromatic allylic alcohols.

It rapidly crosses the blood–brain barrier and enters the brain, where it accumulates in the cerebellum and medulla. Its mechanism of action is unknown but is known to increase GABAergic activity. Common adverse effects include weight loss, loss of appetite, somnolence, ataxia, hypotonia, and dystonia. Less frequently, neutropenia may occur, and therefore, routine monitoring of a white blood cell counts while on therapy is necessary. Other less common side effects include nausea, vomiting, aggression, hyperexcitability, and sleep disorders.^{[21](#)[22](#)}

Tiagabine

Tiagabine is a nipecotic acid moiety that is a potent inhibitor of GABA reuptake. This drug is used as adjunctive therapy for complex partial seizures. Possible side effects include dizziness, asthenia, aphasia, and tremor. Mental depression may accompany administration of tiagabine perhaps reflecting this drug's ability to increase GABA concentrations. Drug interactions are unlikely despite the high protein binding of tiagabine reflecting the small amount of drug needed to achieve clinical efficacy. Tiagabine has no effect on hepatic enzymes.

Topiramate

Topiramate is a broad-spectrum antiepileptic drug that is indicated as monotherapy or adjunctive therapy in children and adults for the control of partial, generalized tonic-clonic, and absence seizures. Efficacy in treatment of other neurologic and psychiatric disorders has been reported including bulimia, migraine headache, and essential tremor. Topiramate inhibits voltage-gated sodium ion channels, high-voltage activated calcium ion channels, and glutamate-mediated neurotransmission at specific receptor subtypes. In addition, topiramate is a weak inhibitor of carbonic anhydrase. Minor side effects may include sedation, dizziness, and ataxia. Nephrolithiasis occurs in about 1.5% of treated patients perhaps reflecting this drug's action on carbonic anhydrase. Enzyme-inducing drugs decrease plasma concentrations of topiramate, but topiramate does not affect hepatic P450 enzymes and undergoes minimal protein binding.

Valproic Acid

Valproic acid is a branched-chain carboxylic acid that is effective in the treatment of all primary generalized epilepsies and all convulsive epilepsies. It is somewhat less effective for the suppression of nonconvulsive partial seizures. This drug acts by limiting sustained repetitive neuronal firing through voltage-dependent sodium channels.

Pharmacokinetics

Valproic acid is available as a syrup and in an enteric-coated formulation, which is preferred because it decreases gastrointestinal side effects. After oral administration, absorption is prompt, with peak plasma concentrations of valproic acid occurring in 1 to 4 hours. Binding to plasma proteins is >80%. More than 70% of the drug can be recovered as inactive glucuronide conjugates. The elimination half-time is 7 to 17 hours. The usual daily dose of valproic acid is 1 to 3 g to achieve a therapeutic plasma concentration of 50 to 100 µg/mL. Nevertheless, the daily variation in plasma concentrations of valproic acid is great, and routine monitoring may not be helpful unless it is correlated with the patient's clinical condition.

Side Effects

Gastrointestinal side effects include anorexia, nausea, and vomiting. Weight gain is common in patients treated chronically with valproic acid. At higher doses, a fine distal tremor may develop. Thrombocytopenia is seen frequently at higher doses. The most serious side effect of valproic acid is hepatotoxicity occurring in about 0.2% of children younger than 2 years of age being treated chronically with this drug. The incidence of this potentially fatal hepatic necrosis decreases dramatically after 2 years of age. Approximately 20% of treated patients have hyperammonemia without hepatic damage. Sedation and ataxia are infrequent side effects of valproic acid.

Because valproic acid is partly eliminated as a ketone-containing metabolite, the urine ketone test may show false-positive results. Valproic acid can displace phenytoin and diazepam from protein binding sites,

resulting in increased pharmacologic effects produced by the displaced drug.

Valproic acid is an enzyme inhibitor. As a result of this enzyme inhibition, the metabolism of phenytoin is slowed by valproic acid. Valproic acid causes the plasma concentration of phenobarbital to increase almost 50%, presumably due to inhibition of hepatic microsomal enzymes. However, valproic acid does not interfere with the action of oral contraceptives.

Vigabatrin

Vigabatrin is used to treat refractory complex partial seizures. It may also be used as monotherapy to treat infantile spasms. Tablet and powder preparations are available and are bioequivalent. Its mechanism of action is imperfectly understood but is thought to involve irreversible inhibition of the GABA transaminase enzyme, thereby increasing the amount of GABA in the CNS. It is not protein bound and undergoes no significant metabolism. It is excreted unchanged in the urine. Dosage must therefore be adjusted if renal impairment is present. Significant side effects include permanent visual loss, anemia, somnolence, and fatigue.²³

Zonisamide

Zonisamide is a broad-spectrum antiepileptic drug used as adjunctive therapy for management of partial and secondarily generalized seizures. Modulation of voltage-dependent calcium ion channels seems to be an important mechanism for this drug's ability to control seizures. In addition, zonisamide enhances GABA-mediated neuronal inhibition. Adverse side effects include sedation, dizziness, ataxia, anorexia, and behavioral disorders in children and manic responses in adults. Nephrolithiasis may occur in 3% of treated patients. Pharmacokinetic drug interactions are unlikely as zonisamide does not displace other drugs from protein binding sites and effects on metabolism of other drugs is minimal.

Benzodiazepines

Benzodiazepines display anxiolytic, sedative, muscle-relaxant, and anticonvulsant effects (see [Chapter 5](#)). Benzodiazepine receptors in the brain are a subset of GABA_A receptors. The binding of benzodiazepines to these receptors potentiates GABA-mediated neuronal inhibition, which increases chloride permeability and thereby leads to cellular hyperpolarization and inhibition of neuronal firing. In low doses, benzodiazepines suppress polysynaptic activity in the spinal cord and decrease neuronal activity in the mesencephalic reticular system.

Clonazepam

Clonazepam is generally added to other drug therapy and is used as a first-line drug only for myoclonic seizures.

Pharmacokinetics

Absorption of clonazepam after oral administration is rapid, with peak plasma concentrations occurring within 2 to 4 hours (see [Table 13.4](#)). An IV administration of clonazepam results in rapid CNS effects. Approximately 50% of the drug is bound to plasma proteins. Clonazepam is extensively metabolized to inactive products, with <2% of an injected dose appearing unchanged in urine. The elimination half-time of this long-acting drug is 30 to 40 hours. The oral maintenance dose is unlikely to exceed 0.25 mg/kg. Therapeutic plasma concentrations of clonazepam are 0.02 to 0.08 µg/mL.

Side Effects

Sedation is present in approximately 50% of patients but tends to subside with chronic administration (see [Table 13.3](#)). Skeletal muscle incoordination and ataxia occur in approximately 30% of patients. Personality changes occur in approximately 25% of patients, manifesting as behavioral disturbances, including hyperactivity, irritability, and difficulty in concentration, especially in children. Elderly patients treated with clonazepam may experience depression. Increased salivary and bronchial secretions may be particularly prominent in children. Generalized seizure activity may be precipitated if the drug is discontinued abruptly.

Diazepam

Diazepam is a mainstay for the treatment of status epilepticus and local anesthetic-induced seizures. The typical approach is administration of 0.1 mg/kg IV every 10 to 15 minutes until seizure activity has been suppressed or a maximum dose of 30 mg has been administered (see [Chapter 5](#)). Diazepam has a long elimination half-time of 27 to 48 hours. Metabolism of diazepam results in active metabolites.

Lorazepam

Lorazepam has a shorter elimination half-time (8-25 hours) than diazepam but a longer duration of antiepileptic action because it is not rapidly redistributed. Lorazepam is metabolized in the liver and has no active metabolites. Lorazepam, which is available in parenteral and oral formulations, is used to treat status epilepticus and as intermittent therapy for seizure clusters.

Clobazam

Clobazam is used for complex partial, tonic-clonic, and myoclonic seizures primarily as a second-line agent. It is metabolized in the liver and has an active metabolite and is excreted by the kidneys. The elimination half-life is 16 to 18 hours. Its potential for sedation, lethargy, and loss of therapeutic effect is significantly lower than other benzodiazepines. Like other drugs of this class, significant withdrawal may occur if discontinuation is not gradual.²⁴

Status Epilepticus

Status epilepticus is a medical emergency where the patient experiences prolonged or rapidly recurring convulsions for 5 minutes or more. The motor manifestations of convulsive status epilepticus may be symmetrical with tonic and then clonic activity. Rapid seizure control is associated with improved clinical outcome.²⁵

Treatment

Treatment begins with ensuring a patent upper airway and administration of oxygen. Maintenance of ventilation may require tracheal intubation. An IV access is obtained in anticipation of administering antiepileptic drugs. If hypoglycemia cannot be excluded, the patient is treated empirically with IV glucose (50 mL of 50% glucose for adults). Drug therapy of status epilepticus is typically with a benzodiazepine such as diazepam, lorazepam, or midazolam. In the absence of IV access, a rectal gel form of diazepam or an intranasal form of midazolam is available. Ventilatory depression necessitating support of ventilation may accompany administration of benzodiazepines. If benzodiazepines are not successful in extinguishing the seizure, other choices include fosphenytoin; phenytoin; phenobarbital; valproic acid; and continuous infusions of valproic acid, levetiracetam, and propofol. Hypotension and prolongation of the QT interval on the electrocardiogram may accompany administration of fosphenytoin necessitating a slowing in the rate of IV infusion.^{25,26}

Drugs Used for Treatment of Parkinson Disease

Parkinson disease affects 1% of the population, predominantly in those older than 60 years, although onset can occur significantly earlier. It is a chronically progressive neurodegenerative disease that results from the loss of dopaminergic neurons in the substantia nigra pars compacta region of the basal ganglia. The presence of Lewy bodies is also a consistent feature.²⁷ Dopamine is thought to act principally as an inhibitory neurotransmitter and acetylcholine as an excitatory neurotransmitter within the extrapyramidal system, and a proper balance is necessary for normal function. Approximately 80% of the dopamine in the brain is concentrated in the basal ganglia, mostly in the caudate nucleus and putamen. In patients with Parkinson disease, the basal ganglia content of dopamine may be as low as 10% of normal. As a result, an excess of excitatory cholinergic activity manifesting as progressive tremor, skeletal muscle rigidity, bradykinesia, and disturbances of posture results.

The objective in treating Parkinson disease is to treat debilitating symptoms. Currently all approved medications offer only palliative relief, as they do not affect progression of the disease. Often, combinations

of drugs with effects on the dopaminergic and cholinergic components of the extrapyramidal nervous system are used. Management decisions, including when to commence treatment, takes into account numerous factors including age, symptoms, stage of the disease, and the degree of interference with activities of daily living. Treatment strategies can be divided into those addressing motor symptoms, those addressing other adverse effects of the disease including nausea, depression, autonomic disturbances and cognitive impairment, and those addressing medication related side effects.²⁷ Failure of pharmacologic therapy is an indication for deep brain stimulation, with the primary targets being the globus pallidus internus or subthalamic nucleus.²⁸

Levodopa

Because dopamine does not readily cross the blood–brain barrier, the major approaches to therapy have involved the administration of its precursor, levodopa, or drugs that mimic the action of dopamine. Levodopa is the cornerstone of symptomatic therapy of Parkinson disease and its efficacy is unsurpassed even by newer drugs. Levodopa crosses the blood–brain barrier and is converted to dopamine by aromatic-L-amino-acid decarboxylase (dopa decarboxylase enzyme), acting to replenish dopamine stores in the basal ganglia. Levodopa is usually administered with a peripheral decarboxylase inhibitor (carbidopa or benserazide) to maximize entrance of this precursor into the brain before it is converted to dopamine. Furthermore, side effects associated with increased peripheral concentrations of dopamine are less when it is combined with a decarboxylase inhibitor. Absorption of levodopa from the gastrointestinal tract is efficient, but the brief elimination half-time (1-3 hours) requires frequent dosing intervals to maintain a therapeutic concentration. Recently, controlled release and extended release preparations has increased dosing intervals and reduced some side effects. An IV formulation of levodopa is not available.

The beneficial therapeutic response to levodopa typically diminishes after 5 to 10 years of treatment, presumably reflecting progression of the disease process and continuing loss of nigrostriatal neurons with a capacity to store dopamine. Abrupt discontinuation of levodopa therapy may result in a precipitous return of symptoms of Parkinson disease and has been associated with a neuroleptic malignant-like syndrome. For this reason, levodopa should be continued throughout the perioperative period.

Metabolism

Approximately 95% of orally administered levodopa is rapidly decarboxylated to dopamine during the initial passage through the liver. The resulting dopamine cannot easily cross the blood–brain barrier to exert beneficial effects, whereas increased plasma concentrations of dopamine often lead to undesirable side effects. In this regard, inhibition of the peripheral activity of the decarboxylase enzyme greatly increases the fraction of administered levodopa that remains intact to cross the blood–brain barrier.

At least 30 metabolites of levodopa have been identified. Most of these metabolites are converted to dopamine, small amounts of which are subsequently metabolized to norepinephrine and epinephrine. Metabolism of dopamine yields 3,4-dihydroxyphenylacetic acid (homovanillic acid). Dietary methionine is necessary as a source of methyl donors to permit continued activity of catechol-O-methyltransferase (COMT), which is necessary for the metabolism of the excess amounts of dopamine that result from high doses of levodopa. Most metabolites of dopamine are excreted by the kidneys.

Side Effects

The most common side effects that occur during the first weeks of therapy with levodopa and dopamine agonists are nausea and hypotension. These side effects are associated with peak plasma concentrations of dopamine and may be minimized by taking medications after light meals or snacks. The most common problems that occur during long-term therapy are dyskinesias, fluctuations in mobility, increasing confusion, and psychosis. These problems become progressively more frequent after the first 3 years of therapy.

Gastrointestinal Dysfunction

Nausea and vomiting occur in about 80% of patients during the early period of treatment with levodopa. These responses reflect dopamine-induced stimulation of the chemoreceptor trigger zone, which is not

protected by the blood–brain barrier.²⁹ Nausea can be effectively treated with domperidone, which does not easily cross the blood–brain barrier and is therefore unlikely to exacerbate symptoms of Parkinson disease. Domperidone inhibits dopamine-2 receptors in the chemoreceptor trigger zone of the medulla oblongata.³⁰ Trimethobenzamide can also be used and has a direct action on the chemoreceptor trigger zone and is devoid of dopaminergic action.³¹ Dopamine receptor antagonist antiemetics such as prochlorperazine, metoclopramide, and promethazine must be avoided because they significantly worsen symptoms of Parkinson disease. Gastrointestinal side effects tend to disappear with continuing therapy as tolerance develops.²⁷

Parkinsonism-Hyperpyrexia Syndrome

Sudden cessation or dose reduction of levodopa or dopamine antagonists may lead to a life-threatening emergency termed *parkinsonism-hyperpyrexia syndrome*. The clinical presentation is similar to neuroleptic malignant syndrome, with rigidity, pyrexia, autonomic instability, and a decreased level of consciousness. Potential complications include renal failure, aspiration pneumonia, deep venous thrombosis, pulmonary embolism, and death. Prompt recognition and management are imperative as this carries a 4% mortality rate. Treatment involves replacing Parkinson medications at the current dose. Levodopa can be given orally or, if necessary, by a nasogastric tube. A rotigotine patch or an apomorphine infusion can be commenced in an intensive care unit where careful observation for dysautonomia can be achieved along with supportive measures.³²

Cardiovascular Changes

Cardiovascular changes associated with levodopa most likely reflect α- and β-adrenergic responses evoked by increased plasma concentrations of dopamine and its metabolism to norepinephrine and epinephrine. Transient flushing of the skin is common during levodopa therapy.

Orthostatic Hypotension

Approximately 30% of patients develop orthostatic hypotension early in therapy. This can be due to autonomic dysfunction from the disease or as a result of levodopa treatment. It can be a significant problem in some patients and warrants continuous evaluation as it can result in syncopal episodes. Initial treatment consists of increased fluid and sodium intake, elevation of the head of the patient's bed, and compression stockings. If symptoms are persistent, administration of fludrocortisone, domperidone, or midodrine may be useful. Orthostatic hypotension becomes less prominent with continued therapy.^{27,29}

Cardiac Dysrhythmias

Cardiac dysrhythmias, including sinus tachycardia, atrial and ventricular premature contractions, atrial fibrillation, and ventricular tachycardia, although rare, have been associated with levodopa therapy. Presumably, the potential β-adrenergic effects of dopamine and its metabolites on the heart contribute to cardiac dysrhythmias, although a cause-and-effect relationship has not been documented. Patients with preexisting disturbances of cardiac conduction or coronary artery disease are most likely to develop cardiac dysrhythmias in association with levodopa therapy. Propranolol is an effective treatment when cardiac dysrhythmias occur in these patients.²⁹

Abnormal Involuntary Movements

Abnormal involuntary movements in the form of faciolingual tics; grimacing; and rocking movements of the arms, legs, or trunk are the most common side effects of chronic levodopa therapy, developing in about 50% of patients within 1 to 4 months after initiation of therapy. Rarely, exaggerated respiratory movements can produce an irregular gasping pattern, presumably reflecting dyskinesias of the diaphragm and intercostal muscles. Tolerance does not develop to abnormal involuntary movements.

Fluctuations in mobility are characterized by increasing bradykinesia at the end of an interval between doses. High-protein meals are avoided in patients who experience sudden loss of mobility because a large influx of dietary amino acids can interfere with the transport of levodopa into the brain.

Psychiatric Disturbances

Confusion, visual hallucinations, and paranoia may reflect the natural disease process as well as its treatment. Elderly patients are particularly vulnerable to psychotic reactions, especially if treatment includes combinations of levodopa and anticholinergic drugs and the patient has a prior psychiatric history. Psychiatric disturbances usually begin as nocturnal phenomena, emphasizing the possible value of decreasing or discontinuing the last evening dose of levodopa. Neuroleptic drugs are not recommended for the treatment of psychiatric disturbances because these drugs may cause a protracted exacerbation of symptoms of Parkinson disease. Quetiapine is a commonly prescribed medication as is clozapine. The routine laboratory monitoring with clozapine due to the risk agranulocytosis often makes quetiapine a more attractive option.²⁷ Patients who develop drug-induced psychosis with no features of dementia may respond to electroconvulsive therapy.

Impulsive and compulsive behavior may also result from dopaminergic therapy. A history of obsessive-compulsive disorder, addiction, or impulsive personality traits increases the likelihood. The development of these behaviors should be monitored regularly. Treatment is aimed at symptomatic relief primarily with dopamine agonists and less commonly with zonisamide, amantadine, topiramate, and valproate.^{27,33}

Endocrine Changes

Dopamine inhibits the secretion of prolactin, presumably by stimulating the release of a prolactin inhibitory factor. The release of growth hormone that occurs in response to the administration of levodopa to normal patients is minimal or absent when levodopa is administered to patients with Parkinson disease. Indeed, signs of acromegaly or diabetes mellitus do not occur in patients treated with levodopa. Large doses of levodopa may cause hypokalemia associated with increased plasma levels of aldosterone.

Laboratory Measurements

Urinary metabolites of levodopa cause false-positive tests for ketoacidosis. These metabolites also color the urine red and then black on exposure to air. Mild, transient increases in the blood urea nitrogen concentration may occur and can usually be controlled by increasing fluid intake. Increased liver transaminase concentrations occasionally occur. Positive Coombs tests have been attributed to levodopa.

Drug Interactions

Drug interactions may occur in patients being treated with levodopa, resulting in increased or decreased therapeutic effects. Chronic treatment of animals with levodopa does not consistently change anesthetic requirements.

Antipsychotic Drugs

Antipsychotic drugs such as butyrophenones and phenothiazines can antagonize the effects of dopamine. For this reason, these drugs should not be administered to patients with known or suspected Parkinson disease. Indeed, administration of droperidol to patients being treated with levodopa has produced severe skeletal muscle rigidity and even pulmonary edema, presumably reflecting sudden antagonism of dopamine. Droperidol has even produced a Parkinson disease–like syndrome in otherwise healthy patients. Metoclopramide may also interfere with dopamine activity.

Monoamine Oxidase Inhibitors

Nonspecific monoamine oxidase inhibitors interfere with the inactivation of catecholamines, including dopamine. As a result, these drugs can exaggerate the peripheral and CNS effects of levodopa. Hypertension and hyperthermia are side effects associated with the concurrent administration of these drugs.

Anticholinergic Drugs

Anticholinergic drugs act synergistically with levodopa to improve certain symptoms of Parkinson disease, especially tremor. Large doses of anticholinergics, however, can slow gastric emptying such that absorption of levodopa from the gastrointestinal tract is decreased.

Pyridoxine

Pyridoxine, in doses as low as 5 mg as present in multivitamin preparations, can abolish the therapeutic efficacy of levodopa by enhancing the activity of pyridoxine-dependent dopa decarboxylase and thus increasing the metabolism of levodopa in the circulation before it can enter the CNS.

Peripheral Decarboxylase Inhibitors

Levodopa is usually administered with a peripheral carboxylase inhibitor such as carbidopa or benserazide. As a result, more levodopa escapes metabolism to dopamine in the peripheral circulation and is available to enter the CNS. Furthermore, side effects related to high systemic concentrations of dopamine are decreased when levodopa is administered with a peripheral decarboxylase inhibitor. Nausea, vomiting, and cardiac dysrhythmias are diminished or absent. The incidence of abnormal involuntary movements and psychiatric disturbances is not altered by the combination of levodopa with a decarboxylase inhibitor.

Several combinations of levodopa and a peripheral carboxylase inhibitor are available as a levodopa augmentation strategy. Sinemet is composed of levodopa and carbidopa in a 10:1 or 4:1 ratio. Madopar is composed of levodopa and benserazide in a 4:1 ratio. Controlled-release preparations of levodopa and carbidopa provide a more constant therapeutic effect, but the onset of action is slower and the bioavailability is decreased compared with the standard combinations. Both carbidopa and benserazide are noncompetitive inhibitors of decarboxylase, so there is no value in administering progressively higher doses of these enzyme inhibitors. Carbidopa and benserazide do not cross the blood-brain barrier and lack pharmacologic activity when administered alone.

Catechol-O-methyltransferase Inhibitors

The COMT is partially responsible for the peripheral breakdown of levodopa. Accordingly, another levodopa augmentation strategy consists of blocking the COMT enzyme activity in the gastrointestinal tract with tolcapone or entacapone. Administration of either of these drugs slows the elimination of carbidopa-levodopa, thus increasing the plasma concentrations by 10% to 15%. In patients treated with tolcapone, the daily dose of carbidopa-levodopa may need to be decreased by 10% to 30% to avoid dyskinesias or other hyperdopaminergic side effects.

Side Effects

Both tolcapone and entacapone worsen levodopa-induced dyskinesias and cause nausea and diarrhea. Tolcapone may cause hepatotoxicity in rare patients emphasizing the need to monitor liver function tests in treated patients. Rhabdomyolysis has been associated with tolcapone therapy. Entacapone can cause the patient's urine to appear orange. Both drugs can cause piloerection.

Synthetic Dopamine Agonists

Synthetic dopamine agonists require neither transformation nor facilitated transport across the blood-brain barrier. Available drugs include the nonergot alkaloids pramipexole, ropinirole, and rotigotine as well as the tetracyclic ergot alkaloid bromocriptine, which is less commonly prescribed due to significant side effects. Pramipexole and ropinirole are oral preparations, which can be administered in an immediate- or extended-release fashion. Pramipexole and ropinirole may precipitate "sleep attacks," especially patients at higher doses. Factors that may increase the risk of experiencing these episodes include administration of sedatives and concurrent sleep disorders.³⁴ Rotigotine is a daily transdermal patch and is preferred by patients for convenience or due to an inability to swallow pills. After oral administration, the elimination half-time of bromocriptine is longer than for levodopa. Absorption of bromocriptine from the gastrointestinal tract is rapid but incomplete. Extensive hepatic first-pass metabolism occurs, and >90% of the metabolites are excreted in the bile, whereas <10% of the drug is excreted unchanged or as inactive metabolites in urine. Bromocriptine, 0.5 to 1.0 mg orally, is equivalent to levodopa, 100 mg in combination with either 25 mg of carbidopa or 25 mg of benserazide. The effectiveness of bromocriptine in the treatment of acromegaly reflects the paradoxical inhibitory effect of dopamine agonists on secretion of growth hormone. Bromocriptine also suppresses the

excess prolactin secretion that is often associated with growth hormone secretion. A notable benefit of rotigotine is its antidepressant effects.

Side Effects

Visual and auditory hallucinations, hypotension, and dyskinesia occur more frequently in patients treated with bromocriptine than in those treated with levodopa. Synthetic dopamine agonists occasionally cause pleuropulmonary fibrosis, sometimes with pleural effusions. Depending on the severity of this side effect, the dose of agonist drug should be decreased or the drug discontinued. Another uncommon complication of dopamine agonist therapy is the development of erythromelalgia (red, edematous, tender extremities). If this complication occurs, it is usually necessary to discontinue the dopamine agonist. Asymptomatic increases of serum transaminase and alkaline phosphatase concentrations may occur. Vertigo and nausea are occasionally associated with bromocriptine therapy.

Nonergot alkaloids are supposed to cause less nausea and orthostatic hypotension than the ergot derivatives, but this difference appears to be clinically insignificant. Nonergot alkaloids offer no advantage over ergot derivatives with respect to CNS side effects including confusion, hallucinations, and daytime sleep attacks that have been associated with motor vehicle accidents.

Dopamine agonists must not be stopped abruptly because it has been associated with a syndrome resembling neuroleptic malignant syndrome, and is termed *parkinsonism-hyperpyrexia syndrome* (discussed previously in this chapter under “[Side Effects](#)” in “[Levodopa](#)” section).

Anticholinergic Drugs

Anticholinergic drugs such as trihexyphenidyl and benztropine have modest effects on the clinical manifestations of Parkinson disease and are primarily used as a treatment for tremor. These drugs blunt the effects of the excitatory neurotransmitter acetylcholine, thus correcting the balance between dopamine and acetylcholine that is disturbed in the direction of cholinergic dominance. Anticholinergic drugs may help control the tremor and decrease the excess salivation associated with Parkinson disease but seldom are useful for skeletal muscle rigidity and bradykinesia. Although the peripheral and CNS actions of these synthetic anticholinergic drugs are less prominent than those of atropine, side effects, including memory disturbances (especially in elderly patients), hallucinations, confusion, sedation, mydriasis, cycloplegia, adynamic ileus, and urinary retention, may still occur. The mydriatic effect could precipitate glaucoma in a susceptible patient. As more effective drugs have become available, the use of anticholinergic drugs to treat patients with Parkinson disease has diminished.

Amantadine

Amantadine is an antiviral drug used for prophylaxis against infection with influenza A virus. This drug was discovered by chance to also produce symptomatic improvement in patients with Parkinson disease. The mode of action of amantadine is not known, although it has been speculated that it facilitates the release of dopamine from dopaminergic terminals that remain in the nigrostriatal pathway of patients with this disease. In addition, amantadine may delay uptake of dopamine back into nerve endings, exert anticholinergic effects, is a weak glutamate antagonist, and exhibits noncompetitive antagonist effects at *N*-methyl-D-aspartate receptors. Unlike anticholinergic drugs, amantadine may result in some improvement in skeletal muscle rigidity and bradykinesia. Amantadine is well absorbed after oral administration, and the elimination half-time is approximately 12 hours. More than 90% of the drug is excreted unchanged by the kidneys, necessitating dosage adjustments in patients with renal dysfunction. The side effects are similar to those produced by anticholinergic drugs, but, in addition, chronic administration of amantadine tends to induce ankle edema and livedo reticularis of the legs with or without cardiac failure. In older patients, amantadine may aggravate confusion and psychosis.

Monoamine Oxidase Type B Enzyme Inhibitors

This category comprises three drugs; selegiline, rasagiline, and safinamide. These drugs are believed to be of similar efficacy, and choice among them is based on preference of the clinician and/or patient. Selegiline is a

highly selective and irreversible inhibitor of monoamine oxidase type B (MAO-B) enzyme that has a weak antiparkinsonian effect when used alone and a moderate effect when used as an adjunct to carbidopa-levodopa. The MAO-B enzyme activity is one of the principal catabolic pathways for dopamine in the CNS. Blocking MAO-B enzyme activity increases the intrasynaptic half-time of dopamine leading to improved motor fluctuations and tremor. In contrast to nonspecific monoamine oxidase inhibitors, selegiline does not result in life-threatening potentiation of the effects of catecholamines when administered concurrently with a centrally active amine. This reflects the fact that metabolism of norepinephrine in peripheral nerve endings is not altered by selegiline, which minimizes the likelihood of adverse responses during anesthesia in response to sympathomimetics. Insomnia is a significant side effect of selegiline. Other side effects of selegiline include confusion, hallucinations, mental depression, and paranoid ideation.

Rasagiline has created enthusiasm as a potentially neuroprotective agent, but this activity requires further evaluation.³⁵ It has action at both the MAO-A and MAO-B enzyme, but its affinity is up to 16 times greater for MAO-B enzyme. It is recommended both as monotherapy and adjunctive therapy.³⁶ Although a theoretical risk does exist for the precipitation of serotonin syndrome, this was not observed during clinical trials. Similarly, avoidance of tyramine is ideally recommended, although no adverse reactions have been noted.³⁷

Safinamide is a selective, reversible MAO-B inhibitor with both dopaminergic and glutaminergic properties. It is prescribed for patients in mid- to late-stage Parkinson disease as add-on therapy to a levodopa to reduce “off” episodes. It is rapidly absorbed in the gastrointestinal system and reaches peak plasma concentrations in 2 to 3 hours. Similar to rasagiline, there is a theoretical risk for the precipitation of serotonin syndrome, and avoidance of tyramine is recommended.^{38,39}

Nonpharmacologic Treatment

Deep brain stimulation was approved to treat Parkinson disease by the U.S. Food and Drug Administration in 2002. Although not curative, it effectively controls symptoms resistant to medications or allows reduced reliance on drugs whose side effects have proven problematic. The mechanism of action of deep brain stimulation is unknown.²⁸ Other potential therapies under investigation include stem cell transplantation as well as transplantation of fetal mesencephalic tissue.

Central Nervous System Stimulants

Analeptics are drugs that stimulate the CNS. These drugs were previously used in the treatment of generalized CNS depression accompanying deliberate drug overdoses, but this practice has been abandoned because these drugs lack specific antagonist properties and their margin of safety is narrow. The excitability of the CNS reflects a balance between excitatory and inhibitory influences that is normally maintained within relatively narrow limits. Analeptics can increase excitability either by blocking inhibition or by enhancing excitation.

Amphetamine

Amphetamine is an analeptic prescribed primarily for attention deficit hyperactivity disorder, narcolepsy, and obesity. It is also used recreationally at much larger doses due to the intense euphoria, which may be experienced. Amphetamine salts are nonsympathetic amines, which exert a powerful stimulant effect. Amphetamine stimulates release of norepinephrine from central and peripheral nerve terminals. Physiologically, central effects include stimulation of respiratory centers, increased alertness, diminished fatigue, increased muscle strength, euphoria, and improved concentration. Peripherally, increased systolic and diastolic blood pressure, tachycardia or a reflex bradycardia, as well as a weak bronchodilator effect is observed.^{40,41}

Oral amphetamine preparations are well absorbed in the gastrointestinal tract, with increased absorption in higher gastric pH ranges. Oral bioavailability is 70% to 80%, and 30% to 40% is protein bound. The plasma half-life is dependent on urine pH; in a normal pH range, the half-life of most preparations is 10 to 15 hours, but in acidic urine, it is reduced to 5 to 10 hours. Amphetamines are metabolized in the liver. Alkaline

urine may extend the plasma half-life to 30 to 40 hours. Amphetamines are excreted by the kidneys, up to 50% unchanged.^{40,41}

The pattern of use of amphetamine has major impact on the anesthetic care of patients. Acute intoxication with amphetamine increases MAC, and chronic exposure decreases MAC. Chronic exposure, which causes continued stimulation of central and peripheral nerve terminals, results in depleted catecholamine receptor reserves. This is especially relevant during general anesthesia where a blunted physiologic response to hypotension may be observed, which may cause critical hemodynamic instability and critically decreased organ perfusion. Direct-acting vasopressors, which do not act via release of stored synaptic catecholamines, such as epinephrine, phenylephrine, or vasopressin, are the treatment of choice. Although it is recommended that surgery be delayed in all but emergent cases in a patient who is acutely intoxicated with amphetamine, the evidence for withholding chronic prescription stimulant is less clear, and it may be reasonable to continue them through the perioperative period.⁴²

Doxapram

Doxapram is an analeptic that acts centrally and at peripheral chemoreceptors to augment breathing efforts. The stimulus to ventilation produced by administration of doxapram, 1 mg/kg IV, is similar to that produced by a PaO₂ of 38 mm Hg acting on the carotid bodies. An increase in tidal volume, more than an increase in breathing frequency, is responsible for the doxapram-induced increase in minute ventilation. Oxygen consumption is increased concomitantly with the increase in minute ventilation.

Doxapram has a large margin of safety as reflected by a 20- to 40-fold difference in the dose that stimulates ventilation and the dose that produces seizures. Nevertheless, continuous infusion of doxapram, as is required to produce a sustained effect on ventilation, often results in evidence of subconvulsive CNS stimulation (hypertension, tachycardia, cardiac dysrhythmias, vomiting, and increased body temperature). These changes are consistent with increased sympathetic nervous system outflow. Continuous infusion is also required because the duration of action of a single IV dose is relatively short at 5 to 10 minutes. It is metabolized extensively, and less than 5% is excreted unchanged in the urine.

Clinical Uses

Doxapram administered as a continuous infusion (2-3 mg per minute) has been used as a temporary measure to maintain ventilation during administration of supplemental oxygen to patients with chronic obstructive airway disease who otherwise depend on a hypoxic drive to maintain adequate minute ventilation. Its role in the postoperative period has been used in preventing the ventilatory depression produced by opioids without altering analgesia. It has also been shown to be useful in treating postoperative shivering. Its use with apneic neonates in intensive care units can often delay or prevent intubation and ventilation, thus reducing ventilator-associated morbidity and mortality.

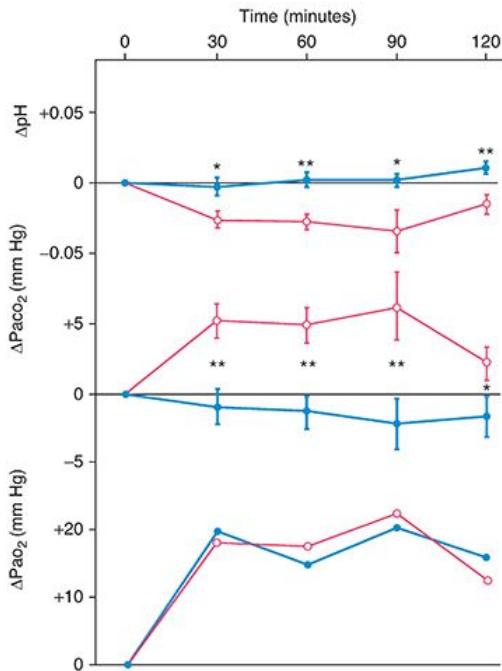

FIGURE 13.1 Doxapram, as a continuous infusion (solid circles), may be used to maintain alveolar ventilation during administration of supplemental oxygen to patients with chronic obstructive airway disease. The open circles represent placebo (* $P < .05$ compared with placebo infusion; ** $P < .01$ compared with placebo infusion). From Moser KM, Luchsinger PC, Adamson JS, et al. Respiratory stimulation with intravenous doxapram in respiratory failure. A double-blind co-operative study. N Engl J Med. 1973;288(9):427-431. Copyright © 1973 Massachusetts Medical Society. Methylphenidate

Methylphenidate is a mild CNS stimulant structurally related to amphetamine. Absorption after oral administration is rapid, and its low protein binding and high lipid solubility results in rapid uptake into the brain. Methylphenidate is useful in the treatment of attention deficit hyperactivity disorder in children and adults.⁴³ Hypertension, tachycardia, priapism, seizures, and serious cardiovascular events such as sudden cardiac death, stroke, and myocardial infarction have been described in patients treated with methylphenidate. Methylphenidate may also be effective in the treatment of narcolepsy, either alone or in combination with tricyclic antidepressants.⁴⁴

Methylxanthines

Methylxanthines are represented by caffeine, theophylline, and theobromine. Solubility of methylxanthines is low and is enhanced by formation of complexes as represented by the combination of theophylline with ethylenediamine to form aminophylline. Methylxanthines have in common the ability to (1) stimulate the CNS, (2) produce diuresis, (3) increase myocardial contractility, and (4) relax smooth muscle, especially those in the airways.

Mechanism of Action

The best characterized cellular action of methylxanthines is antagonism of receptor-mediated actions of adenosine, thus facilitating the release of catecholamines. Theophylline is more active than caffeine or theobromine as an antagonist at these receptors. At high concentrations, theophylline inhibits phosphodiesterase enzymes that are responsible for breakdown of cyclic adenosine monophosphate. Methylxanthines are completely absorbed after oral administration and eliminated primarily by metabolism in

the liver. Unlike adults, premature infants metabolize theophylline in part to caffeine. Furthermore, the clearance of methylxanthines is greatly prolonged in the neonate compared with that in the adult.

Clinical Uses

Methylxanthines are used as analeptics to treat primary apnea of prematurity by stimulating medullary respiratory centers by increasing the sensitivity of these centers to carbon dioxide. The slowed metabolism of methylxanthines in neonates compared to adults is a consideration when using theophylline to stimulate ventilation in neonates. Smooth muscle relaxation and bronchodilation produced by theophylline may reflect a combination of effects including catecholamine release, phosphodiesterase inhibition, and inhibition of inflammation. The administration of theophylline during maintenance of anesthesia appears to have no added bronchodilator effect over that of the volatile anesthetic alone. Selective β_2 -adrenergic agonists delivered by inhalation have largely replaced theophylline preparations in the treatment of bronchospasm associated with asthma.

Toxicity

A single oral dose of theophylline, 5 mg/kg, will produce a peak plasma concentration of 10 $\mu\text{g}/\text{mL}$ in adults within 1 to 2 hours following ingestion. Increased levels of unbound drug may result in signs of toxicity despite therapeutic plasma concentrations of drug (10-20 $\mu\text{g}/\text{mL}$). Theophylline plasma concentrations only slightly greater than the recommended therapeutic range can produce evidence of CNS stimulation (nervousness, tremors) and at higher concentrations or with rapid IV administration seizures are a possibility. Vomiting most likely reflecting CNS stimulation is common when plasma concentrations exceed 15 $\mu\text{g}/\text{mL}$. Tachycardia and cardiac dysrhythmias may appear most likely due to drug-induced release of catecholamines from the adrenal medulla.

Drug Interactions

Drugs may enhance (carbamazepine, rifampin) or inhibit (cimetidine, erythromycin) the hepatic metabolism of theophylline. Larger doses of benzodiazepines may be required in the presence of theophylline as benzodiazepines increase the CNS concentrations of adenosine, a potent CNS depressant, whereas theophylline is an adenosine receptor antagonist. Ketamine may decrease the seizure threshold for theophylline. Theophylline can partially antagonize the effects of nondepolarizing neuromuscular-blocking drugs presumably by inhibition of phosphodiesterase.

Caffeine

Caffeine is a methylxanthine-derived phosphodiesterase inhibitor that is present in a variety of beverages and nonprescription medications. A prominent effect of caffeine is CNS stimulation. In addition, this substance acts as a cerebral vasoconstrictor and may cause secretion of acidic gastric fluid.

Pharmacologic uses of caffeine include administration to neonates experiencing apnea of prematurity.⁴⁵ Treatment of postdural puncture headache has historically been treated with doses ranging from 75 to 300 mg oral caffeine. Despite the limited evidence for this treatment, it continues to be a popular treatment modality.⁴⁶⁻⁴⁸ Caffeine may be included in common cold remedies in an attempt to offset the sedating effects of certain antihistamines.⁴⁹

Almitrine

Almitrine acts on the carotid body chemoreceptors to increase minute ventilation. It has been demonstrated to increase PaO_2 and decrease PaCO_2 in patients with chronic respiratory failure associated with obstructive pulmonary disease. Its mechanism of action has not been elucidated.⁵⁰ It is used as a measure to improve or prevent hypoxia during one-lung ventilation techniques, especially with IV anesthesia techniques.^{51,52} An IV administration of almitrine not only improves PaO_2 in patients with acute lung injury but may also induce lactic acidosis and hepatic dysfunction.⁵³ Side effects of prolonged oral almitrine therapy include dyspnea and peripheral neuropathy that significantly limits its use.⁵⁴

Modafinil

Modafinil is a wakefulness-promoting drug approved for patients with excessive daytime sleepiness associated with narcolepsy, obstructive sleep apnea, and shiftwork sleep disorder.^{55,56} In addition, it may result in euphoria as well as alteration in mood, affect, and thinking. Its mechanism of action is unknown. Its absorption is rapid, and peak plasma concentrations are reached after 4 hours. It undergoes hepatic metabolism, and its inactive metabolites are excreted by the kidneys. A feeling of fatigue and sedation following recovery from general anesthesia may be countered by administration of modafinil.⁵⁶

Centrally Acting Muscle Relaxants

The primary indication for centrally acting muscle relaxants is spasticity, which may accompany pathologic conditions such as stroke, cerebral palsy, multiple sclerosis, amyotrophic lateral sclerosis, and injuries to the CNS. They act directly on the CNS or on skeletal muscles to relieve spasticity. Spasticity of skeletal muscles occurs when there is an abnormal increase in resistance to passive movement of a skeletal muscle group because of hyperactive proprioceptive or stretch reflexes.

Baclofen

Baclofen is the chlorophenol derivative of GABA that acts as an agonist at GABA_B receptors in the dorsal horn of the spinal cord and is often administered for treatment of spastic hypertonia of cerebral and spinal cord origin. Baclofen relieves spasticity by activating G-protein linked presynaptic GABA_B receptors that hyperpolarize muscle spindle afferent neurons, thereby decreasing the number and amplitude of excitatory postsynaptic potentials along the dendrites of motor neurons. This drug has no effect on the neuromuscular junction. Baclofen is particularly effective in the treatment of flexor spasms and skeletal muscle rigidity associated with spinal cord injury or multiple sclerosis. Intrathecal administration of baclofen may be an effective treatment of spinal spasticity that has not responded to oral administration of the drug.

Baclofen is rapidly and almost completely absorbed from the gastrointestinal tract. The elimination half-time is 3 to 6 hours, with approximately 80% of the drug excreted unchanged in urine, emphasizing the need to modify the dose in patients with renal dysfunction. Therapeutic plasma concentrations are 80 to 400 mg/mL.

Use of baclofen is limited by its side effects, which include sedation, skeletal muscle weakness, and confusion. Sudden discontinuation of chronic baclofen therapy may result in severe withdrawal reactions including evidence of multiple organ system failure, tachycardia, and both auditory and visual hallucinations. A case report of cardiac arrest due to baclofen withdrawal has been reported. Vocal cord spasm has been described following abrupt discontinuation of an intrathecal baclofen infusion. Coma, depression of ventilation, and seizures may accompany an overdose of baclofen. The threshold for initiation of seizures may be lowered in patients with epilepsy. Mild hypotension may occur in awake patients being treated with oral baclofen, whereas bradycardia, hypotension, and delayed awakening have been observed when general anesthesia is induced in these patients. Hemodynamic instability and delayed awakening following general anesthesia have been described in a patient receiving an accidental intrathecal overdose of baclofen. A decrease in sympathetic nervous system outflow from the CNS mediated by a GABA-baclofen-sensitive system might contribute to this hemodynamic response. Rarely, increases in liver transaminases and blood glucose levels have occurred.

Benzodiazepines

Benzodiazepines are widely used as centrally acting skeletal muscle relaxants. Diazepam is the most widely prescribed of this class, followed by clonazepam. These drugs are particularly beneficial for spinal spasticity and have little effect on cerebral spasticity. Sedation may limit the efficacy of these drugs as muscle relaxants but may be useful for relief of spasms that limit sleep.⁵⁷

Botulinum Toxin

Botulinum toxin causes irreversible inhibition of presynaptic acetylcholine release. Injections are made into spastic muscles, thereby causing weakening of muscle tone. Botulinum toxin is used in cases of central or

peripheral spasticity, particularly when limited muscle groups are affected. It has been used for spasticity and to prevent contractures in cerebral palsy, multiple sclerosis, and after stroke. Focally, it can be used for blepharospasm, hemifacial spasm, and torticollis.⁵⁸

Cyclobenzaprine is related structurally and pharmacologically to the tricyclic antidepressants. Its anticholinergic effects are similar to those of tricyclic antidepressants and can include dry mouth, tachycardia, blurred vision, and sedation. The mechanism of skeletal muscle relaxant effects produced by cyclobenzaprine is unknown. It must not be administered in the presence of monoamine oxidase inhibitors. In view of the potential adverse side effects of some tricyclic antidepressant drugs on the heart, the use of cyclobenzaprine may be questionable in patients with cardiac dysrhythmias or altered conduction of cardiac impulses.

Tizanidine

Tizanidine is a short-acting α_2 -adrenergic agonist whose structure is similar to clonidine. It reaches peak plasma levels at 2 hours after administration, and its clinical effect lasts only 6 hours, which necessitates repeated dosing if needed. Its absorption is highly variable depending on whether the patient has recently eaten or is fasted. Dosage adjustments must be made in patients with renal and hepatic dysfunction. Significant side effects include hypotension and care must be taken with patients who take antihypertensive agents. Significant sedation can also result, and there is an additive effect with other sedatives such as benzodiazepines. Discontinuation of therapy should be gradual as not to precipitate rebound hypertension, tachycardia, and/or hypertonia.

Dantrolene

Dantrolene exerts antispasmodic effects by inducing relaxation directly on muscle by decreasing calcium release from the sarcoplasmic reticulum. Its absorption from the gastrointestinal tract is slow and incomplete, and its half-life is 9 hours. The starting dose is usually 25 mg twice daily, and dosage can be increased up to 200 mg per day. Laboratory investigation for liver dysfunction should be undertaken prior to starting therapy as there is potential for hepatotoxicity especially in those patients with preexisting hepatic compromise.

PART III Circulatory System

Circulatory Physiology*

Updated by: James Ramsay

Systemic Circulation

The systemic circulation supplies blood to all the tissues of the body including the lungs via the bronchial circulation. Important considerations in understanding the physiology of the systemic circulation include the anatomic components of the systemic circulation, physical characteristics of the systemic circulation and of blood, determinants and control of tissue blood flow, regulation of systemic blood pressure, and regulation of cardiac output and venous return. In addition, the fetal circulation possesses many unique features, which distinguish it from the systemic circulation after birth (see [Chapter 45](#)).

Endothelial Function

The entire vascular system is lined by endothelial cells. Thus, the endothelium is a large and widely distributed structure. Indeed, it is estimated that the adult endothelium is composed of 10 trillion cells and weighs approximately 1 kg.¹ It is now widely appreciated that the endothelium is not simply an inert lining layer of the circulation but is an important “organ” that is involved in many physiologic processes in health and disease ([Tables 14.1](#) and [14.2](#)). The luminal side of the endothelium is lined with a “glycocalyx,” a web of membrane-bound glycoproteins and proteoglycans, which plays an important role in transcapillary flow.² The healthy endothelium promotes vasodilation and confers antithrombotic and antiadhesive properties to the vessel wall; damages to the glycocalyx and endothelium result in increased vascular permeability and adherence of inflammatory mediators and cells. The endothelium also regulates smooth muscle proliferation and has an important role in the regulation of glucose and lipid metabolism. Endothelial dysfunction is an important element of cardiovascular disease and aging. Cardiovascular risk factors including smoking, diabetes mellitus, hyperlipidemia, obesity, and systemic hypertension are related to their adverse effects upon endothelial function.

TABLE 14.1

Physiologic roles of endothelial function

Endothelial function	Example
Regulation of vascular tone	Vasodilator release (nitric oxide, prostacyclin) Vasoconstrictor release (thromboxane A ₂ , leukotriene, endothelia, angiotensin-converting enzyme)
Regulation of coagulation	Procoagulant release Anticoagulant release
Vascular growth regulation (angiogenesis)	Growth factor synthesis and release
Lipid clearance	LDL receptor expression Lipoprotein lipase synthesis
Inflammatory regulation and defense	Inflammatory mediator synthesis and release
Vascular support matrix elaboration	Synthesis of collagen, laminin, fibronectin, proteoglycans, proteases
Regulation of molecular transport	Transport of glucose, amino acid, and albumin

Abbreviation: LDL, low-density lipoprotein.

TABLE 14.2**Pathologic processes associated with endothelial dysfunction**

Systemic hypertension

Pulmonary hypertension

Atherosclerosis

Sepsis and inflammation

Multisystem organ failure

Metastatic tumor spread

Thrombotic disorders

Endothelial Function and Regulation of Vascular Tone

Endothelial synthesis and release of vasoactive mediators are important elements in the regulation of vascular tone. Substances are released by the endothelium in response to both mechanical and humoral stimuli and generally have an immediate effect on the adjacent vascular smooth muscle tone. However, there may also be endothelium-induced long-term effects from vascular remodeling and smooth muscle hypertrophy. Under physiologic conditions, local vascular pressure and flow are the primary stimuli for endothelial vasoactive substance release. Nitric oxide (NO) and prostacyclin are powerful vasodilators released by endothelial cells and both also inhibit platelet aggregation and thrombosis. Continuous NO production maintains vascular tone in a normally low state. This minute-to-minute regulation of local vascular tone is controlled by type 3 constitutive NO synthase (cNOS). The cNOS is a rapidly responding endothelial enzyme that catalyzes the local conversion of L-arginine into small quantities of NO in response to endothelial shear stress during normal pulsatile flow. On the other hand, type 2 inducible NOS (iNOS) is a relatively slow-responding enzyme that catalyzes the production of large amounts of NO in response to inflammatory cytokines. The widespread generation of large amounts of NO via iNOS is responsible for the low systemic vascular resistance and hypotension encountered in septic shock.³ Endothelin-1 (ET-1) is a potent vasoactive compound released by the endothelium. Its predominant effect is vasoconstriction via smooth muscle ET_A receptors. However, ET-1 can also cause vasodilation through its effect on endothelial ET_B receptors. The ET-1 stimulates smooth muscle proliferation and is an important factor in the development of vascular structural changes in systemic and pulmonary hypertension.

Components of the Systemic Circulation

The components of the systemic circulation are the arteries, arterioles, capillaries, venules, and veins.

Arteries

The function of the arteries is to transport blood under high pressure to tissues. Therefore, arteries have strong vascular walls and blood flows rapidly through their lumens.

Arterioles

Arterioles are the last small branches of the arterial system, having diameters of less than 200 microns. Arterioles have strong muscular walls, which are capable of dilating or contracting and thus controlling blood flow into the capillaries. Indeed, blood flow to each tissue is controlled almost entirely by resistance to flow in the arterioles. Metarterioles arise at right angles from arterioles and branch several times, forming 10 to 100 capillaries which in turn connect with venules.

Capillaries

Capillaries are the sites for transfer of oxygen and nutrients to tissues and receipt of metabolic byproducts.

Venules and Veins

Venules collect blood from capillaries for delivery to veins, which act as conduits for transmitting blood to the right atrium. Because the pressure in the venous system is low, venous walls are thin. Nevertheless, walls of veins are muscular, which allows these vessels to contract or expand and thus store varying amounts of blood, depending on physiologic needs. As a result, veins serve an important storage function as well as being conduits to return blood to the right atrium. A venous pump mechanism is important for propelling blood forward to the heart.

Physical Characteristics of the Systemic Circulation

The systemic circulation contains about 80% of the blood volume, with the remainder present in the pulmonary circulation and heart (Figure 14.1).⁴ Of the blood volume in the systemic circulation, about 64% is in veins and 7% is in the cardiac chambers. The heart ejects blood intermittently into the aorta such that blood pressure in the aorta fluctuates between a systolic level of about 120 mm Hg and a diastolic level of about 80 mm Hg (Table 14.3; Figure 14.2).⁴

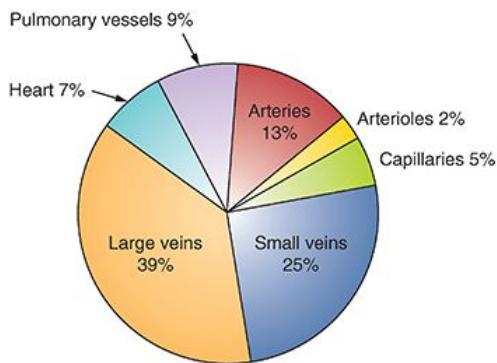

FIGURE 14.1 Distribution of blood volume in the systemic and pulmonary circulation. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

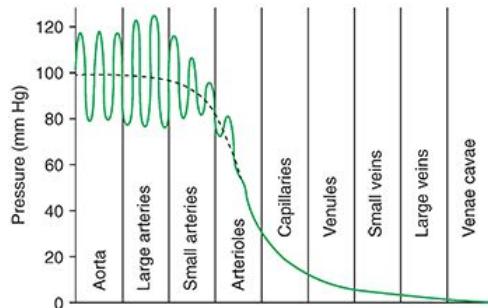

FIGURE 14.2 Systemic blood pressure decreases as blood travels from the aorta to large veins. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

TABLE 14.3

Normal pressures in the systemic circulation

	Mean value (mm Hg)	Range (mm Hg)
Systolic blood pressure ^a	120	90-140
Diastolic blood pressure ^a	80	70-90
Mean arterial pressure	92	77-97

Left ventricular end diastolic pressure	6	0-12
Left atrium		
a Wave	10	2-12
v Wave	13	6-20
Right atrium		
a Wave	6	2-10
c Wave	5	2-10
v Wave	3	0-8

^aMeasured in the radial artery.

One of the primary responsibilities of the anesthesiologist is to maintain organ perfusion with oxygenated blood. Our standard physiologic monitors (heart rate, blood pressure, pulse oximetry, capnography) all serve as surrogate markers of organ perfusion and oxygenation. Currently, our standard monitoring techniques do not allow us to directly monitor the level of perfusion in specific organs or tissues. However, various techniques for monitoring end-organ perfusion are being explored and will likely be increasingly used in the years to come.

Measurement of Systemic Blood Pressure

Measurement of Blood Pressure by Auscultation

Measurement of blood pressure by auscultation uses the principle that blood flow in large arteries is laminar and not audible. If blood flow is arrested by an inflated cuff and the pressure in the cuff is released slowly, audible tapping sounds (Korotkoff sounds) can be heard when the pressure of the cuff decreases just below systolic blood pressure and blood starts flowing in the brachial artery. These tapping sounds occur because flow velocity through the constricted portion of the blood vessel is increased, resulting in turbulence and vibrations that are heard through the stethoscope. Diastolic blood pressure correlates with the onset of muffled auscultatory sounds. The auscultatory method for determining systolic and diastolic blood pressure usually gives values within 10% of those determined by direct measurement from the arteries.

The width of the blood pressure cuff will affect measurements; ideally, the width of the blood pressure cuff should be 20% to 50% greater than the diameter of the patient's extremity. If the cuff is too narrow, the blood pressure will be overestimated. If the cuff is too large, the blood pressure may be underestimated.

Direct Measurement of Blood Pressure With an Intravascular Catheter

In the operating room and intensive care unit, intravascular pressure is measured using an electronic transducer attached to tubing which is in turn connected to a catheter in the blood vessel, for example, a catheter in the radial artery. The transducer is then "zeroed" and "leveled" such that zero is the pressure when the transducer is open to air, and it is placed at the level of the heart (see later under "[Measuring Central Venous Pressure](#)"). The arterial waveform maybe "underdamped," meaning the catheter-transducer system overestimates the systolic pressure due to amplification of the pressure wave, or "overdamped," where the systolic pressure underestimated, usually due to air bubbles in the system or some kind of obstruction at the catheter tip. It is worthwhile to remember that the world literature on blood pressure is almost entirely based on noninvasive measurement (ie, auscultation), and direct measurement does not always give the same numbers.

Progressive Declines in Systemic Blood Pressure

As blood flows through the systemic circulation, perfusion pressure decreases progressively to nearly 0 mm Hg by the time blood reaches the right atrium (see [Figure 14.2](#)).⁴ The decrease in systemic blood pressure in each portion of the systemic circulation is directly proportional to the resistance to flow in the vessels. Resistance to blood flow in the aorta is minimal, and mean arterial pressure decreases only 3 to 5 mm Hg as blood travels into arteries as small as 3 mm in diameter. Resistance to blood flow begins to increase rapidly in small arteries, causing the mean arterial pressure to decrease to about 85 mm Hg at the beginning of the

arterioles. It is in the arterioles that resistance to blood flow is the highest, accounting for about 50% of the resistance in the entire systemic circulation. As a result, systemic blood pressure decreases to about 30 mm Hg at the point where blood enters the capillaries. At the venous end of the capillaries, the intravascular pressure has decreased to about 10 mm Hg. The decrease in systemic blood pressure from 10 mm Hg to nearly 0 mm Hg as blood traverses veins indicates that these vessels impart far more resistance to blood flow than would be expected for vessels of their large sizes. This resistance to blood flow is caused by compression of the veins by external forces that keep many of them, especially the vena cava, partially collapsed.

Pulse Pressure in Arteries

Pulse pressure reflects the intermittent ejection of blood into the aorta by the heart (see [Table 14.3](#)). The difference between systolic and diastolic blood pressure is the pulse pressure. A typical systemic blood pressure curve recorded from a large artery is characterized by a rapid increase in pressure during ventricular systole followed by a maintained high level of blood pressure for 0.2 to 0.3 second ([Figure 14.3](#)). This plateau is followed by the dicrotic notch (incisura) at the end of systole and a subsequent, more gradual decrease of pressure back to the diastolic level. The dicrotic notch reflects a decrease in the intraventricular pressure and a backflow of blood in the aorta, which causes the aortic valve to close.

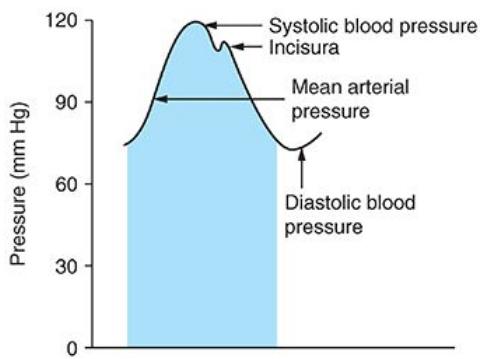

FIGURE 14.3 Schematic depiction of systemic blood pressure recorded from a large systemic artery. Mean arterial pressure is equal to the area under the blood pressure curve divided by the duration of systole.

Factors That Alter Pulse Pressure

The principal factors that alter pulse pressure in the arteries are the left ventricular stroke volume, velocity of blood flow, and compliance of the arterial tree. The larger the stroke volume, the greater the volume of blood that must be accommodated in the arterial vessels with each contraction resulting in an increased pulse pressure. Pulse pressure also increases when capacitance increases for outflow. When systemic vascular resistance decreases, flow of blood from arteries to veins is accelerated. Pulse pressure is also increased in the presence of patent ductus arteriosus and aortic regurgitation, reflecting rapid runoff of blood into the pulmonary circulation or left ventricle, respectively. In this regard, attempts have been made to predict systemic vascular resistance by the position of the dicrotic notch relative to the diastolic pressure. A controlled study, however, failed to confirm a correlation between the position of the dicrotic notch and the calculated systemic vascular resistance ([Figure 14.4](#)).⁵ An increase in heart rate while the cardiac output remains constant causes the stroke volume and pulse pressure to decrease. Pulse pressure is inversely proportional to the compliance (distensibility) of the arterial system. For example, with aging, the distensibility of the arterial walls often decreases (elastic and muscular tissues are replaced by fibrous tissue) and pulse pressure increases.

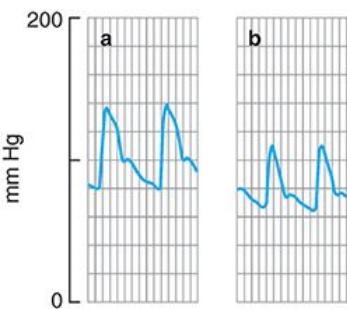

FIGURE 14.4 Despite a different height of the dicrotic notch (measured from baseline to the peak of the notch), the calculated systemic vascular resistance is similar for tracings a and b. *Reprinted with permission from Gerber MJ, Hines RL, Barash PG. Arterial waveforms and systemic vascular resistance: is there a correlation? Anesthesiology. 1987;66(6):823-825. Copyright © 1987 American Society of Anesthesiologists, Inc.*

Transmission of the Pulse Pressure

There is often enhancement of the pulse pressure as the pressure wave is transmitted peripherally ([Figure 14.5](#)).⁴ Part of this augmentation results from the progressive decrease in compliance of the more distal portions of the large arteries. Second, pressure waves are reflected to some extent by the peripheral arteries. Specifically, when a pulsatile pressure wave enters the peripheral arteries and distends them, the pressure on these peripheral arteries causes the pulse wave to begin traveling backward. If the returning pulse wave strikes an oncoming wave, the two summate, causing a much higher pressure than would otherwise occur.

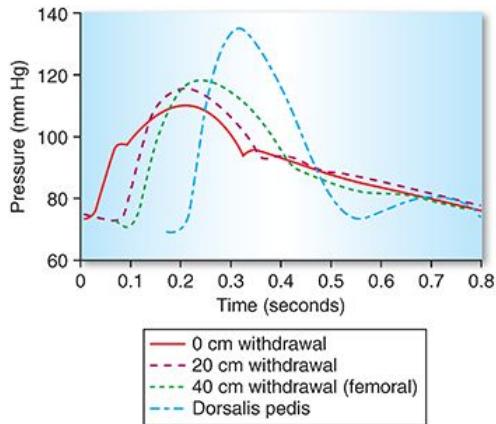

FIGURE 14.5 There is enhancement of the pulse pressure as the systemic blood pressure is transmitted peripherally. *From Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: Saunders; 2000, with permission.*

These changes in the contour of the pulse wave are most pronounced in young patients, whereas in elderly patients with less compliant arteries, the pulse wave may be transmitted virtually unchanged from the aorta to peripheral arteries.

Augmentation of the peripheral pulse pressure must be identified whenever systemic blood pressure measurements are made in peripheral arteries. For example, systolic pressure in the radial artery is sometimes as much as 20% to 30% higher than that pressure present in the central aorta, and diastolic pressure is often decreased as much as 10% to 15%. Mean arterial pressures are similar regardless of the site of blood pressure measurement in a peripheral artery.

Pulse pressure becomes progressively less as blood passes through small arteries and arterioles until it becomes almost absent in capillaries (see [Figure 14.2](#)).⁴ This reflects the extreme distensibility of small vessels such that the small amount of blood that is caused to flow during a pulsatile pressure wave produces

progressively less pressure increase in the more distal vessels. Furthermore, resistance to blood flow in these small vessels is such that flow of blood and, consequently, the transmission of pressure are greatly impeded.

Systemic Blood Pressure Measurement During and After Cardiopulmonary Bypass

Reversal of the usual relationship between aortic and radial artery blood pressures can occur during the late period of hypothermic cardiopulmonary bypass and in the early period after termination of cardiopulmonary bypass ([Figure 14.6](#)).^{6,7} One mechanism proposed for this unpredictable and transient disparity (usually persists for 10-60 minutes after discontinuation of cardiopulmonary bypass) is a high blood flow in the forearm and hand after rewarming on cardiopulmonary bypass, causing an increased pressure drop along the normal resistance pathway provided by the arteries leading to the radial site. Conversely, others describe the appearance of this gradient with initiation of cardiopulmonary bypass, suggesting that the etiology is associated with events such as cross-clamping of the aorta occurring during initiation of cardiopulmonary bypass rather than rewarming or discontinuing cardiopulmonary bypass ([Figure 14.7](#)).^{8,9} Failure to recognize this disparity may lead to an erroneous diagnosis and unnecessary treatment. Systemic blood pressure measured in the brachial artery is more accurate and reliable during the periods surrounding cardiopulmonary bypass, which are most likely to be associated with disparities between the aortic and radial artery blood pressures.¹⁰

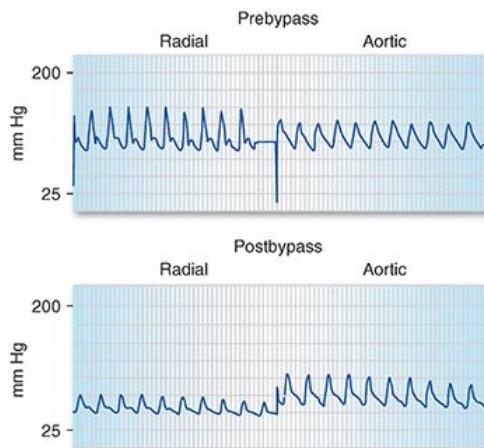

FIGURE 14.6 There may be a reversal of the usual relationship of simultaneous recordings of radial and aortic blood pressures (pre-bypass) in the early period after separation from cardiopulmonary bypass (post-bypass). Pulsus Paradoxus

Pulsus paradoxus is an exaggerated decrease in systolic blood pressure (>10 mm Hg) during inspiration in the presence of increased intrapericardial pressures (cardiac tamponade). During normal inspiration, the decrease in intrathoracic pressure increases the compliance of the pulmonary vasculature, which leads to a relative decrease in pulmonary venous return to the left ventricle. The resultant reduction in left ventricular preload decreases the stroke volume, which manifests as a mildly decreased systolic blood pressure during inspiration (<10 mm Hg). Cardiac tamponade causes an exaggeration of this change in blood pressure with respiration.

Pulsus Alternans

Pulsus alternans is alternating weak and strong cardiac contractions causing a similar alteration in the strength of the peripheral pulse. A variety of physiologic conditions are associated with pulsus alternans. Digitalis toxicity, varying degrees of atrioventricular heart block, and left ventricular dysfunction are commonly associated with pulsus alternans. In the setting of left ventricular dysfunction, pulsus alternans is caused by cyclic alterations in the contractile state of the heart. A reduced stroke volume increases end diastolic volume, which results in increased myocardial contraction and therefore increased ventricular emptying and blood pressure (per the Frank-Starling law). During the subsequent cardiac cycle, the lower filling pressures in the left ventricle result in a decreased stroke volume and therefore decreased ventricular emptying and blood pressure.

Electrical Alternans

Electrical alternans is a phenomenon where the amplitude of the QRS complex changes between heart beats. This electrocardiographic finding is seen in cardiac tamponade and pericardial effusion, where the heart essentially moves within the fluid-filled pericardial sac during contraction.

Pulse Deficit

In the presence of atrial fibrillation or ectopic ventricular beats, two beats of the heart may occur so close together that the ventricle does not fill adequately, and the second cardiac contraction ejects an insufficient volume of blood to create a peripheral pulse. In this circumstance, a second heart beat is audible with a stethoscope applied on the chest directly over the heart, but a corresponding pulsation in the radial artery cannot be palpated. This phenomenon is called a **pulse deficit**.

The Venous Circulation

Right Atrial Pressure

Right atrial pressure is regulated by a balance between venous return and the ability of the right ventricle to eject blood. Normal right atrial pressure is about 5 mm Hg, with a lower limit of about -5 mm Hg, which corresponds to the pressure in the pericardial and intrapleural spaces that surround the heart. Right atrial pressure approaches these low values when right ventricular contractility is increased or venous return to the heart is decreased by hemorrhage. Poor right ventricular contractility or any event that increases venous return (hypervolemia, venoconstriction) tends to increase right atrial pressure. Pressure in the right atrium is commonly designated the **central venous pressure** (CVP). Other factors that increase CVP include tension pneumothorax, heart failure, tamponade, pleural effusion, mechanical ventilation, positive end-expiratory pressure, Valsalva, pulmonary hypertension, and pulmonary embolism.

As the majority of the circulatory volume resides in the systemic veins, the function of the venous system (venous volume, capacitance, resistance, and venous return) is a major determinant of how much blood is pumped by the heart, or the cardiac output. Studies over the last 20 years have clearly shown that in the normal heart, measurement of CVP in response to physiologic challenges (position changes, leg raising, or fluid administration) is a much better indicator of adequacy of circulatory volume or “volume responsiveness” than isolated CVP measurement.¹¹ This is because of the many reflexes and physiologic

compensations in place, which maintain the venous return and filling of the right side of the heart. Exceptions to this principle include severe hypovolemia or hypervolemia where a very low CVP or high CVP likely confirms these states, respectively, and right ventricular dysfunction. Especially in the latter case, isolated CVP measurements can be a helpful indicator of the interaction between circulatory volume and how the right heart is dealing with it.

Measuring Central Venous Pressure

Critical to the interpretation of CVP (and other intravascular pressures) is accurate measurement. This is done with a transducer that is placed (“leveled”) to the tricuspid valve. From surface anatomy, this level or the “phlebostatic axis,” is typically at the fourth interspace in the midaxillary line. As the CVP is usually less than 10 mm Hg, small errors in the transducer level can make a big difference in clinical interpretation. Each centimeter below the hydrostatic point adds 0.77 mm Hg to the measured pressure, whereas 0.77 mm Hg is subtracted for each centimeter above this point. A pressure measurement in mm Hg can be converted to cm H₂O by multiplying the pressure by 1.36, which adjusts for the density of mercury relative to water (10 mm Hg equals 13.6 cm H₂O). Conversely, dividing the CVP measurement in cm H₂O by 1.36 converts this value to an equivalent pressure in mm Hg.

In the intensive care unit, transducers are usually affixed to the patient’s intravenous pole, and a spirit level mounted in a long ruler is used to confirm the transducer is at the phlebostatic axis when the pressure is measured. Another factor that can affect the measurement is patient position: If the patient is supine or up to approximately 30 degrees head up, the CVP is not affected, but if the patient is sitting up more than 45 degrees or is in the head-down position, the CVP will not be the same as in the 0- to 30-degree position. A general principle is to try to measure the CVP with the patient in the same position over time.

The reason for lack of hydrostatic effects at the tricuspid valve is the ability of the right ventricle to act as a regulator of pressure at this site. For example, if the pressure at the tricuspid valve increases, the right ventricle fills to a greater extent, thereby decreasing the pressure at the tricuspid valve toward normal. Conversely, if the pressure decreases at the tricuspid valve, the right ventricle does not fill optimally and blood pools in the veins until pressure at the tricuspid valve again increases to a normal value. In a poorly functioning right heart, these normal adaptations may not be able to be met and the patient’s position in bed may affect the CVP to a greater degree. The pressure measured at the fourth interspace in the midaxillary line may be significantly lower in the sitting position than in the supine position.

Jugular Venous Pressure

Jugular venous pressure or the pressure in the internal jugular vein mirrors the CVP. The normal jugular venous pressure reflects phasic changes in the right atrium and consists of three positive waves and three negative troughs ([Figure 14.8](#)).¹² Abnormalities of these venous waveforms may be useful in the diagnosis of various cardiac conditions ([Table 14.4](#)).¹²

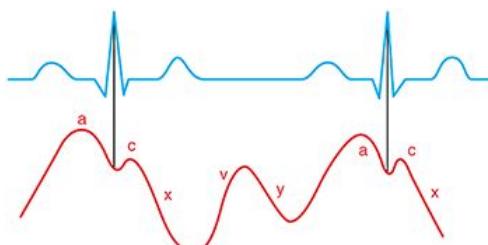

FIGURE 14.8 The jugular or central venous pressure waveform (lower tracing), aligned with the electrocardiogram (upper tracing). The physiologic events associated with the changes in waveform are as follows: *a* wave represents right atrial contraction, *c* wave represents tricuspid valve bulging into the atrium at the onset of ventricular systole, *x* descent represents right atrial relaxation, *v* wave represents rapid filling of the right atrium, and *Yy* descent represents early ventricular filling after opening of the tricuspid valve.

TABLE 14.4**Cardiac conditions associated with changes in central or jugular venous waveforms**

Sinus tachycardia	Reduced or absent <i>a</i> wave
Atrial fibrillation	Absent <i>a</i> wave
Atrial flutter	“Flutter <i>a</i> waves” without subsequent waves/descents
First-degree heart block	Prominent <i>a</i> waves
Tricuspid or pulmonic stenosis	Prominent <i>a</i> waves
Complete heart block	“Cannon” (very large) <i>a</i> waves
Tricuspid regurgitation	Absent <i>x</i> descent, large <i>c-v</i> waves, and rapid <i>y</i> descent
Constrictive pericarditis	Rapid <i>x</i> and <i>y</i> descents
Cardiac tamponade	Decreased <i>y</i> descent

Peripheral Venous Pressure

Large veins offer little resistance to blood flow when they are distended. Most large veins, however, are compressed at multiple extrathoracic sites. For example, pressure in the external jugular vein is often so low that atmospheric pressure on the outside of the neck causes it to collapse. Veins coursing through the abdomen are compressed by intra-abdominal pressure, which may increase 15 to 20 mm Hg as a result of pregnancy or ascites. When this occurs, pressure in leg veins must increase above abdominal pressure. It is important to recognize that veins inside the thorax are not collapsed because of the distending effect of negative intrathoracic pressure.

Effect of Hydrostatic Pressure

Pressure in veins below the heart is increased and that in veins above the heart is decreased by the effect of gravity ([Figure 14.9](#)).⁴ As a guideline, pressure changes 0.77 mm Hg for every centimeter the vessel is above or below the heart. For example, in a standing human, pressure in the veins of the feet is 90 mm Hg because of the distance from the heart to the feet. Conversely, veins above the heart tend to collapse, with the exception being veins inside the skull, where they are held open by surrounding bone. As a result, negative pressure can exist in the dural sinuses and air can be entrained immediately if these sinuses are entered during surgery.

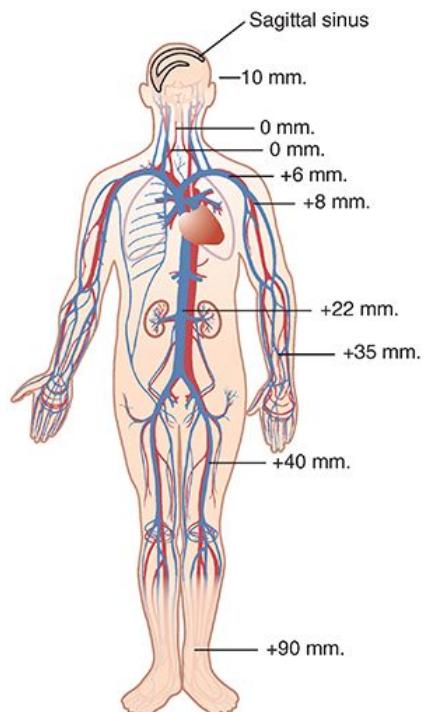

FIGURE 14.9 Effect of hydrostatic pressure on venous pressures throughout the body.

Hydrostatic pressure affects peripheral pressure in arteries and capillaries as well as veins. For example, a standing human who has a systemic blood pressure of 100 mm Hg at the level of the heart has a blood pressure of about 190 mm Hg in the feet.

Venous Valves and the Pump Mechanism

Valves in veins are arranged so that the direction of blood flow can be only toward the heart. In a standing human, movement of the legs compresses skeletal muscles and veins so blood is directed toward the heart. This venous pump or skeletal muscle pump is usually sufficient to maintain venous pressure below 25 mm Hg in a walking human. If an individual stands immobile, the venous pump does not function. As a result, pressures in the veins and capillaries of the legs can increase rapidly, resulting in leakage of fluid from the intravascular space. Indeed, as much as 15% of the blood volume can be lost from the intravascular space in the first 15 minutes of quiet standing.

Varicose Veins

Valves of the venous system can be destroyed when the veins are chronically distended by increased venous pressure as occurs during pregnancy or in an individual who stands most of the day. The end result is varicose veins characterized by bulbous protrusions of the veins beneath the skin of the legs. Venous and capillary pressures remain increased because of the incompetent venous pump, and this causes constant edema in the legs of these individuals. Edema interferes with diffusion of nutrients from the capillaries to tissues, so there is often skeletal muscle discomfort and the skin may ulcerate.

Blood Viscosity

Blood is a viscous fluid composed of cells and plasma. More than 99% of the cells in plasma are erythrocytes. As a result, leukocytes exert a minimal influence on the physical characteristics of blood. The percentage of blood comprising erythrocytes is the hematocrit, which to a large extent determines the viscosity of blood ([Figure 14.10](#)).⁴ When the hematocrit increases to 60% to 70%, viscosity of blood is increased about 10-fold compared with water, and flow through blood vessels is greatly decreased. Plasma protein concentrations influence blood viscosity only minimally.

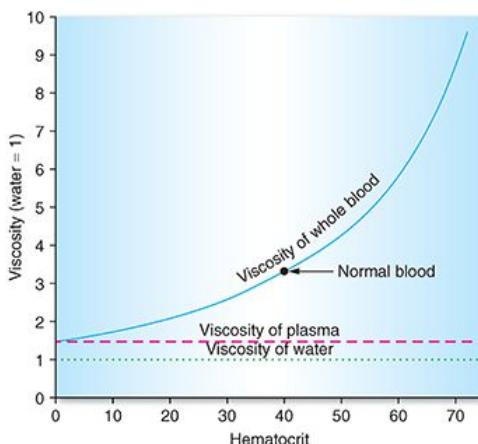

FIGURE 14.10 Hematocrit greatly influences the viscosity of blood. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Viscosity exerts fewer effects on blood flow in capillaries than in larger vessels. This most likely reflects alignment of erythrocytes as they pass through small blood vessels rather than the random arrangement characteristic of flow through larger vessels. This alignment of erythrocytes, which greatly decreases the viscous resistance that occurs normally between cells, is largely offset by a decreased velocity of flow that greatly increases viscosity. The net effect may be that viscous effects in small blood vessels are similar to those that occur in large blood vessels.

Plasma is considered extracellular fluid that is identical to interstitial fluid except for the greater concentrations of proteins (albumin, globulin, fibrinogen) in plasma. These greater concentrations reflect the inability of plasma proteins to pass easily through capillaries into the interstitial spaces. The presence of albumin creates colloid osmotic pressure, which prevents fluid from leaving the capillaries.

Determinants of Tissue Blood Flow

Tissue blood flow is directly proportional to the pressure difference between two points (not absolute pressure) and inversely proportional to resistance to flow through the vessel. This relationship between flow, pressure, and resistance can be expressed mathematically as a variant of Ohm's law, in which blood flow (amperes) is directly proportional to the pressure drop across two points (voltage) and inversely proportional to resistance ([Figure 14.11](#)). Rearrangement of this formula emphasizes that pressure is directly proportional to flow times resistance. Likewise, resistance is directly proportional to pressure and inversely proportional to flow. Furthermore, resistance is directly proportional to viscosity of blood and the length of the vessel and inversely proportional to the fourth power of the radius of the vessel (doubling the radius of the vessel or intravenous catheter size decreases resistance to flow 16-fold [Poiseuille law]).

$$\text{Blood Flow (Q)} = \frac{\text{Pressure Difference Between Two Points (P)}}{\text{Resistance to Flow (R)}}$$

$$\Delta P = Q \times R$$

$$R = \Delta P / Q$$

FIGURE 14.11 The relationship between blood flow, pressure, and resistance to flow can be expressed as a variant of Ohm's law.

It is important to understand that resistance to blood flow cannot be measured but rather is a calculated value based on measurement of driving pressures and the cardiac output. For example, systemic vascular resistance is calculated as the difference between mean arterial pressure and right atrial pressure divided by cardiac output. Pulmonary vascular resistance is calculated as the difference between mean pulmonary artery

pressure and left atrial pressure divided by the cardiac output. Resistance is expressed in dynes/s/cm⁻⁵ and is calculated by multiplying the equation for either systemic vascular resistance or pulmonary vascular resistance just described by a conversion factor of 80. If this factor of 80 is not applied, the simple equation of pressure difference divided by cardiac output results a resistance expressed as “wood units.” This is commonly used when describing pulmonary vascular resistance in the presence of pulmonary hypertension.

Conductance is the reciprocal of resistance and is a measure of the amount of blood flow that can pass through a blood vessel in a given time for a given pressure gradient.

Vascular Distensibility

Blood vessels are distensible such that increases in systemic blood pressure cause the vascular diameter to increase, which in turn decreases resistance to blood flow. Conversely, decreases in intravascular pressure increase the resistance to blood flow. The ability of blood vessels to distend as intravascular pressure increases varies greatly in different parts of the circulation. Anatomically, the walls of arteries are stronger than those of veins. As a result, veins are 6 to 10 times as distensible as arteries. Systemic blood pressure can eventually decrease to a level where intravascular pressure is no longer capable of keeping the vessel open. This pressure averages 20 mm Hg and is defined as the **critical closing pressure**. When the heart is abruptly stopped, the pressure in the entire circulatory system (mean circulatory pressure) equilibrates at about 7 mm Hg.

Vascular Compliance

Vascular compliance is defined as the increase in volume (capacitance) of a vessel produced by an increase in intravascular pressure. The compliance of the entire circulatory system is estimated to be 100 mL for each 1 mm Hg increase in intravascular pressure.⁴ The compliance of veins is much greater than that of arteries. For example, the volume of blood normally present in all veins is about 2,500 mL, whereas the arterial system contains only about 750 mL of blood when the mean arterial pressure is 100 mm Hg. Sympathetic nervous system activity can greatly alter the distribution of blood volume. Enhancement of sympathetic nervous outflow to the blood vessels, especially the veins, decreases the dimensions of the circulatory system, and the circulation continues to function almost normally even when as much as 25% of the total blood volume has been lost. **Vasoconstriction** or **vasodilation** refers to resistance changes in arterioles, whereas changes in the caliber of veins are described as **venoconstriction** or **venodilation**.

Control of Tissue Blood Flow

Control of blood flow to different tissues includes local mechanisms, autonomic nervous system responses, and release of hormones. Total tissue blood flow or cardiac output is about 5 L per minute, with large amounts being delivered to the heart, brain, liver, and kidneys (**Table 14.5**).⁴ In contrast, skeletal muscles represent 35% to 40% of body mass but receive only about 15% of the total cardiac output, reflecting the low metabolic rate of inactive skeletal muscles.

TABLE 14.5

Tissue blood flow^a

	Approximate blood flow (mL per minute)		Cardiac output (% of total)
	(mL/100 g per minute)		
Brain	750	50	15
Liver	1,450	100	29
Portal vein	1,100		
Hepatic artery	350		
Kidneys	1,000	320	20
Heart	225	75	5
Skeletal muscles (at rest)	750	4	15
Skin	400	3	8

Other tissues	425	2	8
Total	5,000		100

^aAdapted from Guyton AC, Hall JE. *Textbook of Medical Physiology*. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Local Control of Blood Flow

Local control of blood flow is most often based on the need for delivery of oxygen or other nutrients such as glucose or fatty acids to the tissues. The response to decreased oxygen delivery may reflect the local release of vasodilatory substances (adenosine, lactic acid, carbon dioxide, potassium ions), which results in increased tissue blood flow and oxygen delivery.

Autoregulation of Blood Flow

Autoregulation is a local mechanism that controls blood flow in which a specific tissue is able to maintain a relatively constant blood flow over a wide range of mean arterial pressures. When the mean arterial pressure increases, the associated increase in tissue blood flow causes the blood vessels to constrict, thereby limiting any increase in blood flow. Conversely, decreases in mean arterial pressure result in vasodilation, which maintains tissue blood flow. Autoregulatory responses to sudden changes in mean arterial pressure occur within 60 to 120 seconds. The ability of autoregulation to return local tissue blood flow to normal is incomplete.

Long-Term Control of Blood Flow

Long-term regulatory mechanisms that return local tissue blood flow to normal involve a change in vascularity of tissues. For example, sustained increases in mean arterial pressure to specific tissues, as occurs above a coarctation of the aorta, is accompanied by a decrease in the size and number of blood vessels. Likewise, if metabolism in a tissue becomes chronically increased, vascularity increases, or if metabolism is decreased, vascularity decreases. Indeed, inadequate delivery of oxygen to a tissue is the stimulus for the development of collateral vessels. Neonates exposed to increased concentrations of oxygen can manifest cessation of new vascular growth in the retina. Subsequent removal of the neonate from a high-oxygen environment causes an overgrowth of new vessels to offset the abrupt decrease in availability of oxygen. There may be so much overgrowth that the new vessels cause blindness (retrolental fibroplasia).

Autonomic Nervous System Control of Blood Flow

Autonomic nervous system control of blood flow is characterized by a rapid response time (within 1 second) and an ability to regulate blood flow to certain tissues at the expense of other tissues. The sympathetic nervous system is the most important component of the autonomic nervous system in the regulation of blood flow; sympathetic stimulation causes release of norepinephrine, which stimulates α -adrenergic receptors to produce vasoconstriction. Constriction of small arteries influences resistance to blood flow through tissues, whereas venoconstriction alters vascular capacitance and distribution of blood in the peripheral circulation. Sympathetic nervous system innervation is prominent in the kidneys and skin and minimal in the cerebral circulation.

Vasomotor Center

The vasomotor center, which is located in the pons and medulla, transmits sympathetic nervous system impulses through the spinal cord to all blood vessels. Evidence for a continuous, sustained state of partial vasoconstriction (vasomotor tone) is the abrupt decrease in systemic blood pressure that occurs when sympathetic nervous system innervation to the vasculature is abruptly interrupted, as by traumatic spinal cord transection or regional anesthesia. Activity of the vasomotor center can be influenced by impulses from a number of sites, including diffuse areas of the reticular activating system, hypothalamus, and cerebral cortex. Sympathetic nervous system impulses are transmitted to the adrenal medulla at the same time they are transmitted to the peripheral vasculature. These impulses stimulate the adrenal medulla to secrete epinephrine

and norepinephrine into the circulation, where they act directly on adrenergic receptors in the walls of vascular smooth muscle.

The medial and lower portions of the vasomotor center do not participate in transmission of vasoconstrictor impulses but rather function as an inhibitor of sympathetic nervous system activity, which allows blood vessels to dilate. Conceptually, this portion of the vasomotor center is functioning as the parasympathetic nervous system.

Mass Reflex

The mass reflex is characterized by stimulation of all portions of the vasomotor center, resulting in generalized vasoconstriction and an increase in cardiac output in an attempt to maintain tissue blood flow. The alarm reaction resembles the mass reflex, but associated skeletal muscle vasodilation and psychic excitement are intended to prepare the individual to confront a life-threatening situation.

Syncope

Emotional fainting (vasovagal syncope) may reflect profound skeletal muscle vasodilation such that systemic blood pressure decreases abruptly, and syncope occurs. Associated vagal stimulation results in bradycardia. This phenomenon may occur in patients who have an intense fear of needles, resulting in syncope during placement of an intravenous catheter.

Hormone Control of Blood Flow

Vasoconstrictor hormones that may influence local tissue blood flow include epinephrine, norepinephrine, angiotensin, and arginine vasopressin (formerly known as **antidiuretic hormone**). Bradykinin, serotonin, histamine, prostaglandins, and low circulating concentrations of epinephrine are vasodilating substances. Local chemical factors, such as accumulation of hydrogen ions, potassium ions, and carbon dioxide, relax systemic vascular smooth muscle and cause vasodilation.

Regulation of Systemic Blood Pressure

Systemic blood pressure is maintained over a narrow range by reciprocal changes in cardiac output and systemic vascular resistance. The autonomic nervous system and baroreceptors play a key role in moment-to-moment regulation of systemic blood pressure. Long-term regulation of blood pressure depends on control of fluid balance by the kidneys, adrenal cortex, and central nervous system.

Systolic, diastolic, and mean arterial pressure tends to increase progressively with age. Because a greater portion of the cardiac cycle is nearer the diastolic blood pressure, it follows that mean arterial pressure is not the arithmetic average of the systolic and diastolic blood pressures. Mean arterial blood pressure is the most important determinant of tissue blood flow because it is the average, tending to drive blood through the systemic circulation.

Rapid-Acting Mechanisms for the Regulation of Systemic Blood Pressure

Rapid-acting mechanisms for regulation of systemic blood pressure involve nervous system responses as reflected by the baroreceptor reflexes, chemoreceptor reflexes, atrial reflexes, and central nervous system ischemic reflex. These reflex mechanisms respond almost immediately to changes in systemic blood pressure. Furthermore, within about 30 minutes, these nervous system reflex responses are further supplemented by activation of hormonal mechanisms and shift of fluid into the circulation to readjust the blood volume. These short-term mechanisms can return systemic blood pressure toward but never entirely back to normal. Indeed, the impact of many of the rapid-acting regulatory mechanisms, such as the baroreceptor reflexes, diminishes with time as these mechanisms adapt to the new level of systemic blood pressure.

Baroreceptor Reflexes

Baroreceptors are nerve endings in the walls of large arteries in the neck and thorax, especially in the internal carotid arteries just above the carotid bifurcation and in the arch of the aorta ([Figure 14.12](#)).¹³ These nerve endings respond rapidly to changes in systemic blood pressure and are crucial for maintaining normal blood

pressure when an individual changes from the supine to standing position. An increase in mean arterial pressure produces stretch of baroreceptor nerve endings, and increased numbers of nerve impulses are transmitted to the depressor portion of the vasomotor center, leading to a relative decrease in the central nervous system outflow of sympathetic nervous system (vasoconstrictive) impulses ([Figure 14.13](#)).¹³ The net effects are vasodilation throughout the peripheral circulation, decreased heart rate, and decreased myocardial contractility, which all act to decrease systemic blood pressure back toward normal. Conversely, decreases in systemic blood pressure reflexively produce changes likely to increase blood pressure. Baroreceptors adapt in 1 to 3 days to sustained changes in systemic blood pressure, emphasizing that these reflexes are probably of no importance in long-term regulation of blood pressure. Volatile anesthetics, particularly halothane, inhibit the heart rate response portion of the baroreceptor reflex that occurs in response to changes in systemic blood pressure (see [Chapter 4](#)).

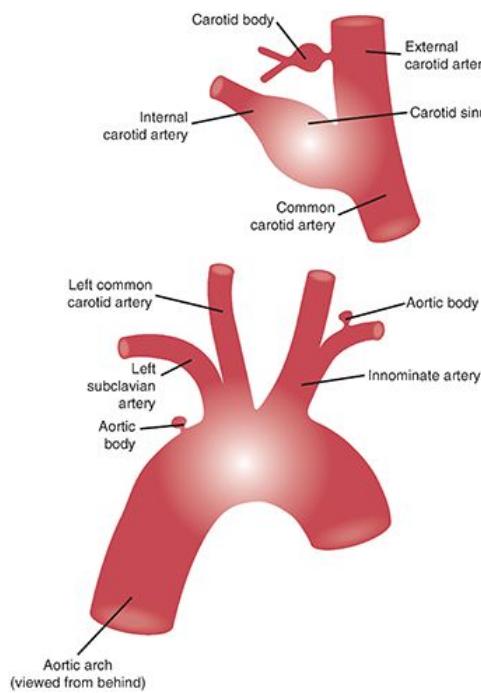

FIGURE 14.12 Baroreceptors are represented by the carotid sinus and receptors in the arch of the aorta. Chemoreceptors are located in the carotid and aortic bodies.

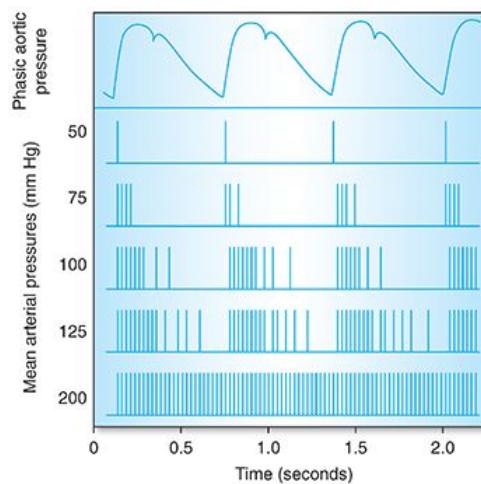

FIGURE 14.13 Discharges (vertical lines) in a single afferent nerve fiber from the carotid sinus at various arterial pressures plotted against changes in aortic pressure with time. New York, NY: Lange Medical Books/McGraw Hill, 2003; permission conveyed through Copyright Clearance Center, Inc.

Chemoreceptor Reflexes

Chemoreceptors are cells that transduce chemical signals into nerve impulses. There are chemoreceptors located in the carotid bodies and aortic body (see [Figure 14.12](#)).¹³ Each carotid or aortic body is supplied with an abundant blood flow through a nutrient artery so that the chemoreceptors are always exposed to oxygenated blood. When the systemic blood pressure, and thus the blood flow, decrease below a critical level, the chemoreceptors in the carotid body are stimulated by decreased availability of oxygen and also because of excess carbon dioxide and hydrogen ions that are not removed by the sluggish blood flow. Impulses from the chemoreceptors are transmitted to the vasomotor center, which results in reflex changes that tend to increase systemic blood pressure back toward the normal. Chemoreceptors do not respond strongly until systemic blood pressure decreases below 80 mm Hg. Chemoreceptors are more important in stimulating breathing when the PaO_2 decreases below 60 mm Hg (ventilatory response to arterial hypoxemia). The ventilatory response to arterial hypoxemia is inhibited by subanesthetic concentrations of most of the volatile anesthetics (0.1 minimum alveolar concentration) as well as injected drugs such as propofol, midazolam, barbiturates, and opioids (see [Chapters 4, 5, and 7](#)).

Bezold-Jarisch Reflex

The Bezold-Jarisch reflex is a circulatory response whereby a decrease in left ventricular volume activates receptors that cause a paradoxical bradycardia. This compensatory decrease in heart rate allows for increased ventricular filling but may also exacerbate hypotension. The bradycardia and hypotension that can occur during spinal or epidural anesthesia have been attributed to this reflex.

Atrial Reflexes

The atria contain low-pressure atrial stretch receptors similar to baroreceptors in large arteries. Stretching of the atria evokes reflex vasodilation and decreases the systemic blood pressure back toward the normal level. An increase in atrial pressure also causes an increase in heart rate (Bainbridge reflex) due to a direct effect of the increased atrial volume on stretch of baroreceptors located in both atria at the venoatrial junctions. The increase in heart rate evoked by stretching of the atria prevents accumulation of blood in the atria, veins, or pulmonary circulation.

Central Nervous System Ischemic Reflex

The central nervous system ischemic reflex response occurs when blood flow to the medullary vasomotor center is decreased to the extent that ischemia of this vital center occurs. As a result of this ischemia, there is an intense outpouring of sympathetic nervous system activity, resulting in profound increases in systemic blood pressure. It is believed that this reflex response is caused by failure of slowly flowing blood to remove carbon dioxide from the vasomotor center. The central nervous system reflex response does not become highly active until mean arterial pressure decreases to less than 50 mm Hg and reaches its greatest degree of stimulation at systemic blood pressures of 15 to 20 mm Hg. This reflex response is not useful for regulation of normal blood pressure but rather acts as an emergency control system to prevent further decreases in systemic blood pressure when cerebral blood flow is dangerously decreased.

Cushing Reflex

The Cushing reflex is a central nervous system ischemic reflex response that results from increased intracranial pressure. When intracranial pressure increases to equal arterial pressure, the Cushing reflex acts to increase systemic blood pressure above intracranial pressure. Cushing triad is defined as having (1)

hypertension, (2) bradycardia, and (3) irregular respirations (due to brainstem dysfunction). The latter is not often seen in this era, as most patients with severe intracranial hypertension are now mechanically ventilated.

Respiratory Variations in Systemic Blood Pressure

Systemic blood pressure normally varies by 4 to 6 mm Hg in a wavelike manner during quiet spontaneous breathing. Systemic blood pressure is increased during end-inspiration and the beginning of exhalation and decreased during the remainder of the breathing cycle. This is due to increased venous return to the right heart during inspiration, which takes a few cardiac cycles to be transmitted to the left heart. Positive pressure ventilation of the lungs produces a reversed sequence of blood pressure change because the initial positive airway pressure simultaneously pushes more blood toward the left ventricle causing an increase in pressure; this is followed by a decrease in left ventricular filling due to the decrease in venous return to the right heart caused by the positive intrathoracic pressure.

Continuous or beat-to-beat monitoring of the changes in arterial blood pressure, pulse pressure, and stroke volume occurring during mechanical ventilation may provide an indication of the patient's ability to respond to volume administration with an increase in cardiac output or "fluid responsiveness." Respiratory variation in these parameters of more than 12% to 15% generally indicates fluid responsiveness. When the chest is closed and an adequate tidal volume is employed, "goal-directed" fluid resuscitation can be guided by such measurements.

Heart Rate Variability

Variations in heart rate occur during normal respiration, whereby inspiration increases heart rate and expiration decreases it. High-frequency heart rate variability is controlled by autonomic reflexes mediated by neural input to the heart supplied by the vagus nerve. Low-frequency heart rate variability results from the interaction between parasympathetic and sympathetic tone. Analysis of heart rate variability provides information regarding the integrity of the autonomic nervous system. High heart rate variability is a sign of good health, and conversely, low heart rate variability can be a manifestation of disease (myocardial infarction, heart failure, neuropathy) and occurs universally following the denervation that occurs during cardiac transplantation.¹⁴

Systemic Blood Pressure Vasomotor Waves

Cyclic increases and decreases in systemic blood pressure lasting 7 to 10 seconds are referred to as **vasomotor** or **Traube-Hering waves**. The presumed cause of vasomotor waves is oscillation in the reflex activity of baroreceptors. For example, increased systemic blood pressure stimulates baroreceptors, which then inhibit the sympathetic nervous system, causing a decrease in systemic blood pressure. Decreased systemic blood pressure decreases baroreceptor activity and allows the vasomotor center to become active once again, increasing the systemic blood pressure to a higher value.

Moderately Rapid-Acting Mechanisms for the Regulation of Systemic Blood Pressure

There are at least three hormonal mechanisms that provide either rapid or moderately rapid control of systemic blood pressure. These hormonal mechanisms are catecholamine-induced vasoconstriction, renin-angiotensin-induced vasoconstriction, and vasoconstriction induced by arginine vasopressin, all of which increase systemic blood pressure by increasing systemic vascular resistance. Circulating catecholamines may even reach parts of the circulation that are devoid of sympathetic nervous system innervation, such as metarterioles. Renin-angiotensin-induced vasoconstriction manifests to a greater degree on arterioles than veins and requires about 20 minutes to become fully active.

In addition to hormonal mechanisms, there are two intrinsic mechanisms (capillary fluid shift and stress-relaxation of blood vessels), which begin to react within minutes of changes in systemic blood pressure. For example, changes in systemic blood pressure produce corresponding changes in capillary pressure, thus allowing fluid to enter or leave the capillaries to maintain a constant blood volume. Stress relaxation is the gradual change in blood vessel size to adapt to changes in systemic blood pressure and the amount of blood

that is available. The stress-relaxation mechanism has definite limitations such that increases in blood volume greater than about 30% or decreases of more than about 15% cannot be corrected by this mechanism alone.

Long-Term Mechanisms for the Regulation of Systemic Blood Pressure

Long-term mechanisms for the regulation of systemic blood pressure, unlike the short-term regulatory mechanisms, have a delayed onset but do not adapt, providing a sustained regulatory effect on systemic blood pressure. The renal–body fluid system plays a predominant role in long-term control of systemic blood pressure because it controls both the cardiac output and systemic vascular resistance. This crucial role is supplemented by accessory mechanisms, including the renin-angiotensin-aldosterone system and arginine vasopressin regulation.

Renal–Body Fluid System

Increased systemic blood pressure, as provoked by modest increases in blood volume, results in sodium ion and water excretion by the kidneys. The resultant decrease in blood volume leads to decreases in cardiac output and systemic blood pressure. After several weeks, the cardiac output returns toward normal, and systemic vascular resistance decreases to maintain the lower but more acceptable blood pressure. Conversely, a decrease in systemic blood pressure stimulates the kidneys to retain fluid. A special feature of this regulatory mechanism is its ability to return systemic blood pressure completely back to normal values. This contrasts with rapid-acting to moderately rapid-acting mechanisms, which cannot return systemic blood pressure entirely back to normal.

Renin-Angiotensin System

Aldosterone secretion that results from the action of angiotensin II on the adrenal cortex exerts a long-term effect on systemic blood pressure by stimulating the kidneys to retain sodium and water. The resulting increase in extracellular fluid volume causes cardiac output, and subsequently systemic blood pressure, to increase.

Regulation of Cardiac Output and Venous Return

Cardiac output is the amount of blood pumped by the left ventricle into the aorta each minute (product of stroke volume and heart rate), and venous return is the amount of blood flowing from the veins into the right atrium each minute. Because the circulation is a closed circuit, the cardiac output must equal venous return. Cardiac output for the average person weighing 70 kg and with a body surface area of 1.7 m^2 is about 5 L per minute. This value is about 10% less in women.

Determinants of Cardiac Output

Venous return is the main determinant of cardiac output. The metabolic requirements of tissues control cardiac output through alterations in resistance to tissue blood flow. For example, increased local metabolic needs lead to regional vasodilation, with a resulting increase in tissue blood flow and thus venous return. Cardiac output is increased by an amount equivalent to the venous return.

Any factor that interferes with venous return can lead to decreased cardiac output. Hemorrhage decreases blood volume such that venous return decreases and cardiac output decreases. Acute venodilation, such as that produced by spinal anesthesia and accompanying sympathetic nervous system blockade, can so increase the capacitance of peripheral vessels that venous return is reduced and cardiac output declines. Restoration of venous tone (with a vasoconstrictor) and/or administration of fluid can restore cardiac output. Positive pressure ventilation of the lungs, particularly in the presence of a decreased blood volume, causes a decrease in venous return and cardiac output.

Factors that increase cardiac output are associated with decreases in systemic vascular resistance. For example, anemia decreases the viscosity of blood, leading to a decrease in systemic vascular resistance and increase in venous return. An increased blood volume increases cardiac output by increasing the gradient for flow to the right atrium and by distending blood vessels, which decreases resistance to blood flow. Increased cardiac output caused by an increased blood volume lasts only 20 to 40 minutes because increased capillary

pressures cause intravascular fluid to enter tissues, thereby returning blood volume to normal. Furthermore, increased pressure in veins caused by the increased blood volume causes the veins to distend (stress relaxation). Cardiac output increases during exercise, in hyperthyroidism, and in the presence of arteriovenous shunts associated with hemodialysis, reflecting decreases in systemic vascular resistance.

Sympathetic nervous system stimulation increases myocardial contractility and heart rate to increase cardiac output beyond that possible from venous return alone. Maximal stimulation by the sympathetic nervous system can double cardiac output. Nevertheless, this sympathetic nervous system–induced increase of cardiac output is only transient, despite sustained increases in nervous system activity. A reason for this transient effect is autoregulation of tissue blood flow, which manifests as vasoconstriction to decrease venous return and thus decrease cardiac output back toward normal. In addition, increased systemic blood pressure associated with increases in the cardiac output causes fluid to leave the capillaries, thereby decreasing blood volume, venous return, and cardiac output.

An increase in myocardial contractility or inotropy can increase the stroke volume and thereby the cardiac output. Cardiac muscle is sensitive to calcium; most hormones and drugs that increase contractility augment intracellular calcium use. One newer agent available outside of the United States that is used to provide inotropic support in severe heart failure (levosimendan) sensitizes the myofibrils to calcium. Decreased contractility is caused by many anesthetic agents. Strictly speaking, changes in inotropic state should be defined in the absence of changes in preload and afterload; because many inotropic drugs affect these parameters as well, changes in cardiac output are not always due only to the inotropic activity.

Ventricular Function Curves

Ventricular function curves (Frank-Starling curves) depict the cardiac output at different atrial (ventricular end diastolic) filling pressures ([Figure 14.14](#)). Clinically, ventricular function curves are used to estimate myocardial contractility. Improved cardiac function (sympathetic nervous system stimulation) is characterized by a shift of the cardiac output curve to the left of the normal curve (greater cardiac output for a given filling pressure), whereas a shift of the curve to the right of normal (myocardial infarction, cardiomyopathy) reflects decreased cardiac function. Even with a normal ventricular function curve, as preload is increased, a point is reached where further stretching of the cardiac muscle results in no further increase and eventually to a decrease in cardiac output.

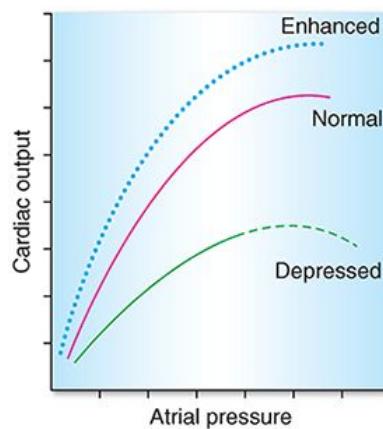

FIGURE 14.14 Ventricular function curves (Frank-Starling curves) depict the volume of forward ventricular ejection (cardiac output) at different atrial filling pressures and varying degrees of myocardial contractility.

Pressure-Volume Loops

Pressure-volume loops describe the dynamic characteristics of cardiac function ([Figure 14.15](#)). If ventricular pressure is plotted against ventricular volume, each cardiac cycle can be depicted by a pressure-volume loop.

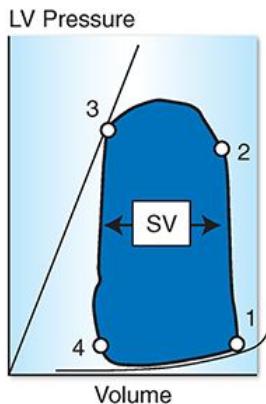

FIGURE 14.15 Pressure-volume loop representing one cardiac cycle for the left ventricle. The four segments of the loop represent, respectively: diastole or ventricular filling ending in mitral valve closure (point 1), isovolumic contraction ending in aortic valve opening (point 2), systole ending in aortic valve closure (point 3), and isovolumic relaxation ending in mitral valve opening (point 4). The width of the loop is the stroke volume; the end-systolic relationship (line through point 3) is a measure of contractility with increased contractility reflected by a steeper slope, and decreased contractility with a shallower slope.

Shock Syndromes

Circulatory shock is characterized by inadequate tissue blood flow and oxygen delivery to cells resulting in generalized deterioration of cellular and organ function. Inadequate tissue flow is due to inadequate cardiac output and can result from decreased venous return, myocardial depression, or both. Cellular metabolism is depressed, and the amount of heat liberated is decreased resulting in a decreased body temperature particularly when the ambient environment is cold. In the early stages of shock, consciousness is usually maintained, although mental clarity may be impaired. Consciousness is likely to be lost as shock progresses. Low cardiac output greatly decreases urine output, eventually leading to anuria as glomerular pressure decreases below the critical value required for filtration of fluid into Bowman's capsule. Furthermore, the kidneys have such a high rate of metabolism that decreased renal blood flow may cause acute tubular necrosis (see [Chapter 16](#)). An important feature of persistent shock is eventual progressive deterioration of the heart. In addition to myocardial depression caused by decreased coronary artery blood flow, myocardial function can also be depressed by lactic acid, bacterial endotoxins, and myocardial depressant factor released from an ischemic pancreas.

Hemorrhagic Shock

Hemorrhage is the most common cause of shock due to decreased venous return. Any decrease in systemic blood pressure initiates powerful baroreceptor-mediated increases in sympathetic nervous system activity, manifesting as arterial constriction, vasoconstriction, and direct myocardial stimulation. Vasoconstriction is particularly important for sustaining venous return to the heart and, thus, maintaining cardiac output. Arterial constriction is responsible for initially maintaining systemic blood pressure despite decreases in cardiac output. This maintenance of systemic blood pressure sustains cerebral and coronary artery blood flow as significant vasoconstriction does not occur in these organs. In other organs, such as the kidneys, intense sympathetic nervous system-mediated vasoconstriction may decrease blood flow dramatically.

Nonhemorrhagic Hypovolemic Shock

Loss of plasma volume from the circulation can result in shock similar to that produced by hemorrhage. Intestinal obstruction results in fluid loss into the gastrointestinal tract and reduction in plasma volume. Severe burns may also be associated with sufficient loss of plasma volume to result in shock. Severe dehydration from any cause can also lead to hypovolemic shock due to reduction in plasma volume. Hypovolemic shock that results from a reduction in plasma volume has the same clinical characteristics as

hemorrhagic shock except that selective reduction of the plasma volume greatly increases the viscosity of blood and exacerbates sluggish blood flow.

Neurogenic Shock

Neurogenic shock occurs in the absence of blood loss when vascular capacity increases so greatly that even a normal blood volume is not capable of maintaining venous return and cardiac output. Common causes of loss of vasomotor tone and subsequent neurogenic shock are traumatic transection of the spinal cord and acute blockade of the peripheral sympathetic nervous system by spinal or epidural anesthesia.

Septic Shock

Septic shock is characterized by profound peripheral vasodilation, increased cardiac output secondary to decreased systemic vascular resistance, increased vascular permeability with fluid loss from the vascular compartment, and development of disseminated intravascular coagulation. Septic shock is most commonly caused by gram-positive bacteria and less commonly by endotoxin-producing gram-negative bacteria. Endotoxins are bacterial membrane lipopolysaccharides that are made up of a toxic fatty acid (lipid A) core and a complex polysaccharide coat. Analogous molecules in the walls of gram-positive bacteria and fungi can also cause septic shock. The septic response is likely to reflect a systemic inflammatory response produced by exposure to bacterial cell products that ultimately lead to a progressively dysfunctional host response and multisystem organ failure. Elderly patients and those with immunosuppression are vulnerable to the development of sepsis and associated septic shock. The end stages of septic shock are not greatly different from the end stages of hemorrhagic shock, even though the initiating factors are markedly different. Mortality approaches 50% in septic shock despite significant improvements in supportive care.¹⁵

Measurement of Cardiac Output

The management of patients in the operating room and intensive care unit involves therapeutic interventions intended to optimize tissue oxygen delivery. Common interventions include fluid administration, blood transfusion, inotrope and vasoactive pharmacotherapy, heart rate and rhythm manipulation, mechanical assist devices, and mechanical ventilation. Ideally these therapies should be guided by measures of adequacy of tissue oxygenation or perfusion, but such measures are not yet clinically available. Indicators of global adequacy of perfusion such as serum lactate or central venous oxygen saturation are helpful, but abnormal values may take time to develop making the clinical response reactive rather than proactive. Cardiac output can be measured clinically by a variety of techniques and can be used to guide therapy.

Traditionally, cardiac output measurement has required insertion of a thermistor-tipped pulmonary artery catheter. Recent advances in microprocessor technology, a greater awareness of the limitations and hazards of pulmonary artery catheter insertion, and a need to measure cardiac output in out of operating room settings such as the emergency department, have led to the development of newer monitoring techniques. The general trend has been to develop techniques that are less invasive and allow more frequent, or even continuous, measurement of cardiac output.¹⁶ Nevertheless, the pulmonary artery thermodilution technique represents the clinical standard against which new techniques are compared.¹⁷ Currently used methods of cardiac output measurement include Fick methods, indicator dilution methods, thermodilution, echocardiographic techniques, impedance cardiography, and pulse contour analysis.

Fick Method

Adolf Fick first described use of the “Fick principle” to estimate cardiac output in 1870. Cardiac output is estimated by dividing the oxygen consumption by the arteriovenous difference for oxygen ([Figure 14.16](#)).⁴ Oxygen consumption is measured by a respirometer containing a known oxygen mixture. The patient’s exhaled gases are collected in a large inflatable reservoir (Douglas bag). The volume and oxygen concentrations of the exhaled gases are measured, allowing calculation of oxygen consumption. Clinically, this is rarely feasible, and a nomogram is used to estimate oxygen consumption.

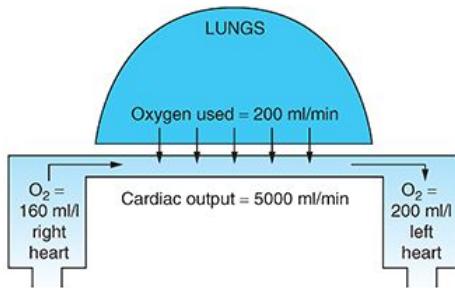

FIGURE 14.16 The Fick method calculates cardiac output as oxygen consumption divided by the arteriovenous difference for oxygen. Republished with permission of McGraw Hill LLC from Ganong WF. Review of Medical Physiology. 21st ed. New York, NY: Lange Medical Books/McGraw Hill, 2003; permission conveyed through Copyright Clearance Center, Inc.

Venous blood used for calculation of oxygen content must be obtained from the right ventricle, or, ideally, the pulmonary artery, to ensure adequate mixing. Blood from the right atrium may not yet be adequately mixed to provide a true mixed venous sample. Blood used for determining the oxygen saturation in arterial blood can be obtained from any artery because all arterial blood is thoroughly mixed before it leaves the heart and therefore has the same concentration of oxygen. With the assumption of oxygen consumption from a nomogram, and the need for a mixed venous sample that requires a pulmonary artery catheter, the Fick technique has largely been supplanted by thermodilution, where all the variables in the equation are measured (see “[Indicator Dilution Method](#)” and “[Thermodilution Method](#)” below).

Indicator Dilution Method

In measuring the cardiac output by the indicator dilution method, a nondiffusible dye (indocyanine green) is injected into the right atrium (or central venous circulation), and the concentration of dye is subsequently measured continuously in the arterial circulation by a spectrophotometer. The area under the resulting time-concentration curve before recirculation of the dye occurs, combined with knowing the amount of dye injected, allows calculation of the pulmonary blood flow, which is the same as the cardiac output. It is necessary to extrapolate the dye curve to zero because recirculation of the dye occurs before the down slope of the curve reaches baseline. Early recirculation of the dye may indicate the presence of a right-to-left intracardiac shunt (foramen ovale), permitting direct passage of a portion of the dye to the left side of the heart without first passing through the lungs.

Thermodilution Method

A bolus of cold fluid may also be considered an indicator and used in the indicator dilution technique. A pulmonary artery catheter with ports in the right atrium and pulmonary artery and a temperature sensor on the distal port is used to measure thermodilution cardiac outputs. Thermodilution cardiac outputs are determined by measuring the change in blood temperature between two points (right atrium and pulmonary artery) after injection of a known volume of cold saline solution at the proximal right atrial port. The change in blood temperature as measured at the distal pulmonary artery port is inversely proportional to pulmonary blood flow (the extent to which the cold saline solution is diluted by blood), which is equivalent to cardiac output. The area under the temperature-time curve is converted to its equivalent in cardiac output. The main assumptions with this technique are unidirectional flow (no right sided valvular regurgitation) and no intracardiac shunts. Advantages of this technique compared with the dye dilution method include dissipation of cold in tissues so recirculation is not a problem, and safety of repeated and frequent measurements because saline is innocuous unless very frequent measurements incur a significant volume load. A modification of this technique is the use of a heated filament around the pulmonary artery catheter to create a small heat signal, and a high sensitivity thermistor to sense the signal. Using sophisticated signal processing, and a sequence of heat application that is repeated every 30 seconds, a semicontinuous automated cardiac output measurement is obtained.

Echocardiographic Techniques

Echocardiography can be used to estimate cardiac output by combining the Doppler principle to determine the velocity of blood in the aorta with two-dimensional views to determine aortic diameter.¹⁶ Conventional transesophageal or transthoracic echocardiographic techniques have the advantage that systolic and diastolic function, volume status, regional wall abnormalities, valve function, and the presence of pericardial effusion may also be evaluated. However, this technique requires significant operator expertise. More recently, Doppler techniques have been developed using transesophageal probes designed solely for the purpose of estimating cardiac output. Aortic dimensions are not measured but are estimated from age-, sex-, and body size-specific nomograms derived from large population studies. Transesophageal Doppler estimates of cardiac output require minimal operator training and allow rapid cardiac output estimation.

Impedance Cardiography

The thorax is a conductor whose impedance is altered by changes in blood volume and velocity with each cardiac cycle. Impedance cardiography is based on the principle of thoracic electrical bioimpedance and involves the placement of electrodes to allow the transmission of current and measurement of voltage across the chest.¹⁸ Thus, thoracic electrical bioimpedance techniques can be used to noninvasively estimate cardiac output. However, the reliability of this technique is limited under several circumstances including patient movement, poor electrocardiogram signal quality, cardiac tachydysrhythmias, excessive thoracic fluid, and open chest wounds with metal retractors.

Pulse Contour Analysis

The first attempt to determine cardiac output from analysis of the pulse contour was made in 1904. The aortic pressure waveform is a function of the stroke volume and its interaction with the vascular tree. The arterial pulse contour can be modeled in a manner analogous to an electrical circuit that has specific values for resistance, compliance, and impedance.¹⁹ Thus, the flow within that system can be estimated from the pressure waveform that is generated. There are several devices now available, using different methods of analysis, which estimate the stroke volume and cardiac output from analysis of the arterial waveform (from an arterial catheter).²⁰ An enhancement of this technique is estimating “stroke volume variation” with respiration in mechanically ventilated patients. As referred to the discussion earlier, a variation of more than 12% to 15% indicates the patient will likely increase their cardiac output if fluid is administered.

Microcirculation

The circulation exists to supply tissues with blood in amounts commensurate with their needs for oxygen and nutrients.⁴ The microcirculation is defined as the circulation of blood through the smallest vessels of the body—arterioles, capillaries, and venules. Capillaries, whose walls consist of a single layer of endothelial cells, serve as the site for the rapid transfer of oxygen and nutrients to tissues and receipt of metabolic byproducts. There are an estimated 10 billion capillaries providing a total surface area that exceeds 6,300 m² for nutrient exchange. Capillary density varies from tissue to tissue. Capillaries are numerous in metabolically active tissues, such as cardiac and skeletal muscles, whereas in less active tissues, capillary density is low. Nevertheless, it is unlikely that any functional cell is greater than 50 microns away from a capillary. The muscular arterioles serve as the major resistance vessels and regulate regional blood flow to the capillary beds. Venules act primarily as collecting channels and storage vessels.

Anatomy of the Microcirculation

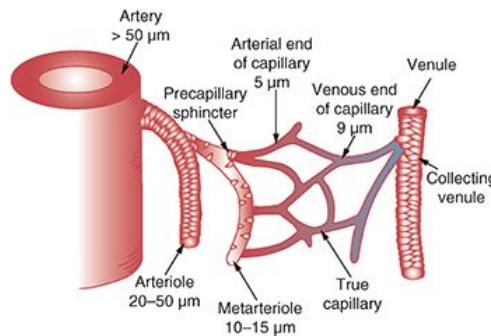

Arterioles give rise to metarterioles, which give rise to capillaries (**Table 14.6**; **Figure 14.17**).¹³ Other metarterioles serve as thoroughfare channels to the venules, bypassing the capillary bed. Capillaries drain via short collecting venules to the venules. Blood flow through capillaries is regulated by muscular precapillary sphincters present at the capillary opening. The arterioles, metarterioles, and venules contain smooth muscle. As a result, the arterioles serve as the major resistance vessels and regulate regional blood flow to the capillary beds, whereas the venules and veins serve primarily as collecting channels and storage or capacitance vessels.

TABLE 14.6

Anatomy of the various types of blood vessels

Vessel	Lumen diameter	Approximate cross-sectional area (cm ²)	Percentage of blood volume contained
Aorta	2.5 cm	2.5	
Artery	0.4 cm	20	13
Arteriole	30 microns	40	1
Capillary	5 microns	2,500	6
Venule	20 microns	250	
Vein	0.5 cm	80	64 ^a
Vena cava	3 cm	8	
Heart			7
Pulmonary circulation		18	9

^aBlood volume contained in venules, veins, and vena cava.

**FIGURE 14.17** Anatomy of the microcirculation.

Capillary walls are about 1 micron thick, lined on the endovascular surface with the glycocalyx ([Figure 14.18](#)). Channels through the endothelium include fenestrations or pores²¹ and interdigitated junctions between cells. The tissue side of the endothelial cell is lined with a basement membrane in many tissues. The structure of the capillary wall varies from tissue to tissue, but in many organs, including those in skeletal, cardiac, and smooth muscle, the interdigitated junction between endothelial cells allows passage of molecules up to 10 nm in diameter. In addition, the cytoplasm of endothelial cells is attenuated to form gaps or pores that are 20 to 100 nm in diameter. These pores permit the passage of relatively large molecules. It also appears that plasma and its dissolved proteins are taken up by endocytosis, transported across endothelial cells, and discharged by exocytosis into the interstitial fluid. In the brain, the capillaries resemble those in skeletal muscles, except the interdigitated junctions between endothelial cells are tighter (blood–brain barrier), permitting passage of only small molecules.

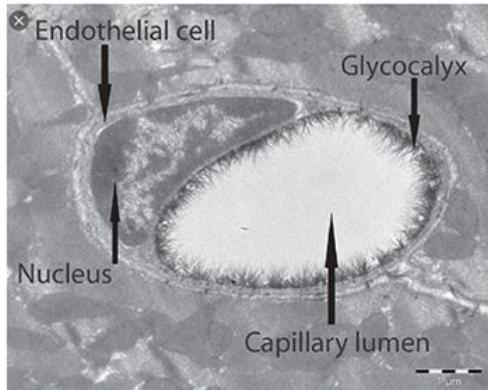

FIGURE 14.18 Transmission electron microscopic image of the glycocalyx in a left ventricular myocardial capillary following Alcian blue 8GX staining. The capillary lumen is enclosed by the endothelial cell. The luminal side of the endothelium is aligned by a polysaccharide layer containing proteoglycans (PG) and glycoproteins (GP). This is the static, membrane-bound part of the glycocalyx. The dynamic part, containing the plasma constituents, is not visualized due to collapse following the preparation and staining procedures. *From Haeren RHL, van de Ven SEM, van Zandvoort MAMAJ, et al. Assessment and imaging of the cerebrovascular glycocalyx. Curr Neurovasc Res. 2016;13(3):249-260.*

The diameter of capillary pores is about 25 times the diameter of water molecules (0.3 nm), which are the smallest molecules that normally pass through capillary channels. Plasma proteins have diameters that exceed the width of capillary pores. Other substances, such as sodium, potassium, and chloride ions and glucose, have intermediate diameters (0.39–0.86 nm) such that permeability of capillary pores for different substances varies according to their molecular weights ([Table 14.7](#)). Oxygen and carbon dioxide are both lipid soluble and readily pass through endothelial cells.

TABLE 14.7

Permeability of capillary membranes

	Molecular weight (da)	Relative permeability
Water	18	1.0
Sodium chloride	58.5	0.96
Glucose	180	0.6
Hemoglobin	66,700	0.01
Albumin	69,000	0.0001

True capillaries are devoid of smooth muscle and are therefore incapable of active constriction. Nevertheless, the endothelial cells that form them contain actin and myosin and can alter their shape in response to certain chemical stimuli. The diameter of capillaries (7–9 µm) is just sufficient to permit erythrocytes to squeeze through in single file. The thin walls of capillaries are able to withstand high intraluminal pressures because their small diameter prevents excessive wall tension (Laplace law).

Blood Flow in Capillaries

Blood flow in capillaries is approximately 1 mm per second and is intermittent rather than continuous. This intermittent blood flow reflects contraction and relaxation of metarterioles and precapillary sphincters in alternating cycles 6 to 12 times per minute.²² The phenomenon of alternating contraction and relaxation is known as **vasomotion**. Oxygen is the most important determinant of the degree of opening and closing of metarterioles and precapillary sphincters. A low P_{O_2} allows more blood to flow through capillaries to supply tissues. In this regard, the impact of oxygen on capillary blood flow provides a form of autoregulation of tissue blood flow.

In addition to nutritive blood flow through tissues that is regulated by oxygen, there is also nonnutritive (shunt) blood flow regulated by the autonomic nervous system. The nonnutritive blood flow is characterized by direct vascular connections between arterioles and venules. Some of these arteriovenous connections have muscular coverings so blood flow can be altered over a wide range. In some parts of the skin, these arteriovenous anastomoses provide a mechanism to permit rapid inflow of arterial blood to warm the skin and dissipate the heat.

Vasoactive Role of the Capillary Endothelium

True capillaries are devoid of smooth muscle and are therefore incapable of active constriction. Nevertheless, the endothelial cells that form them contain actin and myosin and can alter their shape in response to certain chemical and mechanical stimuli. The diameter of capillaries (7-9 μm) is just sufficient to permit erythrocytes to squeeze through in single file. The thin walls of capillaries are able to withstand high intraluminal pressures because their small diameter prevents excessive wall tension (Laplace law).

Prostacyclin, produced by the endothelium, can relax vascular smooth muscle via an increase in cyclic adenosine monophosphate concentration. Prostacyclin is formed in the endothelium from arachidonic acid, and the reaction is catalyzed by prostacyclin synthase. The principal function of prostacyclin is to inhibit platelet adherence to the endothelium and platelet aggregation and thus prevent intravascular clot formation.

The formation and release of NO is also important in the endothelium-mediated vascular dilation.²³ The NO is released when endothelial cells are stimulated by acetylcholine or other vasodilator substances (adenosine triphosphate, bradykinin, serotonin, substance P, and histamine). The NO release can be stimulated by the shear stress of blood flow on the endothelium. A vasoconstrictor peptide synthesized by the capillary endothelium is endothelin. Endothelin may affect vascular tone and blood pressure.

Fluid Movement Between the Capillary Lumen and the Interstitium

Glycocalyx

The understanding of factors determining fluid movement between the capillary lumen and the interstitial space has been revolutionized in the last 25 years by identification and study of the glycocalyx.^{24,25} This is a complex hydrated gel-like layer of proteoglycans and glycoproteins anchored to the endothelium and forming an extensive matrix in which there are also soluble proteins; the glycocalyx interacts with plasma proteins, principally albumin, to form a thicker layer sometimes termed the *endothelial surface layer*. The mean thickness of the glycocalyx in man appears to be approximately 0.5 microns,²⁶ varying by size of vessel and tissue. Remarkably, it has been estimated the total body volume of the glycocalyx approaches 1.7 L.²⁷ The properties of the glycocalyx and the subglycocalyx immediately adjacent to the endothelial cell surface and in the junctions between cells are major determinants of vascular permeability and fluid movement.

Prior to the identification of the glycocalyx, fluid movement to and from the vascular and interstitial compartments was thought to follow the “Starling equation”²⁸ where the hydrostatic and oncotic pressures in the capillary lumen and interstitium, and the cell wall permeability, largely at the site of cell junctions and transmembrane fenestrations or pores, to solutes and proteins (see **Table 14.7**) were principal determinants of fluid flow. In this model at the proximal (arterial) end of the capillary, the net force was to drive protein-free fluid into the interstitium, and at the distal (venous) end of the capillary, the net force was for fluid reabsorption back into the vascular space. Higher hydrostatic pressure in the proximal capillary and higher oncotic pressure in the distal capillary were presumed to be the predominating forces.

In the hundred years following these original concepts, it has become apparent there are significant differences between tissues in the movement of fluid, electrolytes, and proteins across capillary walls. Perhaps most important is experimental studies which failed to demonstrate significant fluid reabsorption at the venous end of the capillary beds of most tissues and showed instead that lymphatic drainage (see following text) is the principal mechanism of maintaining interstitial fluid volume. Rather than the oncotic forces of fluid flux being across the endothelium and its intercellular junctions and pores, it is now apparent that the transglycocalyx oncotic forces determine fluid flux and the glycocalyx is the “molecular sieve” for proteins, predominantly albumin which is largely bound within the glycocalyx, leading to a low subglycocalyx oncotic pressure. This prevents significant fluid reabsorption at the distal capillary. Disruptions

in the glycocalyx result in large increases in capillary hydraulic permeability and protein flux, confirming its important role in this regard. Thus, the original concept of Starling has been revised to the “modified” Starling equation recognizing the transglycocalyx rather than transendothelial forces, with a major contribution from the low oncotic pressure in the subglycocalyx.

In addition to its role in regulating fluid flux, the glycocalyx appears to have, through its complex proteoglycan structure, mechanosensory properties that can translate shear stress and blood pressure elevation to the endothelial cells, inducing nitric oxide production and vasodilation. It also affects local blood viscosity and hematocrit to enhance flow, preventing red cells from contact with the endothelium and preventing interaction of inflammatory cells and platelets with the endothelial cell surface.

The Glycocalyx in Disease States

Damage or loss of the glycocalyx could be predicted to result in tissue edema and inflammation. [Figure 14.19](#) illustrates the normal glycocalyx (left side of illustration) and how loss of the glycocalyx in sepsis (mid and right side of illustration) leads to exposure of adhesion molecules on the endothelial cell surface promoting adhesion of leukocytes, platelets, and then thrombus formation as well as capillary fluid leakage and edema formation.²⁹

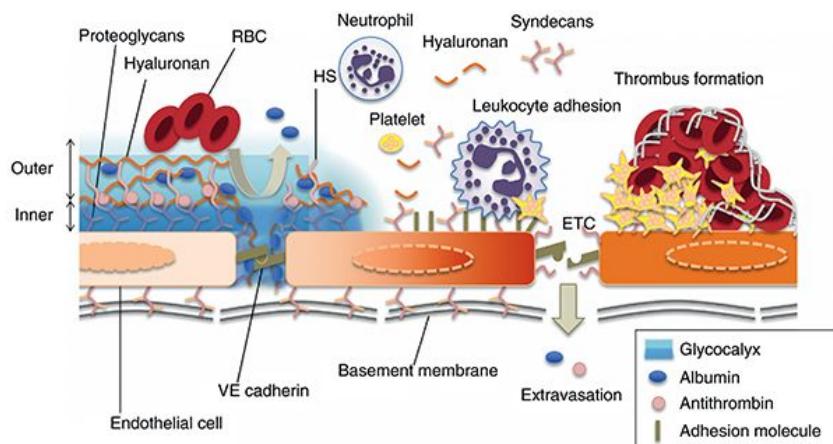

FIGURE 14.19 Derangement of the endothelial glycocalyx in sepsis. From Iba T, Levy JH. Derangement of the endothelial glycocalyx in sepsis. *J Thromb Haemostasis*. 2019;17(2):283-294.

Other disease states associated with glycocalyx shedding or injury include acute hypervolemia, through atrial natriuretic peptide production (due to atrial distension), hemorrhage, ischemia-reperfusion injury, and hyperglycemia.

Detection of glycocalyx damage or loss and therapy to minimize or treat such loss remains experimental, but hypervolemia and hyperglycemia which can be prevented by the anesthesiologist appear likely to be protective. Study of the glycocalyx also contributes to arguments regarding the types of fluid recommended for resuscitation in different settings.³⁰

Diffusion

Oxygen and carbon dioxide (and anesthetic gases) are lipid soluble and transfer directly across cell membranes independent of pores and independent of the function of the glycocalyx. The diffusion rate of these gases is directly proportional to the concentration difference between the two sides of the membrane. For this reason, oxygen moves from the capillaries into the tissues while carbon dioxide moves in the opposite direction. Typically, only slight partial pressure differences suffice to maintain adequate transport of oxygen from the plasma into the cells and interstitium.

Lymphatics

Lymphatic drainage represents the major route by which fluid flows from the interstitial spaces back into the bloodstream. In the steady state, there is continuous flow from one compartment to the next. While the lymphatic vessels drain into major veins in the neck, approximately half the total flow is absorbed by microvessels in the lymph nodes, leading to a total flow of approximately 8 L per day, meaning the entire plasma volume (not including proteins) leaves the circulation every 9 hours.²⁵

Anatomy

The major terminal lymph vessels are the thoracic duct and the right lymphatic duct ([Figure 14.20](#)). The thoracic duct is the larger of the two (2 mm in diameter), entering the venous system in the angle of the junction of the left internal jugular and subclavian veins. The right lymphatic duct is not always present, and if it is, it rarely exists as such because the three vessels that occasionally unite to form it usually open separately into the right internal jugular, subclavian, and innominate veins. Damage (surgical or traumatic) to a thoracic duct can cause intrathoracic fluid accumulation.

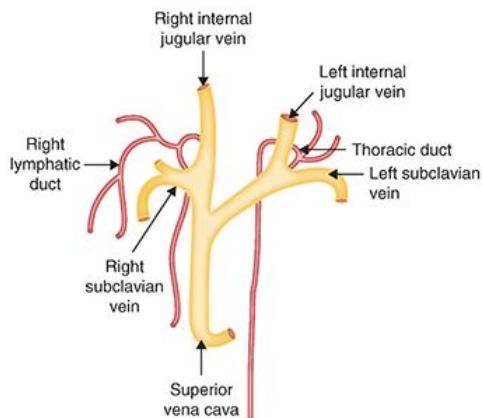

FIGURE 14.20 Depiction of the thoracic duct and right lymphatic duct as they enter the venous system.

Peripheral lymph vessels are small, difficult to identify, and contain flaplike valves between endothelial cells that open toward the interior, allowing the unimpeded entrance of interstitial fluid and proteins but preventing backflow.

Formation and Flow of Lymph

Lymph is interstitial fluid that flows into lymphatic vessels. The protein concentration of peripheral lymph is about 1.8 g/dL, whereas lymph from the gastrointestinal tract and liver contains 2 to 3 times this concentration of protein. The lymphatic system is one of the major channels for absorption of nutrients, especially fat, from the gastrointestinal tract. Bacteria that enter lymph vessels are removed and destroyed by lymph nodes.

Flow of lymph through the thoracic duct is about 100 mL per hour. A decrease in the normally negative value of interstitial fluid pressure increases the flow of interstitial fluid into terminal lymph vessels and consequently increases the rate of lymph flow. For example, at 0 mm Hg interstitial fluid pressure, the rate of lymph flow is increased 10 to 50 times compared with flow at an average interstitial fluid pressure of -6.3 mm Hg. Skeletal muscle contraction and passive movements of the extremities facilitate flow of lymph. For example, during exercise, lymph flow is increased up to 14 times that present at rest. Elevations in CVP can impair the return of lymph to the central circulation.

Edema

Edema is the presence of excess interstitial fluid in peripheral tissues that results from the inability of lymph vessels to adequately transport fluid. This may occur due to damage or obstruction of lymphatic vessels, excessive fluid administration, capillary fluid leakage due to increased permeability, low serum protein concentration, or elevated CVP. Peripheral edema most common in dependent areas may be accompanied by

accumulation of fluid in potential spaces such as the pleural cavity, pericardial space, peritoneal cavity, and synovial spaces. Excessive fluid in the peritoneal space—one of the spaces most prone to develop edema fluid—is called **ascites**. The peritoneal cavity is susceptible to the development of edema fluid because any increased pressure in the liver, such as occurs in cirrhosis or cardiac failure, causes transudation of protein-containing fluids from the surface of the liver into the peritoneal cavity.

Pulmonary Circulation

The pulmonary circulation is a low-pressure, low-resistance system in series with the systemic circulation. Pulmonary arteries have thinner walls and less smooth muscle than systemic arteries, and a relative lack of basal tone likely due to a predominance of endogenous vasodilators. Pulmonary vascular resistance is approximately one-tenth that of systemic resistance.

The volume of blood flowing through the lungs and systemic circulation is essentially identical. Blood passes through pulmonary capillaries in about 1 second, during which time it is oxygenated and carbon dioxide is removed.

Anatomy

Anatomically, the right ventricle is semilunar in shape, wrapped around the medial aspect of the left ventricle. The thickness of the right ventricle is one-third that of the left ventricle, as it normally generates pressures approximately 25% that of the left side.

The pulmonary artery extends only about 4 cm beyond the apex of the right ventricle before division into the right and left main pulmonary arteries. The pulmonary artery is a thin structure with a wall thickness about twice that of the vena cava and one-third that of the aorta. The large diameter and distensibility of the pulmonary arteries allows the pulmonary circulation to easily accommodate the stroke volume of the right ventricle. Pulmonary veins, like pulmonary arteries, are large in diameter and highly distensible. Pulmonary capillaries supply the estimated 300 million alveoli, providing a gas exchange surface of 70 m^2 .

Pulmonary blood vessels are innervated by the sympathetic nervous system, but the density of these fibers is less than in systemic vessels. α -Adrenergic stimulation from norepinephrine produces vasoconstriction of the pulmonary vessels, whereas β -adrenergic stimulation, as produced by isoproterenol, results in vasodilation. Parasympathetic nervous system fibers from the vagus nerves release acetylcholine, which produces vasodilation of pulmonary vessels. Despite the presence of autonomic nervous system innervation, the resting vasomotor tone is minimal, and the larger pulmonary vessels are almost maximally dilated in the normal resting state. Indeed, overall regulation of pulmonary blood flow is passive, with local adjustments of perfusion relative to ventilation being determined by local oxygen tension.

The diameter of thin-walled alveolar vessels changes in response to alterations in the transmural pressure (intravascular pressure minus alveolar pressure). If alveolar pressure exceeds intravascular pressure as occurs in nondependent regions of the lungs during positive pressure ventilation, pulmonary capillaries collapse and blood flow ceases. The size of larger vessels embedded in the lung parenchyma (extra-alveolar vessels) largely depends on lung volume. For example, resistance to flow through these vessels decreases as lung volumes increase because these vessels are tethered to the surrounding tissue ([Figure 14.21](#)). However, the largest pulmonary vessels, those at the hilum of the lung, vary in size in response to changes in intrapleural pressure.

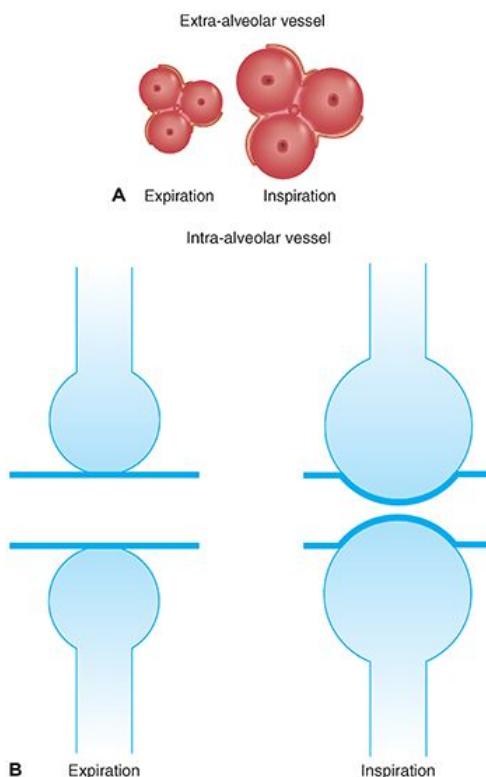

FIGURE 14.21 A, Schematic illustration of the effect of lung inflation on an extra-alveolar vessel surrounded by three alveoli. Extra-alveolar vessels are tethered by surrounding lung parenchyma and increase in caliber with lung inflation. B, Schematic illustration of an intra-alveolar vessel adjacent to two alveoli. Intra-alveolar vessels are compressed during lung inflation.

Bronchial Circulation

Bronchial arteries from the thoracic aorta supply oxygenated blood to supporting tissues of the lungs, including connective tissue and airways. After bronchial arterial blood has passed through supporting tissues, the majority of it empties into pulmonary veins and enters the left atrium rather than passing back to the right atrium. The entrance of deoxygenated blood into the left atrium dilutes oxygenated blood and accounts for an anatomic shunt that is equivalent to an estimated 1% to 2% of the cardiac output. This anatomic shunt plus a part of coronary blood flow which drains directly into the left side of the heart are the reasons the cardiac output of the left ventricle slightly exceeds that of the right ventricle.

Pulmonary Lymph Vessels

Pulmonary lymph vessels extend from all the supportive tissues of the lung to the hilum of the lung and then to the thoracic duct. Pulmonary lymphatic flow facilitates the removal of edema fluid from alveolar spaces. As lymph ultimately drains into the central venous circulation, lymph flow is reduced by elevated venous pressure.

Particulate matter entering the alveoli is also eventually removed by lymph vessels.

Pulmonary Vascular Pressure

The normal pressure in the pulmonary artery is about 22/8 mm Hg, with a mean pulmonary artery pressure of 13 mm Hg ([Figure 14.22](#)).⁴ The mean pulmonary capillary pressure is about 10 mm Hg, and the mean pressure in the pulmonary veins is about 4 mm Hg, such that the pressure gradient across the pulmonary circulation is only 9 mm Hg. The resistance to blood flow in the pulmonary circulation is about one-tenth the resistance in the systemic circulation.

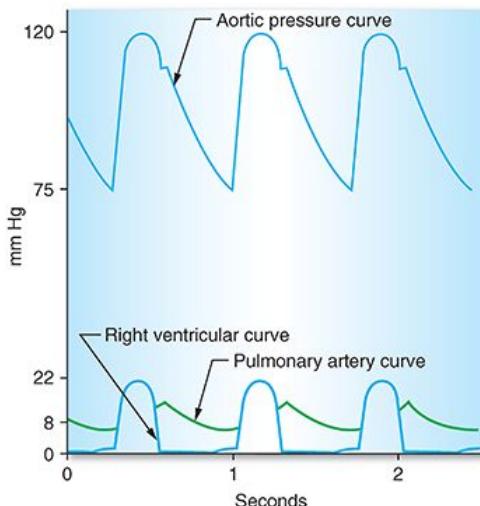

FIGURE 14.22 Comparison of intravascular pressures in the systemic and pulmonary circulations. Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.

Pulmonary artery pressure is not typically influenced by left atrial pressures of less than 7 mm Hg. However, when left atrial pressure exceeds approximately 7 mm Hg, previously collapsed pulmonary veins are expanded, and pulmonary artery pressure increases in parallel with increases in left atrial pressure. In the absence of left ventricular failure, even marked increases in systemic vascular resistance do not cause the left atrial pressure to increase significantly. Consequently, the right ventricle continues to eject its stroke volume against a normal pulmonary artery pressure despite increased workloads imposed on the left ventricle. Accordingly, the right ventricular stroke volume is not measurably altered by changes in systemic vascular resistance unless the left ventricle fails.

Should the left ventricle fail, left atrial pressures can increase to greater than 15 mm Hg. Mean pulmonary artery pressures also increase, placing an increased workload on the right ventricle. If this occurs acutely, the right ventricle may also fail as it may not be able to generate an adequate stroke volume due to its structure (see earlier discussion). If pulmonary artery pressures rise gradually over time, the right ventricle may adapt with remodeling and dilation but will eventually begin to fail.

Measurement of Left Atrial Pressure

The left atrial pressure can be estimated by inserting a balloon-tipped catheter into a small pulmonary artery (ie, a pulmonary artery catheter placed in a major vein and advanced through the right heart to the pulmonary artery).

When the balloon is temporarily inflated and the vessel is completely occluded, a stationary column of blood is created distal to the catheter tip. As a result, the pressure measured immediately distal to the balloon is equivalent to that downstream in the pulmonary veins. This measurement is termed the **pulmonary artery occlusion pressure** (PAOP) and is usually 2 to 3 mm Hg higher than left atrial pressure. If the balloon is deflated, flow will resume and the pulmonary artery end diastolic pressure can be measured. This measurement correlates with the PAOP in the absence of pulmonary hypertension. A number of conditions can however make measurement of the PAOP unreliable, including where in the lung the tip of the catheter resides, the presence of high positive end-expiratory pressure, and vascular conditions making the PAOP higher than the LA pressure such as precapillary pulmonary hypertension or mitral valve stenosis.

Interstitial Fluid Space

The interstitial fluid space in the lung is minimal, and a continual negative pulmonary interstitial pressure of about -8 mm Hg dehydrates interstitial fluid spaces of the lungs and keeps the alveolar epithelial membrane in close approximation to the capillary membranes. As a result, the diffusion distance between gas in the

alveoli and the capillary blood is minimal, averaging about 0.4 micron. Negative pressure in pulmonary interstitial spaces draws fluid from alveoli through alveolar membranes and into the interstitium, keeping the alveoli dry. Mean pulmonary capillary pressure is about 10 mm Hg, whereas plasma colloid osmotic pressure is about 28 mm Hg. This net pressure gradient of about 18 mm Hg discourages the movement of fluid out of capillaries, decreasing the likelihood of pulmonary edema.

Pulmonary Blood Volume

Blood volume in the lungs is about 450 mL. Of this amount, about 70 mL is in capillaries and the remainder is divided equally between pulmonary arteries and veins. Cardiac failure or increased resistance to flow through the mitral valve causes pulmonary blood volume to increase.

Cardiac output can increase nearly 4 times before pulmonary artery pressure becomes increased ([Figure 14.23](#)).⁴ This reflects the distensibility of the pulmonary arteries and opening of previously collapsed pulmonary capillaries. The ability of the lungs to accept greatly increased amounts of pulmonary blood flow, as during exercise, without excessive increases in pulmonary artery pressures is important in preventing development of pulmonary edema or right ventricular failure.

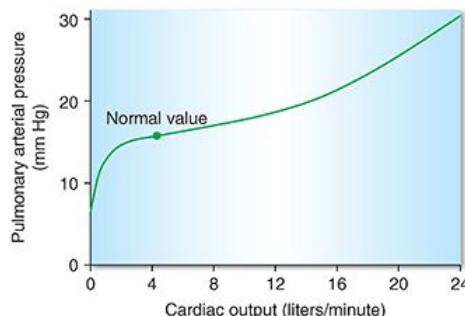

FIGURE 14.23 Cardiac output can increase nearly fourfold without greatly increasing the pulmonary arterial pressure. *Reprinted from Guyton AC, Hall JE. Textbook of Medical Physiology. 10th ed. Philadelphia, PA: W.B. Saunders; 2000. Copyright © 2000 Elsevier. With permission.*

Pulmonary blood volume can increase up to 40% when an individual changes from the standing to the supine position. This sudden shift of blood from the systemic circulation to pulmonary circulation is responsible for the decrease in vital capacity in the supine position and the occurrence of orthopnea in the presence of left ventricular failure.

Pulmonary Blood Flow and Distribution

Optimal oxygenation depends on matching ventilation to pulmonary blood flow.³¹ Shunt occurs in lung areas that are perfused but inadequately ventilated, whereas dead space ventilation occurs in lung areas that are ventilated but inadequately perfused ([Figure 14.24](#)). Although the lungs are innervated by the autonomic nervous system, it is doubtful that neural influences exert a major effect in the normal control of pulmonary blood flow. There is no doubt, however, that decreases in PaO_2 cause increases in pulmonary artery and right ventricular pressures.

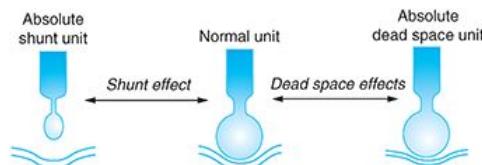

FIGURE 14.24 Gas exchange is maximally effective in normal lung units with optimal ventilation-perfusion (V/Q) relationships. The continuum of V/Q relationships is depicted by the ratios between normal and absolute shunt or dead space units.

Clinically, segmental pulmonary blood flow can be studied by intravenous injection of radioactive xenon while monitoring is performed externally over the chest with radiation detectors. Xenon rapidly diffuses from capillaries into alveoli, and radioactivity is detected early in well-perfused regions of the lung.

Endothelial Regulation of Pulmonary Blood Flow

Active vasodilation is crucial to the maintenance of the low resting tone of the normal pulmonary circulation. The pulmonary vascular endothelium is responsible for the synthesis and secretion of various compounds that regulate smooth muscle activity in the pulmonary circulation. The primary vasodilatory compounds are NO and prostacyclin. The predominant influence of a healthy pulmonary endothelium is to reduce pulmonary vascular tone. Endothelin is also released by the pulmonary endothelium and may have both a constrictive or dilatory effect depending on the circumstances. There are several negative feedback mechanisms in effect that regulate vascular tone. The synthesis and release of NO, prostacyclin, ET-1, and other vasoactive compounds are integrated into a system that optimizes pulmonary vascular tone and facilitates local control of ventilation-perfusion matching.³²

Nitric Oxide and Prostacyclin

NO is produced in endothelial cells of the pulmonary vasculature and similar to the systemic circulation plays a major role in maintaining low vascular tone. It is the most widely studied potent pulmonary vasodilator, produced via the action of cNOS, which oxidizes L-arginine into L-citrulline and NO; the NO then activates soluble guanylate cyclase in surrounding smooth muscle, which produces cyclic guanylate monophosphate, reducing intracellular calcium and myofilament sensitivity to calcium. The activity of cNOS is rapidly up- or downregulated and produces picomolar amounts of NO in response to stimuli such as shear stress and local oxygen tension. In pathologic states, another NOS isoform, iNOS, produces considerably larger quantities of NO but takes longer to upregulate and downregulate. The iNOS is located in vascular smooth muscle cells and inflammatory macrophages. Inflammatory mediators are potent upregulators of iNOS activity. The NO induces vasorelaxation by stimulating the production of cyclic guanosine monophosphate (cGMP) by the enzyme guanylate cyclase. The cGMP is promptly metabolized by phosphodiesterases. Increased cGMP production appears to stimulate phosphodiesterase upregulation, thus causing accelerating cGMP clearance. Indeed, phosphodiesterase upregulation may be partly responsible for suboptimal responses to inhaled NO (iNO) and for rebound pulmonary hypertension after NO withdrawal. Type V phosphodiesterase is the predominant enzyme type in the pulmonary circulation. Selective inhibitors of type V phosphodiesterase such as sildenafil can both selectively decrease pulmonary vascular resistance when given alone and significantly potentiate the effects of iNOS and prostacyclin.

Whereas oral agents that stimulate the production of cGMP (eg, riociguat) or inhibit its breakdown (eg, sildenafil) are useful for outpatient management of pulmonary hypertension,³³ iNO is only available for clinical use in the critical care or operating room setting. With its very short half-life, it has no systemic effects and is truly a selective pulmonary vasodilator. It is delivered only to ventilated alveoli and therefore improves oxygenation by better matching blood flow to ventilation. Its only US Food and Drug Administration-approved indication is for neonatal hypoxic respiratory failure (with proven outcome benefit), but iNO is also widely used in adult settings of severe refractory hypoxemia, pulmonary hypertension not related to left heart failure, and in right heart failure. It is used in the setting of heart and lung transplantation for both its effect on oxygenation and reduction in pulmonary artery pressure.³⁴

Prostacyclin or PGI₂ is one of a number of prostaglandins produced in endothelial cells; PGI₂ activates adenylate cyclase causing increased adenosine 3',5'-cyclic adenosine monophosphate release, promoting relaxation of vascular smooth muscle. Phosphodiesterase inhibitors reduce the breakdown of cyclic adenosine monophosphate; therefore, oral phosphodiesterase inhibitors increase the vasodilating actions of both iNO and PGI₂. Intravenous administration of PGI₂ through a dedicated central catheter has been used for chronic use in severe pulmonary hypertension (not due to left heart failure) for some time; it is not, however, a selective pulmonary dilator and must be initiated and uptitrated in a monitored setting. As a nonselective dilator, it may worsen ventilation-perfusion mismatch, and abrupt withdrawal can result in severe increases in

pulmonary artery pressures and right heart failure. When aerosolized, PGI₂ becomes more selective, but its elimination is slower than that of iNO, and systemic effects are possible. The PGI₂ has been employed in hypoxic respiratory failure and similar perioperative settings to those described earlier with iNO; published evaluations of the two drugs suggest they are similar in efficacy, and there is no benefit to administering both at the same time. Whereas its administration is a little more complex, aerosolized PGI₂ is significantly less expensive than iNO. Both are generally administered to intubated patients, but both can be administered through facemask or nasal cannula as well, most often as the patient is recovering from their condition and being weaned from the drugs. Dosage in this setting is of course much less predictable than when the patient is intubated. Other formulations or analogues of PGI₂ are used in outpatient therapy but less often in the perioperative or critical care setting.

Endothelin

Endothelin (ET-1) is a potent endogenous vasoconstrictor made in endothelial cells, which then acts on specific receptors on vascular smooth muscle cell membranes. Some types of pulmonary hypertension may be related to either increased production or reduced elimination of ET-1. The oral drug bosentan is an endothelin receptor antagonist used in outpatient treatment of pulmonary hypertension.³³

Hypoxic Pulmonary Vasoconstriction

Alveolar hypoxia ($\text{PaO}_2 < 70 \text{ mm Hg}$) evokes vasoconstriction in the pulmonary arterioles supplying these alveoli. The net effect is to divert blood flow away from poorly ventilated alveoli. As a result, the shunt effect is minimized, and the resulting PaO_2 is maximized. The mechanism for hypoxic pulmonary vasoconstriction is presumed to be locally mediated, as this response occurs in isolated and denervated lungs as well as intact lungs. Indeed, this vasoconstrictor response is apparent in isolated pulmonary artery strips and isolated smooth muscle cells. There are probably multiple mechanisms responsible for hypoxic pulmonary vasoconstriction, and these mechanisms likely differ during acute and chronic responses. The suppression of endothelial release of the potent vasodilator NO is likely an important element of both the acute and chronic response. A crucial component of the acute response is the inhibition of potassium channels that leads to membrane depolarization. Membrane depolarization increases calcium influx, which in turn activates the intracellular contractile response. Chronic vascular responses to hypoxia may be, in part, mediated by endothelin release and eventually involve vascular remodeling, eventually leading to irreversible increases in pulmonary vascular resistance (pulmonary hypertension).

Drug-induced inhibition of hypoxic pulmonary vasoconstriction could result in unexpected decreases in PaO_2 in the presence of lung disease. Potent vasodilating drugs such as nitroprusside and nitroglycerin may be accompanied by decreases in PaO_2 attributed to this effect.³⁵ Other antihypertensive agents such as angiotensin-converting enzyme inhibitors, calcium antagonists, and likely all arterial vasodilators may reduce hypoxic pulmonary vasoconstriction and worsen oxygenation.

Although animal studies suggest that potent inhaled anesthetic agents inhibit hypoxic vasoconstriction in a dose-dependent manner, in clinically relevant concentrations, these findings have not been supported by clinical studies in patients (Figure 14.25).^{36,37} The present consensus is that potent volatile anesthetics are acceptable choices for thoracic surgery requiring one-lung ventilation, particularly in view of the beneficial effects of these drugs on bronchomotor tone and their high potency that permits delivery of maximal concentrations of oxygen.³⁸

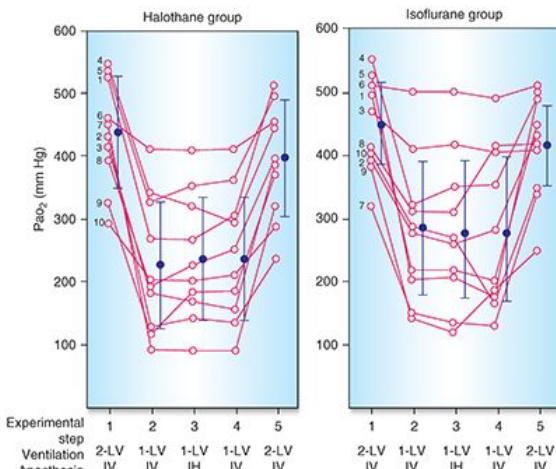

FIGURE 14.25 PaO_2 was measured during two-lung ventilation (2-LV) and then during one-lung ventilation (1-LV) in patients anesthetized with fentanyl and diazepam without halothane or isoflurane (experimental steps 2 and 4) and with halothane or isoflurane (experimental step 3). Addition of halothane or isoflurane (about 1.2 minimum alveolar concentration) does not alter the PaO_2 , suggesting these drugs do not inhibit hypoxic pulmonary vasoconstriction. Clear circles are individual patient data and closed circles are mean \pm standard deviation for each group. *Reprinted with permission from Rogers SN, Benumof JL. Halothane and isoflurane do not decrease PaO_2 during one-lung ventilation in intravenously anesthetized patients. Anesth Analg. 1985;64(10):946-954. Carbon Dioxide and Acid–Base Effect

Both respiratory and metabolic acidosis cause pulmonary vasoconstriction in the absence of hypoxemia.³⁹ Where there is hypoxic vasoconstriction, however, hypercarbia or acidosis may have a vasodilating effect. Hypocarbia and metabolic alkalosis cause pulmonary vasodilation, which can moderate hypoxic vasoconstriction. As changes in carbon dioxide and acid–base status are common during anesthesia, close attention needs to be paid when managing patients with pulmonary hypertension.

Effect of Breathing

During spontaneous respiration, venous return to the heart is increased due to contraction of the diaphragm and abdominal muscles, which decreases intrathoracic pressure. The resulting augmented blood flow to the right atrium increases right ventricular stroke volume. In contrast to spontaneous breathing, positive pressure ventilation increases intrathoracic pressure and thus impedes venous return to the heart and decreases right ventricular stroke volume.

Regional Blood Flow in the Lungs

Although traditional teaching has focused on the gravitational effect of blood flow within the lungs, more recent work has demonstrated that the gravitational “zone”⁴⁰ (**Figure 14.26**) has a relatively minor role in blood flow distribution. On average, pulmonary blood flow is greater in areas of the lung below the heart as compared to those above the heart,⁴¹ but measurements have demonstrated greater variation from spot to spot in any isogravitational plane than there is on average from the top of the lung to the bottom. Indeed, only 25% of the variability in pulmonary blood flow is accounted for by gravitational effects. Furthermore, the local differences in flow at any isogravitational level are fairly constant over time, suggesting that approximately 75% of the distribution of pulmonary blood flow is determined by the branching structure of the pulmonary vascular tree.

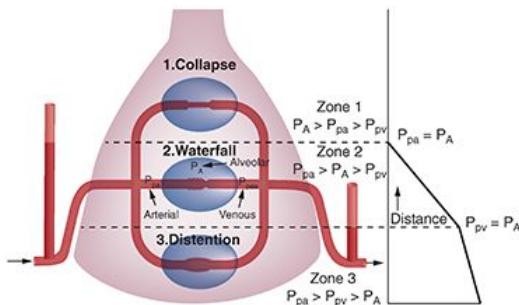

FIGURE 14.26 The lung is divided into three pulmonary blood flow zones reflecting the impact of alveolar pressure (P_A), pulmonary artery pressure (P_{pa}), and pulmonary venous pressure (P_{pv}) on the caliber of pulmonary blood vessels. *Reprinted with permission from West JB, Dollery CT, Naimark A. Pulmonary Circulatory Pathology

Pulmonary Edema

Pulmonary edema is present when there are excessive quantities of fluid either in pulmonary interstitial spaces or in alveoli. Mild degrees of pulmonary edema may be limited to only an increase in the interstitial fluid volume. The alveolar epithelium, however, is not able to withstand more than a modest increase in interstitial fluid pressure before fluid spills into alveoli. Dehydrating forces of the colloid osmotic pressure of the blood in the lungs provide a large safety factor against development of pulmonary edema. In humans, plasma colloid osmotic pressure is about 28 mm Hg, so pulmonary edema rarely develops below a pulmonary capillary pressure of 30 mm Hg. The most common cause of acute pulmonary edema is greatly increased pulmonary capillary pressure resulting from left ventricular failure, and the lymphatic flow cannot adequately remove the increased fluid.

During chronic increases of left atrial pressure, pulmonary edema may not occur despite pulmonary capillary pressures as high as 45 mm Hg. Enlargement of the pulmonary lymph vessels allowing lymph flow to increase up to 20 times is the most likely reason pulmonary edema does not occur in the presence of chronically increased left atrial pressures. At the other end of the spectrum, a transplanted lung does not have any lymphatic drainage and is acutely sensitive to fluid overload or increased in left atrial pressure.

Pulmonary edema can also result from local capillary damage that occurs with inhalation of acidic gastric fluid or irritant gases, such as smoke. The result is rapid transudation of fluid and proteins into alveoli and interstitial spaces. This is called **permeability pulmonary edema** to distinguish it from “hydrostatic” pulmonary edema, which is due to increased pulmonary capillary pressure. In either case, increased interstitial fluid and fluid-filled alveoli interfere with gas exchange, decrease lung compliance, and result in an increase in the work of breathing.

Pulmonary Embolism

Embolism of venous clots to the lungs may be chronic with small emboli or acute with massive embolus. Total blockage of a major branch of a pulmonary artery by an embolus is usually not immediately fatal because other lung regions may be able to accommodate all the pulmonary blood flow, but major emboli may result in right ventricular strain and failure. Tachypnea and dyspnea are characteristic responses in awake patients experiencing pulmonary embolism; in the anesthetized patient, an acute decrease in end-tidal carbon dioxide may occur due to a sudden increase in dead space (loss of perfusion but not ventilation to major part of the lung). Depending on the circumstance, anticoagulation, thrombolysis, or pulmonary embolectomy may be indicated.

Pulmonary Hypertension

The World Health Organization has classified pulmonary hypertension according to etiology (**Table 14.8**),⁴² but the hemodynamic diagnosis in all causes is made when the sustained mean pulmonary artery pressure is above 25 mm Hg. The cause may be “primary” or idiopathic (type 1) or in association with other disease (other types). As mentioned earlier, gradual increases in pulmonary artery pressure may be tolerated by the right heart, but with progressive increases in pressure, right ventricular failure will eventually occur. In addition, many of the causes of pulmonary hypertension are associated with the development of hypoxemia. As the pathophysiologies of the different types of pulmonary hypertension are quite different, so are the treatments. As hypoxemia is a feature of all types for the disease, especially in the later stages, oxygen therapy is generally indicated. Similarly, thrombotic disease can occur even when this is not the primary cause (type 4), so anticoagulation may be indicated. Where left heart failure is the cause (type 2), pulmonary vasodilator therapy may actually worsen the heart failure; treatment must directly address left heart function. Similarly, with thromboembolic disease, thromboendarterectomy and anticoagulation rather than pulmonary dilators are the mainstay of treatment. Chronic intravenous therapy with PGI₂ or intermittent aerosol (inhaler) treatment with a prostacyclin analogue are generally used in severe type 1 disease.³³ As described earlier, acute treatment with iNO or continuous aerosolized PGI₂ is reserved for severe disease in the inpatient with hypoxic respiratory failure in association with pulmonary hypertension and right heart dysfunction. When medical treatment fails, ultimately lung or heart-lung transplant may be required.

TABLE 14.8

Classification of pulmonary hypertension^a

I	Pulmonary arterial hypertension (PAH) Idiopathic PAH (majority) and heritable PAH Drug- and toxin-induced PAH Connective tissue disease–associated PAH HIV-associated PAH Portal hypertension–associated PAH Congenital heart diseases Schistosomiasis
II	Pulmonary hypertension due to left heart disease LV systolic and diastolic dysfunction Valvular disease Congenital/acquired left heart inflow/outflow tract obstruction Developmental lung diseases
III	Pulmonary hypertension due to lung diseases or hypoxia COPD, ILD, mixed restrictive/obstructive pattern disease Sleep-disordered breathing and alveolar hypoventilation disorders Chronic exposure to high altitude Developmental lung diseases
IV	Chronic thromboembolic pulmonary hypertension
V	Pulmonary hypertension due to multifactorial mechanisms Hematologic: chronic anemia, myeloproliferative disorders, splenectomy Systemic: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis Metabolic: glycogen storage disease, Gaucher disease, thyroid disease Others: tumor obstruction, fibrosis mediastinitis

Abbreviations: COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; ILD, interstitial lung disease; LV, left ventricular.

Cardiac Physiology*

Updated by: Teresa A. Mulaikal • Andrea N. Miltiades • Sumeet Goswami • Bessie Kachulis

The heart has four chambers and can be characterized as two pumps connected in series, each composed of an atrium and a ventricle. The atria function primarily as conduits to the ventricles, but they also contract weakly to facilitate movement of blood into the ventricles during the filling phase, diastole. The ventricles serve as pumps during systole to supply the main force that propels blood through the systemic and pulmonary circulations. Specialized excitatory and conductive fibers in the heart maintain cardiac rhythm and transmit action potentials through cardiac muscle to initiate contraction. Because the heart is coupled to two circulations in series, its function is influenced by the characteristics of both.

Cardiac Anatomy

Pericardium

The pericardium is a fibrous sac that contains the heart and the proximal portions of great vessels. It consists of two layers: the fibrous and serosal pericardium. The fibrous layer is fibrocollagenous and is continuous superiorly with the adventitia of the great vessels and the pretracheal fascia and inferiorly with the diaphragm. Anteriorly, the fibrous layer attaches to the sternum through the sternopericardial ligaments. The aorta, pulmonary arteries, and pulmonary veins also receive extensions from the fibrous pericardium. The serosal layer of the pericardium is enclosed within the fibrous pericardium and consists of a single, continuous membrane that is divided into two parts: the visceral and the parietal pericardium. The visceral layer surrounds the heart and the great vessels and is reflected on to the parietal layer that lines the inner surface of the fibrous pericardium.¹⁻³

The potential space between visceral and parietal pericardium normally contains 15 to 35 mL of pericardial fluid. The inelastic nature of the pericardium limits acute dilation of the heart and enhances the resulting mechanical interaction of the four cardiac chambers. Acutely, the pericardium can only accommodate a small amount of pericardial fluid without changes in intrapericardial pressure. Once the amount of pericardial fluid exceeds a limited reserve capacity, the intrapericardial pressure increases steeply with small amounts of pericardial fluid, leading to tamponade physiology. Chronically, the pericardium can accommodate a large amount of fluid without causing tamponade because its size and compliance increase in compensation.¹⁻³

Heart

The heart consists of four chambers. The right atrium receives deoxygenated blood from the superior vena cava, the inferior vena cava, the coronary sinus (CS), and Thebesian cardiac veins. It pumps deoxygenated blood into right ventricle through the tricuspid valve. The right atrium is divided into three regions: the posteriorly located smooth-walled venous component, the anteriorly located vestibule of the tricuspid valve, and the right auricle. The venous component, or the sinus venosum, receives the venae cavae and the CS. The venous part of the atrium is separated from atrium proper and the auricle by a ridge of muscle called the **crista terminalis**. The pectinate muscles are muscular trabeculae that extend anterolaterally from crista terminals into the auricle. Anterior to the orifice of inferior vena cava is the eustachian valve, which in the fetal circulation directs oxygen-rich blood from placenta into left atrium through the foramen ovale of atrial septum. The fossa ovalis is the thin part of the atrial septum, above and to the left of the orifice of inferior vena cava. The vestibule of the tricuspid valve is the anteroinferior portion of right atrium.¹⁴

The atrioventricular (AV) valvular complex, both on the right and the left side (tricuspid and mitral valve), consists of the annulus, the leaflets, the chordae tendineae, and the papillary muscles. The tricuspid valve is so named as it has three leaflets, one each located anterosuperiorly, septally, and inferiorly. The

chordae tendineae are fibrous collagenous structures that support the leaflets of tricuspid and mitral valves during systole. True chordae arise usually from the papillary muscles or from the ventricular free wall and the septum. There are three papillary muscles in the right ventricle: two larger, located in the anterior and posterior positions of the right ventricle, and a smaller muscle arising from the ventricular septum.^{1,4}

The right ventricle consists of the inlet adjacent to the tricuspid valve and the apex, both of which are trabeculated. The smooth-walled infundibulum or the outlet connects to the pulmonic valve. The inlet and outlet components are separated by a transverse ridge of muscle called the supraventricular crest or the crista supraventricularis. The many muscular ridges and protrusions into the inner surface of the inlet and apex are known as trabeculae carneae. The septal band or the septomarginal trabecula reinforces the septal surface; at the apex, it supports the anterior papillary muscle, from where it crosses to the parietal wall of the ventricle as the moderator band. The pulmonic valve is located at the distal end of the infundibulum and consists of three semilunar cusps, an anterior, a right, and a left cusp.^{1,4}

The left atrium is normally smaller in size than the right but has thicker walls. The right atrium is anterior and somewhat to the right of the left atrium. The right and the left atrium are separated by the obliquely positioned atrial septum. The superior posterior aspect of the left atrium receives the pulmonary veins and forms the anatomic base of the heart. The left auricle is longer and narrower than the right auricle and is the only portion of the left atrium that is trabeculated.^{1,4}

The mitral valve apparatus consists of an orifice with an annulus, anterior and posterior leaflets, many chordae tendineae, and two papillary muscles. The anterior and posterior leaflets converge at the anterolateral and posteromedial commissures, each of which is associated with a papillary muscle. The anterior leaflet is semicircular and occupies one-third of the circumference, whereas the posterior leaflet is elongated and narrow and is attached to the remaining two-thirds of the annulus. The posterior leaflet is divided into three parts based on the presence of two indentations: a lateral P1, a central P2, and a medial P3 scallop. The segments of anterior leaflet opposing the posterior leaflet are similarly designated as A1, A2, and A3 scallop ([Figure 15.1](#)).⁵

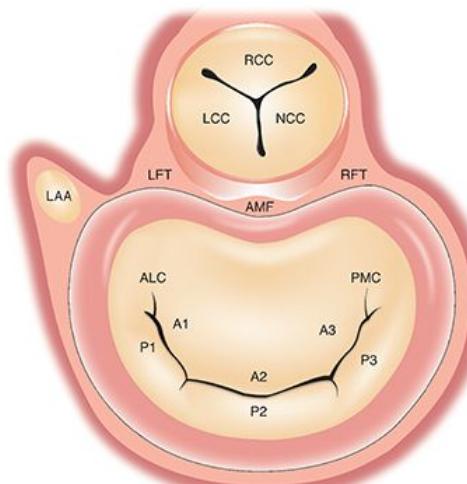

FIGURE 15.1 Representation of mitral valve anatomy.⁵ Anterior mitral valve leaflet with segments A1, A2, and A3; posterior mitral valve leaflet with scallops P1, P2, and P3. Abbreviations: ALC, anterolateral commissure; AMF, aortic-mitral fibrosa; LAA, left atrial appendage; LCC, left coronary cusp of aortic valve; LFT, left fibrous trigone; NCC, noncoronary cusp of aortic valve; PMC, posteromedial commissure; RCC, right coronary cusp of aortic valve; RFT, right fibrous trigone. Reprinted with permission from Debonnaire P, Palmen M, Marsan NA, et al. Contemporary imaging of normal mitral valve anatomy and function. *Curr Opin Cardiol.* 2012;27(5):455-464.

The subvalvular apparatus consists of chordae tendineae and the papillary muscles. The chordae tendineae attach to the edges of mitral leaflets or to its ventricular surface. The left ventricle has two papillary

muscles: the anterolateral papillary muscle and the posteromedial papillary muscle. The chordae tendineae arise from the papillary muscle and attach to the ipsilateral half of anterior and posterior mitral leaflets.¹⁴

The left ventricle is a cone-shaped structure that is longer and narrower than the right ventricle. In the long axis, it descends forward and to the left from its base at the AV groove to form the cardiac apex. Its walls are normally about 2 to 3 times thicker than the right ventricle. It consists of the inlet region, the apical trabecular component, and the smooth-walled outflow tract. Unlike the valvular orifices of the right ventricle, the orifices of the aortic and mitral valve are in fibrous continuity. The left ventricular outflow tract (LVOT) ends at the aortic valve. The aortic valve consists of three semilunar cusps that are supported within the three aortic sinuses of Valsalva. The cusps and the sinuses are called **left**, **right**, and **noncoronary**.¹⁴

The Coronary Circulation

A unique feature of the coronary circulation is that the heart requires a continuous delivery of oxygen by coronary blood flow to function. At rest, the myocardium extracts about 75% of the oxygen delivered by coronary blood flow more than any other tissue in the body. So whenever myocardial oxygen demand increases, as with exercise, the coronary arteries must dilate to increase blood flow and oxygen delivery to meet the demand, or ischemia results. This coronary artery dilation is mediated through the local release of vasodilator substances within the myocardium.^{6,7}

The right (RCA) and the left (LCA) coronary arteries arise respectively from the upper part of the right and the left CS of Valsalva and are the first branches of the aorta ([Figure 15.2](#)). The RCA usually supplies most of the right ventricle, a small part of the diaphragmatic aspect of left ventricle, the right atrium, part of left atrium, and posteroanterior one-third of interventricular septum. The first segment of the RCA gives rise to right ventricular and atrial branches. The right ventricular branches are the right conus artery or the infundibular artery and the acute marginal arteries. The atrial branch in majority of the population is the artery to the sinoatrial (SA) node. The RCA passes directly into the right interventricular groove and descends to the right cardiac border, where it curves posteriorly and approaches the junction of interatrial and interventricular grooves (the crux of the heart) and gives rise to the posterior descending artery (PDA). Coronary artery dominance is defined by the artery that supplies the PDA. In 70% of the population, the PDA is supplied by the RCA, coronary circulation referred to as **right dominant**. In 10% of the population, the PDA is supplied by circumflex artery (Cx A) and is left dominant. In the remainder, the PDA is supplied by both the RCA and the Cx A, and the coronary circulation is considered codominant.^{1,6}

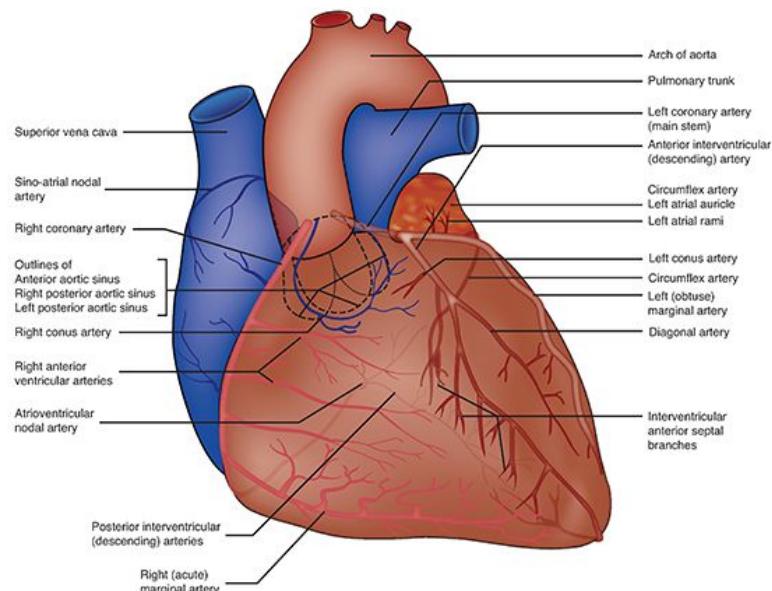

FIGURE 15.2 The coronary circulation.¹

The left main coronary artery usually supplies the free wall of the left ventricle, a narrow strip of the right ventricle anteriorly, the anterior two-thirds of ventricular septum, and most of left atrium. After arising from the left CS, the left main coronary artery passes to the left AV groove, where it branches into left anterior descending artery (LAD) and the CxA. The LAD, also known as **anterior interventricular artery**, runs in the anterior interventricular groove and gives off right and left diagonal and septal branches. The right diagonal branches are small and rare; the left diagonal arteries can vary in number anywhere from two to nine and cross the anterior surface of the left ventricle. The septal branches supply most of the interventricular septum. The first septal branch is usually targeted for ablation in interventional treatment for hypertrophic cardiomyopathy. The CxA curves left in AV groove giving rise to obtuse marginal branches extending over the posterolateral wall toward the apex. The CxA continues into the posterior part of the AV groove, usually terminating prior to the crux of the heart, but in 10% of individuals, it continues to supply the PDA.^{1,6}

The cardiac veins that run in AV and interventricular grooves drain a large part of coronary arterial blood into the right atrium via the CS. The great cardiac vein that accompanies the LAD is joined by the oblique vein of the left atrium in the left AV groove to become the CS. Prior to draining into the right atrium, the middle cardiac vein that runs in the inferior interventricular groove and small cardiac vein that runs in right AV groove drain into the CS.^{1,6}

The Cardiac Conduction System

The cardiac conduction system consists of the SA node, the AV node, the AV bundle also known as the **bundle of His**, the bundle branches, and the Purkinje fibers (**Figure 15.3**). The cardiac impulse is normally initiated by the SA node. This causes the atria to contract, first the right atrium followed by the left atrium. The blood supply to the SA node may be from either the RCA or the CxA.

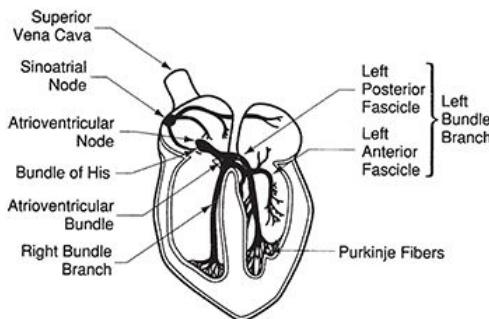

FIGURE 15.3 Cardiac conduction system.

From the SA node, the impulse is conducted to the AV node via the atrial myocardium. The AV node is located at the apex of region formed by the opening of the CS, the septal leaflet of the tricuspid valve, and the atrial septum, called the **triangle of Koch**. The AV node is supplied by the RCA in a large majority of population, in the rest by the CxA. The cardiac electrical impulse is delayed in the AV node about a fifth of a second before being conducted to the bundle of His and on to the ventricles, so that the atria contract just before the ventricles to augment end diastolic filling. The bundle of His branches into right and left bundle branches. The left bundle splits further into anterior and posterior fascicles. The bundle branches descend through the ventricular septum, where they continue on as the Purkinje fibers that end up directly stimulating the myocardium to contract. The bundle of His and bundle branches are insulated from the myocardium by a fibrous sheath, thus forming specialized network of conduction tissue. This functional organization results in a coordinated, synchronized contraction of the atria and ventricles, improving the efficiency of the heart.^{1,6,8,9}

Clinical Electrophysiology and Electrocardiogram

Body fluids are good electrical conductors, making it possible to record the sum of the action potentials of the cardiac cells on the surface of the body. Continuous monitoring of this electrocardiogram (ECG) during anesthesia is considered to be a standard of monitoring for all patients under the anesthesiologist's care. It is an essential tool for detecting myocardial ischemia, arrhythmias, and conduction system abnormalities.

Electrocardiogram Leads

The cardiac electrical activity is usually measured by electrodes placed on the skin. Bipolar leads consist of two electrodes: one positive and one negative. Unipolar leads consist of one positive electrode (exploring) and a composite pole that averages electrical activity from a number of other leads to zero potential, referred to as the **indifferent electrode**. Depolarization directed toward the positive electrode produces a positive deflection, whereas directed away from it produces a negative deflection. When the depolarization wave is perpendicular to the lead, a biphasic deflection is recorded ([Figure 15.4](#)). The 12-lead ECG consists of three bipolar standard limb leads, six unipolar precordial leads, and three unipolar augmented limb leads. The standard limb leads and the augmented limb leads record electrical impulses that flow in the frontal plane, whereas the precordial leads record impulses in the horizontal plane.

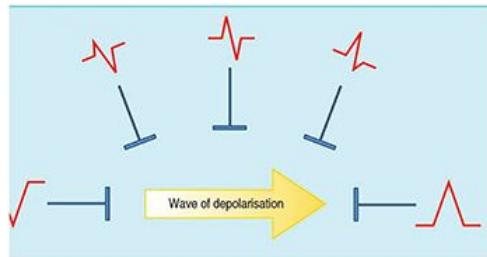

FIGURE 15.4 Wave of depolarization. Shape of QRS complex in any lead depends on orientation of that lead to vector of depolarization. *Reproduced from Meek S, Morris F. Introduction. I—leads, rate, rhythm, and cardiac axis. BMJ. 2002;324(7334):415-418 with permission from BMJ Publishing Group Ltd.*

Standard Limb Leads. The standard limb leads, named I, II, and III, record the potential difference between two points of the body ([Figure 15.5](#)). In lead I, the electrodes are placed on the left shoulder (positive) and right shoulder (negative). In lead II, the positive electrode is on the left leg and the negative is on the right shoulder. In lead III, the positive electrode is on the left leg and the negative on the left arm. The limb leads form the triangle of Einthoven, which is used together with the augmented limb leads to calculate the electrical axis of the heart in the frontal axis. The direction of the depolarization of the atria parallels lead II, resulting in a prominent P wave in this lead.

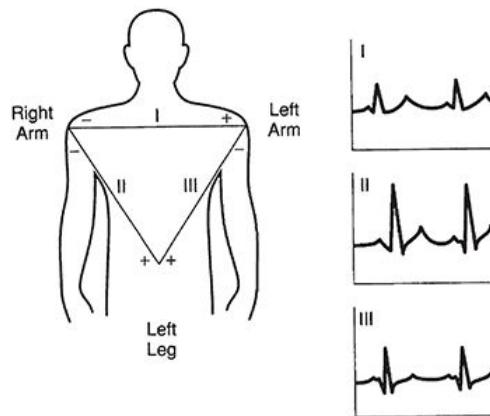

FIGURE 15.5 Standard limb leads of the electrocardiogram and typical recordings.

Augmented Limb Leads. Augmented leads are similar to the standard limb leads but are unipolar. Linking the three limb leads through equal resistances ($5,000 \Omega$), a central terminal is created with zero potential (Wilson central terminal). This is based on Einthoven theory that the R wave in lead II equals the sum of the R waves in leads I and III. The central terminal presents a stable reference potential point that is used to measure the varying potential at the exploring electrode ([Figure 15.6](#)). Goldberger modified the central terminal by

removing its link from the exploring electrode, achieving augmentation on the ECG deflections.¹⁰ The positive (exploring) electrode for augmented voltage right arm (aVR) is on the right shoulder; for augmented voltage left arm (aVL), on the left shoulder; and for augmented voltage foot (aVF), on the left leg.

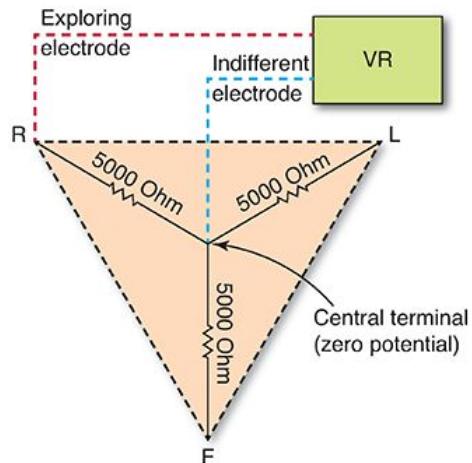

FIGURE 15.6 Unipolar limb lead circuit (VR).

Precordial Leads. The precordial leads (V_1-V_6) are unipolar leads that are placed on the chest wall, with the exploring electrode over one of six separate points (Table 15.1). The “indifferent” electrode is represented by the Wilson central terminal, which is the average of the standard limb leads and normally has zero potential. The proximity of the heart surface to the electrode allows for detection of relatively small abnormalities in the ventricles without augmentation. Electric current flow is normally from the base to the apex of the heart. Therefore, leads V_1 and V_2 , being near the base, record a negatively deflected QRS. Conversely, V_4 to V_6 , being nearer the apex, record a positively deflected QRS.

TABLE 15.1

Placement of precordial leads

V_1	Fourth intercostal space at the right sternal border
V_2	Fourth intercostal space at the left sternal border
V_3	Equidistant between V_2 and V_4
V_4	Fifth intercostal space in the left midclavicular line
V_5	Fifth intercostal space in the left anterior axillary line
V_6	Fifth intercostal space in the left midaxillary line

Electrocardiographic Axis of the Heart

The axis represents the overall direction of the electric impulse in the heart and is created by averaging all the action potentials. It is biased toward the left because of the larger muscle mass of the left ventricle compared to the right. The standard limb leads combined with the augmented limb leads form the hexaxial diagram, which is used to calculate the electrical axis of the heart on the frontal plane (Figure 15.7). This axis normally ranges between -30 and 90 degrees. Hypertrophy of the left ventricle shifts the axis to the left, and hypertrophy of the right shifts it to the right. Left axis deviation is defined as an axis less than -30 degrees and right axis deviation as more than 90 degrees. Abnormalities in the normal conduction pathway (blocks) in the heart also cause changes in the electrical axis.

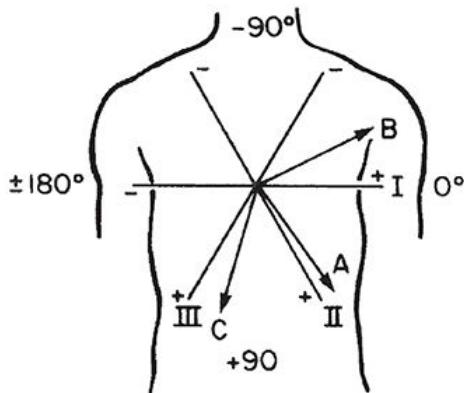

FIGURE 15.7 Electrical axis of the heart as determined from the standard limb leads of the electrocardiogram. In the normal heart, the electrical axis is approximately 59 degrees (A). Left axis deviation shifts the electrical axis to less than 0 degrees (B); right axis deviation is associated with an electrical axis of greater than 100 degrees.

Electrocardiogram Lead Systems

The three-lead system is the most basic ECG system. It consists of three electrodes, placed on the right arm, left arm, and left leg. It monitors electrical activity recorded by the bipolar standard limb leads (I, II, and III). Only one lead at a time is available. Two electrodes are used to form the selected lead, and the third becomes the ground. Although the three-lead ECG provides adequate monitoring for arrhythmias, its use for detection of myocardial ischemia is limited.

In the modified three-lead bipolar standard limb lead system, the electrodes are placed in different locations on the chest wall. This allows for improved detection of arrhythmias (taller P waves) and monitoring for ischemia of the heart surface closer to each exploring pole. In the central subclavicular lead system (SC_5), one electrode is placed under the right clavicle, one in the V_5 position, and the ground electrode on the left leg. Other modified systems include the modified central leads (MCL), central manubrial (CM_5), central back (CB_5), and central cardiac 5 (V_5) lead systems ([Figure 15.8](#)).

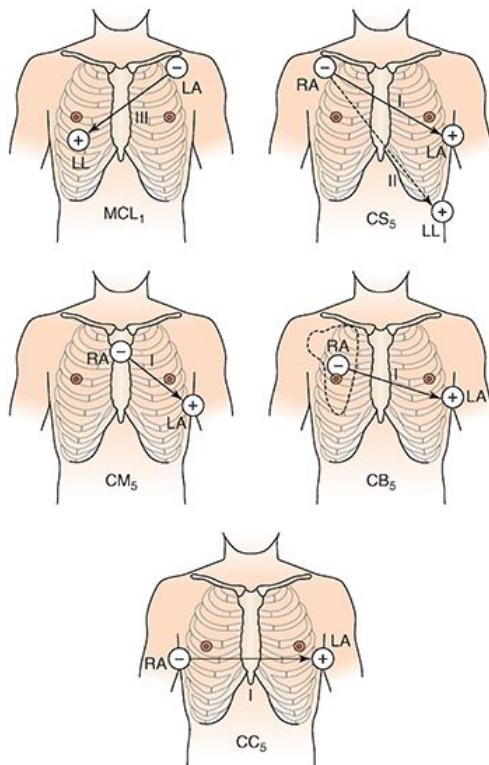

FIGURE 15.8 Modified bipolar standard limb lead system.

The 5-lead system uses 5 electrodes placed on the right arm, right leg, left arm, left leg, and one on the chest wall in any one position from V_1 to V_6 . Seven leads at a time may be monitored: 6 bipolar (I, II, III, aVR, aVL, aVF) and 1 unipolar (usually V_5). The 10-lead system allows monitoring of 12 leads simultaneously, the 3 standard limb leads (I, II, III), the 3 augmented limb leads (aVR, aVL, aVF), and 6 precordial leads (V_1 - V_6). The electrodes are placed on the right arm and leg, left arm and leg, and on the anterior and anterolateral chest wall. This allows for monitoring of specific areas of the heart. Leads V_1 to V_4 monitor the anterior wall; leads I, aVL, V_5 , and V_6 , the lateral wall; and II, III, and aVF, the inferior wall.

London and colleagues¹¹ examined lead sensitivity for detecting intraoperative myocardial ischemia. They concluded that using single-lead monitoring, V_5 had the greatest sensitivity, 75%, whereas V_4 had 61%. V_4 and V_5 combined had 90%. Sensitivity for the standard combination used in the clinical setting, II and V_5 , was 80%. Adding V_4 to II and V_5 increased the sensitivity to 96%. Although lead V_4 is more sensitive in detecting ischemia, lead II is superior in monitoring atrial arrhythmias.¹¹

Invasive ECG may monitor the cardiac electrical activity using leads placed in the trachea, the esophagus, in the cardiac cavities, or the coronary vessels but are not used in the routine anesthesia practice. The His bundle ECG uses an electrode on a catheter in the heart placed near the tricuspid valve (Figure 15.9). It records the activation of the AV node (A), the spreading of the electrical activity through the His bundle (H), and the ventricular depolarization (V). Information from the standard ECG and the His bundle ECG can be used to measure the time required for the impulse to travel between the sinus node and the AV node (AH) and through the AV node to the bundle of His and the ventricles. This allows detection of the site of a conduction delay, important for prognosis and treatment.

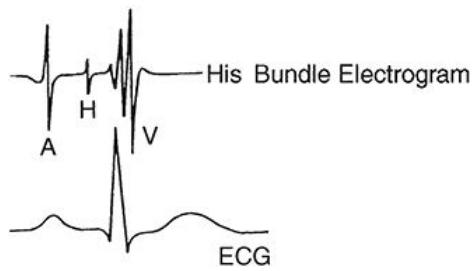

FIGURE 15.9 A normal His bundle electrogram and the corresponding electrocardiogram (ECG).

Decreased voltage on the ECG may be caused by multiple small myocardial infarcts, which prevent generation of large quantities of electrical currents or abnormal conditions around the heart that impede current conduction from the heart to the skin, such as pericardial fluid and pulmonary emphysema.

It is important to differentiate artifacts from real ECG findings. Artifacts may be caused by malfunctioning ECG system (cables, connections, etc), improper skin preparation (oil, hair), lead misplacement/poor contact, patient's tremor/shivering, or muscular activity. External sources emitting electrical fields (electrocautery, 60-Hz power lines/light fixtures), cardiopulmonary bypass, somatosensory-evoked potential monitoring, and stimulators may also interfere with ECG recordings. All modern ECG monitors have incorporated filters for signal processing to minimize the presence of electrical artifacts.

Recording of the Electrocardiogram

The ECG is recorded digitally or on a graph paper consisting of 1-mm squares with every five squares separated by a darker line. Each 1-mm horizontal line represents 0.04 second, and each 1-mm vertical line represents 0.1 mV, assuming proper calibration 1 cm/1 mV and standardized paper speed of 25 mm per second. Therefore, the distance between two darker lines represents 0.2 second and 0.5 mV on the horizontal and the vertical axes, respectively. One minute (60 seconds) corresponds to 1,500 small or 300 big squares. The heart rate in beats per minute can be calculated by dividing 300 by the number of large boxes (or 1,500 by the number of small boxes) counted between two beats. Another method of calculating heart rate in beats per minute is to divide 60 by the number of seconds ($= 0.04 \text{ second} \times \text{number of small boxes}$) between two consecutive beats.

The electrical activity that activates the cardiac contraction is observed on a monitor display as a graph of voltage change through time. Modern monitors also have paper recorders allowing more thorough analysis of the ECG in complex situations. The Holter monitor is a small portable digital recorder that enables recording of the ECG for prolonged periods in ambulatory individuals to detect infrequent events.

Normal Electrocardiographic Deflections

Normally, the cardiac electrical impulse is initiated at the SA node, which is located at junction of the superior vena cava to the right atrium. Any part of the conduction system can spontaneously depolarize and initiate an impulse, but the SA node normally has the highest rate of depolarization and is the pacemaker of the heart. The impulse is transmitted through the right and left intra-atrial pathways to the AV node and then to the bundle of His and through the Purkinje fibers to the ventricular subendocardium, which causes the myocardium to depolarize from the endocardium to the epicardium. Repolarization happens in the reverse direction, from the epicardium to the endocardium. The speed of conduction is different between the various areas of the system, with the slowest through the AV node producing AV synchrony for optimal end diastolic filling from atrial contraction. The normal ECG consists of a P wave (atrial systole), a QRS complex (ventricular systole), and a T wave (ventricular repolarization). The atrial repolarization wave is obscured by the larger QRS complex ([Figure 15.10](#)).

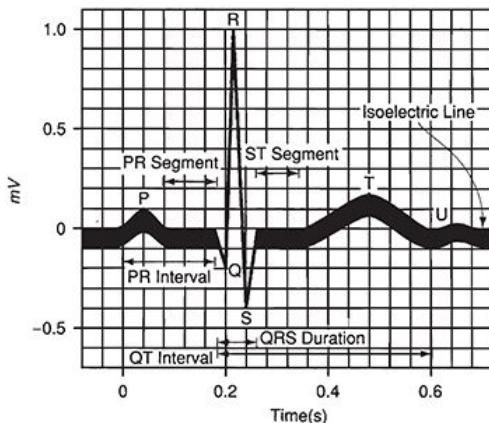

FIGURE 15.10 The normal waves and intervals on the electrocardiogram.

P Wave. The P wave represents the atrial depolarization and has a normal duration and amplitude of 0.08 to 0.12 second and less than 2.5 mm in the limb leads. Morphologically, it is positive in the standard limb leads and negative in aVR. Enlarged P wave signifies atrial enlargement.

P-R Interval. The P-R interval corresponds to the time from the beginning of the atrial depolarization to the beginning of the ventricular depolarization. It is measured from the start of the P wave to the start of the QRS and should not be confused with the PR segment, which is measured from the end of the P wave to the start of the QRS. The normal duration of the P-R interval is 0.12 to 0.2 second. Prolonged P-R interval is called first-degree AV block. In pericarditis, the P-R interval is depressed in most leads (whereas ST is elevated) and elevated in aVR (knuckle sign) ([Figure 15.11](#)).

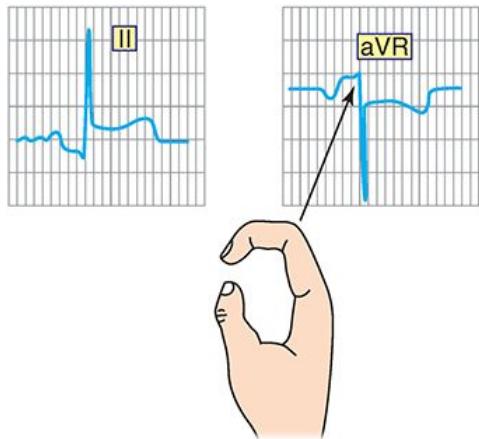

FIGURE 15.11 Acute pericarditis. Look for widespread ST segment elevation with concomitant PR depression in the same leads. The PR segment in aVR sticks above the baseline like a knuckle, reflecting atrial injury.

Q Wave. The Q wave is defined as an initial negative deflection of the QRS and is usually absent in leads aVR, V₁, and V₂. Normally, its duration is shorter than 0.04 second and its amplitude less than 0.4 to 0.5 mV. A Q wave whose amplitude is more than one-third of the corresponding R wave, duration is longer than 0.04 second, and depth is greater than 1 mm, is indicative of myocardial infarction (MI). The Q wave occurs because there is no electrical activity in the affected area. Therefore, the direction of the sum of the action potentials in the specific plane changes and is recorded accordingly. In the presence of anterior wall MI, Q

waves develop in leads V₂ to V₄; in anteroseptal MI, in leads V₁ to V₃; in anterolateral MI, in leads V₄ to V₆, I, and aVL; in lateral MI, in leads V₅, V₆, I, and aVL; and in inferior MI, in leads II, III, and aVF.

QRS Complex. The QRS complex is caused by the depolarization of the ventricles and normally has a duration of less than 0.10 second. A prolonged QRS duration may be due to left ventricular hypertrophy (LVH), impaired ventricular conduction (bundle branch block), beats initiated outside the conduction system (ectopic or paced beats), and beats passing through abnormal conduction pathways (Wolff-Parkinson-White syndrome). Normally, the QRS amplitude gradually increases in the precordial leads from V₁ to V₅, a phenomenon called **R wave progression**. The R wave is usually upright in the limb leads and downwardly deflected in aVR and V₁. Various criteria exist for defining LVH using the QRS amplitude. According to the Cornell criteria, LVH is present when the sum of the R wave in aVL and S wave in V₃ is greater than 28 mm in males and 20 mm in females. Based on the Sokolow-Lyon criteria, LVH is present when the S wave in V₁ + (R in V₅ or R in V₆) is greater than 35 mm or R in aVL is greater than 11 mm.

ST Segment. The ST segment starts when all myocardial cells are depolarized (end of QRS) and ends when ventricular repolarization begins (T wave). It is normally isoelectric, and elevation or depression more than 1 mm from the baseline may indicate myocardial ischemia. Hyperkalemia and pericarditis may also cause ST elevation. J point elevation (where QRS and ST segment connect) and normal variants of early repolarization are nonpathologic findings that must be excluded ([Figure 15.12](#)).

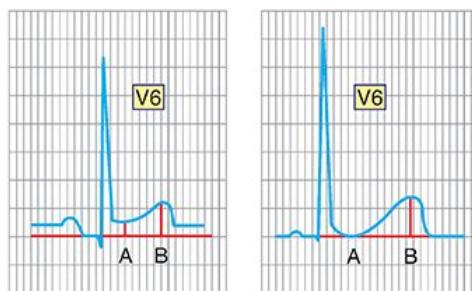

FIGURE 15.12 Differentiating pericarditis from early repolarization. Only lead V₆ is used. If A/B is greater than 25%, suspect pericarditis. If A/B is less than 25%, suspect early repolarization.

T Wave. The T wave is caused by the repolarization of the ventricles, and its normal amplitude is less than 10 mm in the precordial leads and 6 mm in the limb leads. Usually, in any lead, the T wave is deflected in the same directions as the QRS. Delay of conduction of cardiac impulses through the ventricles (prolonged depolarization), as occurs with myocardial ischemia, bundle branch blocks, or ectopic ventricular beats, may result in T-wave polarity opposite the QRS complex. Symmetrical or deeply inverted T waves may be indicative of myocardial ischemia. Inverted T waves in V₁ to V₃ in children (juvenile T waves) and occasionally in women can be a normal variant. Peaked T waves may be present in hyperkalemia, LVH, and intracranial bleeding.

U Wave. The U wave, when present, follows the T wave, and it probably represents part of the ventricular repolarization. It is most prominent in V₂ and V₃. Causes of increased U wave amplitude (>1.5 mm) include LVH, bradycardia, ischemia, electrolyte abnormalities (low potassium, magnesium, calcium), and medications.

QT Interval. The QT interval includes both ventricular depolarization and repolarization. It is measured from the beginning of the QRS to the end of the T wave and varies in duration according to heart rate. The QT interval corrected for heart rate (QTc) is calculated by dividing the QT interval by the squared root of the R-R interval. Prolonged QTc (>0.44 second) may be associated with ventricular arrhythmias. Causes of prolonged

QT include hypocalcemia, hypomagnesemia, medications, severe bradycardia, hypothermia, ischemia, intracranial hemorrhage, and myxedema of hypothyroidism.

Cardiac Physiology

Myocardium

The myocardium is the involuntary, striated muscle tissue in the heart between the epicardium and the endocardium; its cells are called **cardiomyocytes**. The primary structural proteins of the cardiac muscle are actin and myosin filaments, which interdigitate and slide along each other during contraction in a manner similar to skeletal muscle. But unlike the skeletal muscle in which the actin and myosin filaments are linear and longitudinal, in cardiomyocytes, they are branched ([Figure 15.13](#)).¹² Also, the cardiac T tubules are larger and broader and fewer in number than skeletal muscle. Cardiac muscle T tubules form dyads with the sarcoplasmic reticulum intercalated discs with permeable junctions that allow rapid diffusion of ions so that action potentials travel easily from cell to cell. Thus, cardiomyocytes are functionally interconnected in a syncytium so that activation of one cell results in the spread to all connected cells. The atrial syncytium is separated from the ventricular syncytium by the fibrous tissues around the AV valves, and the cardiac action potential is normally only conducted from the atria to the ventricles by a specialized conduction pathway through the AV node.¹³

FIGURE 15.13 “Syncytial” interconnecting nature of cardiac muscle fibers.¹² Reprinted from Hall JE. Guyton and Hall Textbook of Medical Physiology. 12th ed. Philadelphia, PA: Saunders/Elsevier; 2011. Copyright © 2011 Elsevier. With permission.

Cardiac Action Potential

At the initiation of an action potential in a cardiomyocyte, the cell membrane rapidly depolarizes as the transmembrane potential rises from -85 mV to $+20\text{ mV}$. The membrane remains depolarized for about 0.2 second, the plateau phase, which is then followed by rapid repolarization. This plateau causes the contraction of a cardiomyocyte to last much longer than a skeletal muscle cell and is due to the slow calcium channels, which open after the sodium channels and remain open several tenths of a second. Depolarization of the cardiomyocyte is also prolonged by a decrease in permeability of the potassium channels after initiation of the action potential, another difference from skeletal muscle. During the plateau phase, the cardiomyocyte cannot be restimulated for about 0.25 to 0.3 second, called the **refractory period**. This is followed for additional 0.05 second by the relative refractory period, when the myocardium can only be stimulated by a strong excitatory signal.^{12,14}

Excitation-Contraction Coupling

Excitation-contraction coupling in both cardiac and skeletal muscle occurs when the action potential spreads into the cell through transverse tubules (T tubules). Depolarization of the T tubule causes influx of calcium into the sarcoplasm, which binds to troponin activating the contraction of actin and myosin filaments. In the

cardiomyocyte, however, the initial influx of calcium ions is just a small fraction of the amount needed for contraction, and it triggers an additional release of calcium from the sarcoplasmic reticulum into the sarcoplasm. The structural differences between cardiac and skeletal muscle reflect the difference in coupling mechanism. Myocardium has sparser and less developed sarcoplasmic reticulum, and the T tubules are larger and store more calcium.^{15,16}

Control of Cardiac Function

Neural Control

Heart function is controlled by the autonomic nervous system by both adrenergic and muscarinic acetylcholine receptors, modulating the cardiac output (CO) by influencing heart rate and myocardial contraction. The sympathetic nervous system, through adrenergic receptors with the neurotransmitter norepinephrine, has positive inotropic, chronotropic, and lusitropic effects on the heart. The parasympathetic nervous system, acting through muscarinic receptors with the neurotransmitter acetylcholine, has a more direct inhibitory effect on the heart through the vagal nerve, reducing heart rate, AV node conduction, and cardiac contractility. The atria are innervated by both the sympathetic and parasympathetic nervous system, but the ventricles are supplied principally by the sympathetic nervous system (**Figure 15.14**).^{12,17}

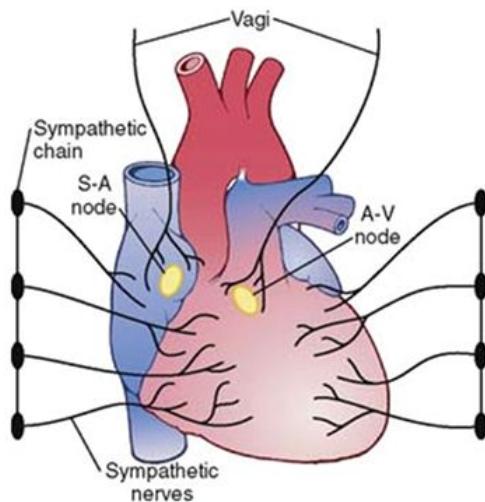

FIGURE 15.14 Cardiac sympathetic and parasympathetic nerves.¹² Abbreviations: A-V, atrioventricular; S-A, sinoatrial. Reprinted from Hall JE. Guyton and Hall Textbook of Medical Physiology. 12th ed. Philadelphia, PA: Saunders/Elsevier; 2011. Copyright © 2011 Elsevier. With permission.

Sympathetic nervous system fibers to the heart continually discharge at a slow rate maintaining a strength of ventricular contraction about 20% to 25% above the unstimulated state. Maximal sympathetic nervous system stimulation can increase CO by about 100% above normal. Conversely, maximal parasympathetic nervous system stimulation decreases ventricular contractile strength only by about 30%, as the vagal innervation is sparse in the ventricles. Strong stimulation of the parasympathetic system can result in a period of asystole, followed by an escape rhythm between 20 and 40 beats per minute.^{12,18}

Hormonal Control

Many hormones can have direct and indirect action on the heart during normal or pathophysiologic conditions. These hormones are produced within cardiomyocytes or by other tissues in the body. The hormones secreted by cardiomyocytes include natriuretic peptide, adrenomedullin, aldosterone, and angiotensin II.^{19–21} Atrial (ANP) and B-type (BNP) natriuretic peptides are released from atria and ventricle in response to increased stretch of the chamber wall. Both ANP and BNP participate in homeostasis of body fluids, in regulation of blood pressure, and in growth and development of cardiac tissue. In chronic heart failure, high ANP and BNP levels have been associated with increased mortality.¹⁹ Adrenomedullin is a

peptide hormone that increases level of cyclic adenosine monophosphate and has positive inotropic and chronotropic effects on the heart and is a vasodilator. The renin-angiotensin system is an important regulator of the cardiovascular system. Angiotensin II stimulates AT₁ receptors with positive inotropic and chronotropic effects. Synthetic angiotensin II has been shown to effectively increase blood pressure in patients with catecholamine resistant shock.²² However, the FDA warns administration may be associated with increased thrombosis risk.²³

It also mediates cell growth and proliferation of cardiomyocytes, thus playing an important role in development of remodeling during cardiac hypertrophy and heart failure.²¹

Cardiac Cycle

Electrical and Mechanical Events

The cardiac cycle is a series of coordinated electromechanical events that result in the ejection of blood from the heart into the great vessels. Ventricular systole is defined as the period of myocardial contraction when the aortic and pulmonic valves are open and diastole as the period of relaxation and ventricular filling when the mitral and tricuspid valves are open. Each mechanical event is preceded by an electrical depolarization that generates an action potential and subsequent contraction.

Wiggers²⁴ elegantly illustrated the mechanical, electrical, and acoustic events of the cardiac cycle. His diagram depicts the aortic, ventricular, and atrial pressure tracings with concomitant ECG, ventricular volume, and auscultatory findings (**Figure 15.15**).²⁴ Systole begins with isometric contraction (A-C), followed by opening of the aortic valve and ejection of blood into the aorta, with a period of maximum ejection (C-D) and reduced ejection (D-F). Isometric contraction starts with closure of the mitral valve and ends with opening of the aortic valve, during which time no volume enters or leaves the ventricle. Approximately two-thirds of stroke volume (SV) is ejected during the period of maximum ejection and one-third during the period of reduced ejection. The ventricular volume curve that coincides with this event is inversely related to the aortic and ventricular pressure curves. Simultaneous electrical depolarization corresponds with the QRS complex of the ECG.

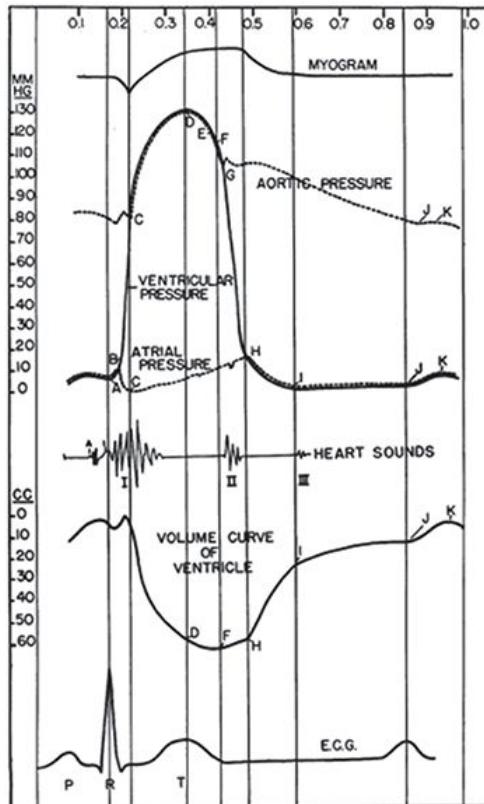

FIGURE 15.15 Cardiac cycle: mechanical, electrical, and acoustic events. Reprinted with permission from Wiggers CJ. Dynamics of ventricular contraction under abnormal conditions. Circulation. 1952;5(3):321-348. Copyright © 1952 American Heart Association, Inc.

Diastole follows systole and is divided into prodiastole (F and G), isometric relaxation (G and H), rapid ventricular filling (H and I), diastasis (I and J), and filling by atrial contraction (J and K). During prodiastole, the semilunar, aortic, and pulmonic valves close. This is followed by isometric relaxation, the time between closure of the aortic valve and opening of the mitral valve. Ventricular filling depends on both the relaxation of the myocardium and chamber compliance.²⁵ There is a period of diastasis with minimal flow during which the ventricular volume remains relatively constant. This is followed by atrial contraction during late diastole, synchronous with the P wave of atrial depolarization on the ECG.

The atrial pressure tracing, or central venous waveform, begins with an “a” wave that corresponds to atrial contraction at end diastole. The “c” wave represents ventricular systole during which time the right atrial pressure increases slightly as the right ventricle contracts against a closed tricuspid valve. The subsequent downward slope in the waveform, the “x descent,” corresponds to atrial relaxation. The “v” wave occurs during venous filling of the right atria toward the end of systole. The “y descent” represents a fall in right atrial pressures as the tricuspid valve opens and the right ventricle fills in diastole ([Figure 15.16](#)).²⁶

FIGURE 15.16 Central venous waveform. Reprinted with permission from Pittman J, Ping JS, Mark JB. Arterial and central venous pressure monitoring. Int Anesthesiol Clin. 2004;42(1):13-30.

Myocardial Performance, Preload, and Afterload

In the early 1900s, Frank Otto and Ernest Henry Starling described what is known today as the Frank-Starling mechanism. In a series of publications, they demonstrated that myocardial stretch, called **preload**, induced by increased venous return to the heart augments cardiac output²⁷ and that increased end diastolic volume (EDV) or right atrial pressure enhances myocardial contractility.^{28,29}

In canine experiments, Arthur C. Guyton³⁰ identified two factors affecting venous return or preload to the ventricle: right atrial pressure and mean circulatory filling pressure. Higher right atrial pressure diminishes venous return to the heart, whereas higher mean circulatory filling pressure, as measured by temporary cessation of CO and equilibration of peripheral pressures, increases venous return. Increasing mean circulatory filling pressure, for example, by transfusion, enhances venous return to the heart, thereby augmenting CO without affecting contractility. He synthesized these findings with the Frank-Starling mechanism and graphically displayed superimposing cardiac response and venous return curves ([Figure 15.17](#)).^{30,31}

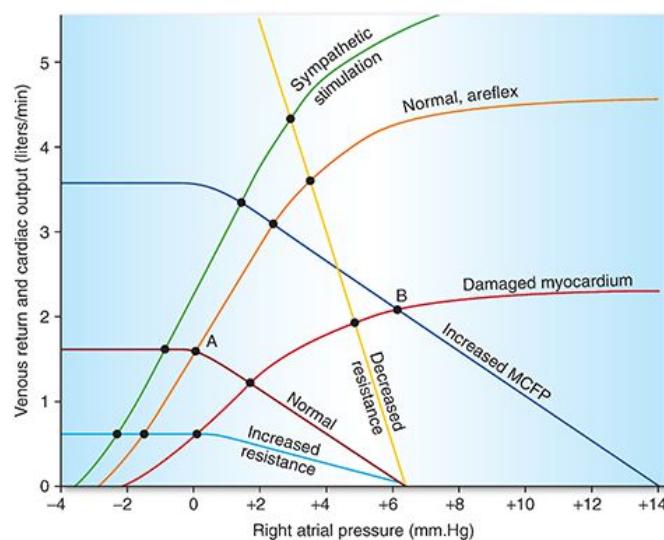

FIGURE 15.17 Determinants of cardiac output. MCFP, mean circulatory filling pressure. Reprinted with permission from Guyton AC. Determination of cardiac output by equating venous return curves with cardiac response curves. Physiol Rev. 1955;35(1):123-129. Copyright © 1955 the American Physiological Society.

Afterload refers to the resistance or pressure against which the ventricle contracts. Mechanical obstruction such as aortic stenosis increases afterload and adversely affects myocardial performance. Pharmacologic interventions such as the administration of phenylephrine can increase afterload as well by increasing systemic vascular resistance (SVR). Afterload in its simplest interpretation often refers to the mean arterial pressure (MAP).

The LV pressure-volume loops can be used to demonstrate how changes in preload and afterload affect SV and end systolic and end diastolic pressure-volume relationships. The entire loop represents a single cardiac cycle with volume on the x-axis and pressure on the y-axis. The difference between EDV and end systolic volume (ESV) equals SV. At end diastole, after closure of the mitral valve, isometric contraction increases the pressure in the LV cavity marking the beginning of systole. When the LV pressure exceeds that in the aorta, the aortic valve opens and ejection begins. After end systole and peak LV pressure, the aortic valve closes. This is followed by a brief period of isometric relaxation marking the beginning of diastole during which LV pressure falls and the LV volume does not change. Then the mitral valve opens, the LV fills accommodating the SV to be ejected during the subsequent cardiac contraction ([Figure 15.18A](#)).

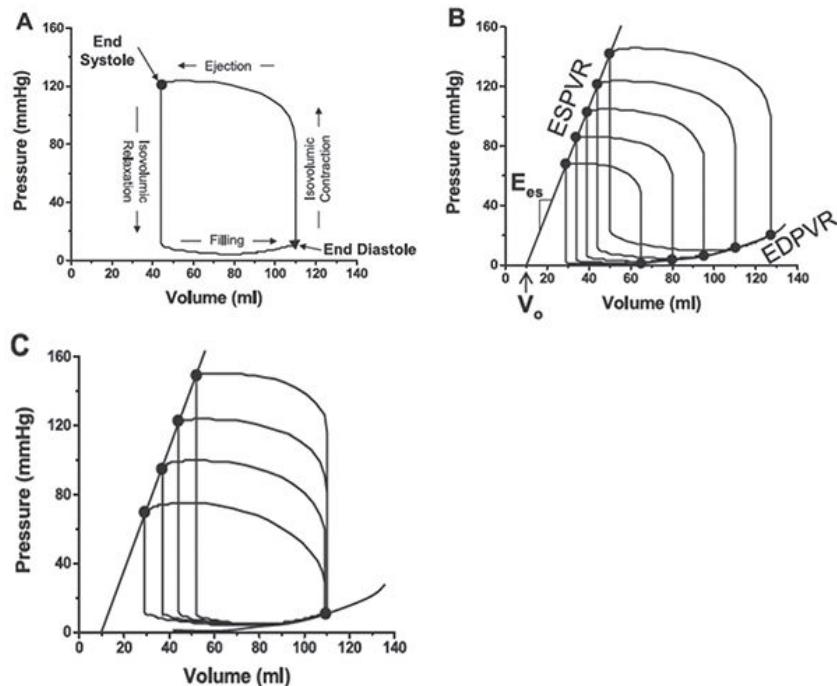

FIGURE 15.18 A, Pressure-volume loop of a single cardiac cycle. B, A reduction in ventricular filling pressure causes the loops to shift toward lower end systolic and end diastolic function. C, When afterload is increased, the loops get narrower and longer. Abbreviations: EDPVR, end diastolic pressure-volume relationship; E_{es} , slope of linear ESPVR; ESPVR, end systolic pressure-volume relationship; V_o , volume axis intercept. Reprinted with permission from Burkhoff D, Mirsky I, Suga H. Assessment of systolic and diastolic ventricular properties via pressure-volume analysis: a guide for clinical, translational, and basic researchers. Am J Physiol Heart Circ Physiol. 2005;289(2):H501-H512. Copyright © 2005 by the American Physiological Society.

A drop in preload, for example, with clamping of the inferior vena cava, will decrease SV, ESV, and EDV. The shape of the pressure-volume loop narrows, shortens, and shifts to the left ([Figure 15.18B](#)).³² An increase in afterload, for example, with administration of phenylephrine, will cause end systolic pressure and volume to increase and SV to decrease, the loops get narrower and longer ([Figure 15.19C](#)).³² The slope of the end systolic pressure-volume relationship is referred to as **elastance** and labeled “ E_{es} ” in the figures. It

stays constant during changes in preload and afterload, is a measure of the strength of contraction, or contractility, and is steeper with increased contractility.^{33,34}

Hemodynamic Calculations

The CO is equal to heart rate multiplied by SV. As illustrated in the previous LV pressure-volume loops, $SV = EDV - ESV$. Mean arterial pressure (MAP) is two-thirds diastolic blood pressure plus one-third systolic blood pressure. The MAP is also CO multiplied by SVR (**Table 15.2**).

TABLE 15.2

Hemodynamic equations

$$CO = HR \times SV$$

$$CI = CO / BSA$$

$$SV = EDV - ESV$$

$$MAP = CO \times SVR$$

$$MAP = 2/3 \text{ diastolic pressure} + 1/3 \text{ systolic pressure}$$

$$SVR = [(MAP - CVP) / CO] \times 80$$

$$PVR = [(mean PAP - wedge) / CO] \times 80$$

Abbreviations: BSA, body surface area; CI, cardiac index; CO, cardiac output; CVP, central venous pressure; EDV, end diastolic volume; ESV, end systolic volume; HR, heart rate; MAP, mean arterial pressure; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; SV, stroke volume; SVR, systemic vascular resistance.

There are several methods to measure CO, the volume of blood delivered by the heart to the body per minute, including thermodilution, the Fick method, and echocardiography. The thermodilution method uses a pulmonary artery (Swan-Ganz) catheter through which cool saline is injected into the right atrium. The cool saline mixes with warmer blood, and the temperature change is recorded by a thermistor at the tip of the catheter, positioned in the main pulmonary artery. The CO is inversely proportional to the integral of the time-temperature curve.^{35,36} Limitations of this method include tricuspid regurgitation and the presence of intracardiac shunts. Tricuspid regurgitation will underestimate the CO, as the cool injectate travels retrograde into the vena cava increasing the time it takes to reach the pulmonary artery. Conversely, intracardiac left to right shunts can falsely overestimate the CO.

The CO can also be measured using the Fick method. Fick CO (liters per minute) = (oxygen consumption VO_2) / [(arteriovenous oxygen difference) $\times 10$] Oxygen consumption can be estimated based on a nomogram that accounts for patient age, sex, height, and weight. It can also be directly measured by exhaled breath analysis. The value 250 mL oxygen per minute is often used as a standardized reference. The difference in arterial versus venous oxygen content ($Cao_2 - Cvo_2$) is calculated by the following formula:

$$(Cao_2 - Cvo_2) = (1.34 \times Hgb \times SaO_2) - (1.34 \times Hgb \times Svo_2)$$

where SaO_2 is the arterial oxygen saturation and Svo_2 is the mixed venous oxygen saturation, that is, the saturation of pulmonary arterial blood. The arterial venous oxygen difference is inversely related to CO as long as the oxygen consumption of the body is constant.

Lastly, CO can be calculated by echocardiography. Pulsed wave Doppler is used to record the velocity profile of flow in the LVOT. Tracing this profile gives the velocity time integral (VTI) in centimeters. The LVOT VTI is multiplied by area of the LVOT in square centimeters to obtain the SV in milliliters. The LVOT is assumed to be circular in shape. The area of a circle is πr^2 . The diameter of the LVOT is measured with two-dimensional echocardiography and divided by two to obtain the radius in the area calculation. Therefore, $SV = LVOT VTI \times LVOT \text{ area } (\pi r^2)$. A similar calculation can be made to obtain the SV through the right ventricular outflow tract. The two numbers are identical provided there is no intracardiac shunt or regurgitation of the aortic or pulmonic valves. Multiplying the SV by the patient's heart rate yields CO.

After obtaining CO by one of these three methods, one can calculate SVR and pulmonary vascular resistance. The SVR in Wood units is the MAP less the central venous pressure divided by CO (see [Table 15.2](#)). To convert from Woods units to dynes/s/cm⁵, the result is multiplied by 80. Similarly, to calculate pulmonary vascular resistance, the pulmonary artery occlusion pressure (a surrogate for the left atrial pressure) is subtracted from the mean pulmonary arterial pressure, and the result is divided by CO. The same conversion from Woods units applies. Obtaining CO and calculating SVR can often aid in narrowing a differential diagnosis in various types of shock. An Svo₂ can also assist in narrowing the differential. Together, this information can guide therapeutic intervention toward inotropic support, volume administration, titration of vasopressors, or consideration of mechanical assist devices. In cardiogenic shock, for example, CO will be low, SVR high, and mixed venous saturation low. This is in contrast to vasodilatory or septic shock in which CO will be high, SVR low, and mixed venous saturation usually high. Normal hemodynamic values are listed in [Table 15.3](#).

TABLE 15.3

Normal hemodynamic values

Cardiac index = 2.4 L per minute

Cardiac output = 5-7 L per minute

Stroke volume = 70-90 mL (1 mL/kg)

MAP = 60-90 mm Hg

CVP = 5-10 mm Hg

SVR = 800-1,200 dyne/s/cm⁵

PVR = <250 dyne/s/cm⁵

PAOP = 6-12 mm Hg

Mean PAP = 10–20 mm Hg

Abbreviations: CVP, central venous pressure; MAP, mean arterial pressure; PAOP, pulmonary artery occlusion pressure; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

Pathophysiology

Ischemic Heart Disease

Ischemic heart disease refers to atherosclerosis of the coronary arteries that obstructs blood flow to the myocardium resulting in either stable symptoms, which can be medically managed, or unstable acute coronary syndromes (ACS), which may call for more invasive intervention such as revascularization by percutaneous coronary intervention (PCI) or coronary artery bypass graft surgery. The development of atherosclerosis is an inflammatory process mediated by adherent leukocytes (phagocytes and T lymphocytes), cytokines, and smooth muscle cells that generate a lipid-rich necrotic plaque.³⁷⁻³⁹ Coronary microvascular disease is an important consideration in patients with a nonobstructive cardiac catheterization, who may also be at risk for major adverse cardiac events.⁴⁰ Risk factors for ischemic heart disease include diabetes, renal impairment, hypertension, cigarette smoking, hyperlipidemia, and abdominal obesity.

The ACS are categorized as non-ST elevation ACS (including unstable angina) or ST elevation MI (STEMI). All suspected patients are evaluated with a 12-lead ECG and troponin. For patients with possible ACS and negative workup, coronary CT angiography is recommended (class IIa).⁴¹

Those with suspected non-ST elevation ACS are managed with dual antiplatelet therapy (DAPT), anticoagulation, and either an ischemia-guided strategy (initial noninvasive evaluation for low risk patients) or early invasive strategies. Invasive strategy includes evaluation with diagnostic angiography for consideration of PCI or coronary artery bypass graft. Timing depends on patient stability and symptoms and classified as immediate (<2 hours), early (within 24 hours), or delayed (25-72 hours).^{41,42}

Medical management of stable ischemic heart disease begins with risk factor reduction. β Blockade has been shown to confer a survival benefit in patients with prior MI or a low ejection fraction and decreases myocardial oxygen consumption. Oral or sublingual nitrates are effective in angina prophylaxis or during acute episodes. Antiplatelet agents such as aspirin are indicated unless bleeding precludes their use.⁴³⁻⁴⁵ A DAPT is indicated for patients who have received a PCI. The duration of DAPT depends on the indication for PCI and type of stent, either bare metal or drug eluting. For those patients receiving a drug-eluting stent after an MI, DAPT is indicated for a year.^{46,47} Longer duration of DAPT can be considered by calculating a DAPT score.⁴⁸ Both prasugrel and ticagrelor have been shown to be superior to clopidogrel after MI when combined with aspirin.^{49,50} In a recent study, prasugrel was shown to be superior to ticagrelor in ACS with a lower incidence of death, MI, and stroke. Both groups had similar rates of bleeding.⁵¹ Guidelines will continue to evolve based on this literature. Statins are indicated for their lipid-lowering effects and antiinflammatory properties. Angiotensin-converting enzyme inhibitors assist in ventricular remodeling after MI and are class I indicated in patients with chronic kidney disease or LV ejection fraction <40%, hypertension, or diabetes mellitus.⁴¹ Diuretics optimize volume status and provide symptom relief in patients with heart failure.

Heart Failure

Heart failure is defined as “a complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood.”⁵²⁻⁵³ The underlying etiologies are numerous and include ischemia, hypertension, and diabetes. Other less common causes are valvular heart disease, infections such as viral myocarditis, toxins (alcohol, chemotherapeutic agents), and obesity.^{54,55}

The American College of Cardiology/American Heart Association and the New York Heart Association functional classifications describe heart failure according to symptoms (**Table 15.4**). Heart failure can also be classified by ventricular function or ejection fraction. Heart failure with preserved ejection fraction, or diastolic heart failure, comprises those patients with an ejection fraction greater than 50% with echocardiographic evidence of abnormal diastolic function, an impairment in relaxation, and ventricular filling. The most important risk factor for diastolic heart failure is hypertension. Diastolic heart failure is more common in the elderly, female, and obese populations^{55,56} and has now surpassed systolic heart failure as the leading class of heart failure.⁵⁷ Hospitalizations for heart failure with preserved ejection fraction are increasing over time, with minimal advancement in treatment modalities.⁵⁸ Risk factor modification including treatment of underlying hypertension is imperative.

TABLE 15.4

ACCF/AHA stages of HF and NYHA functional classification

ACCF/AHA stages of HF	NYHA functional classification	
A At high risk for HF but without structural heart disease or symptoms of HF		None
B Structural heart disease but without signs or symptoms of HF	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF.
C Structural heart disease with prior or current symptoms of HF	I II III	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF. Slight limitation of physical activity. Comfortable at rest but ordinary physical activity results in symptoms of HF. Marked limitation of physical activity. Comfortable at rest but less than ordinary activity causes symptoms of HF.
D Refractory HF requiring specialized interventions	IV	Unable to carry on any physical activity without symptoms of HF or symptoms of HF at rest
	IV	Unable to carry on any physical activity without symptoms of HF or symptoms of HF at rest

Abbreviations: ACCF, American College of Cardiology Foundation; AHA, American Heart Association; HF, heart failure; NYHA, New York Heart Association.

Heart failure with reduced ejection fraction occurs in patients with an ejection fraction less than 40%. Patients often have concomitant diastolic dysfunction. One of the main risk factors for heart failure with reduced ejection fraction is coronary artery disease. Treatment modalities range from oral medication to intravenous inotropes to mechanical assist devices. Diuretics, angiotensin-converting enzyme inhibitors, and β -blockers have been the foundation of medical management. Digoxin provides symptom relief and decreases hospital admissions, although it has no mortality benefit.⁵⁹ It can be useful in patients with associated atrial fibrillation to control heart rate. Patients with decompensated systolic heart failure may require acute positive inotropic therapy with milrinone, dobutamine, or epinephrine. More invasive methods to support the failing ventricle include intra-aortic balloon counterpulsation, ventricular assist devices, and cardiac transplantation.^{60,61} New ventricular assist device technology is rapidly evolving, and the use of a fully magnetically levitated LV assist device, a centrifugal pump, known as the HeartMate 3 (Abbott, Santa Clara, CA), has been shown to have a decreased incidence of stroke and reoperation for device thrombosis compared to the earlier generation axial flow HeartMate II (Abbott, Santa Clara, CA) LV assist device.^{62,63} Both hemorrhagic and ischemic strokes, either disabling or nondisabling, have been associated with markedly reduced long-term survival with LV assist device therapy.⁶⁴

Valvular Heart Disease

Aortic Stenosis

Aortic stenosis is the most common valvular heart disease in elderly patients. It occurs as the trileaflet aortic valve calcifies with age, with congenitally bicuspid aortic valves in a younger patient population, or secondary to rheumatic heart disease. Symptoms usually develop when the valve area is less than 1 cm^2 , considered within the severely stenotic range. The typical presentation is either chest pain, syncope, or dyspnea (ie, heart failure) at which time patients are estimated to have a 5-, 3-, or 2-year 50% mortality, respectively.⁶⁵ Other conditions that may resemble aortic stenosis include hypertrophic cardiomyopathy, supravalvular stenosis, or subaortic membrane. The ventricle usually hypertrophies as a compensatory response to the increased afterload of the stenotic orifice, and diastolic dysfunction is a common finding. Even with normal coronary arteries, patients are at risk for subendocardial ischemia due to the severity of LVH. Hemodynamic optimization of these patients, especially during induction of anesthesia, includes maintaining adequate preload, a higher MAP, and lower heart rate. This allows more time for ventricular filling in the noncompliant heart while maintaining acceptable systemic perfusion to compensate for the increased transvalvular pressure gradient and relatively fixed CO.

Aortic Insufficiency

Aortic insufficiency can develop acutely or be more chronic in nature. Acute aortic insufficiency can be a result of trauma, endocarditis, or dissection. The pathophysiology of the two entities differs given that with chronic regurgitation, the ventricle has time to compensate by dilating and increasing diastolic compliance. This does not occur if the regurgitation occurs acutely. Aortic regurgitation in type A aortic dissection can be due to annular and aortic root dilation, asymmetric cusp coaptation due to pressure from a false lumen, flail aortic cusp due to annular disruption, or prolapse of the intimal flap through the valve ([Figure 15.19](#)).⁶⁶ Acute, severe aortic insufficiency results in severe elevation in LV end diastolic pressure and can cause presystolic closure of mitral valve during diastole, diastolic mitral regurgitation, acute pulmonary edema, and heart failure.⁶⁶

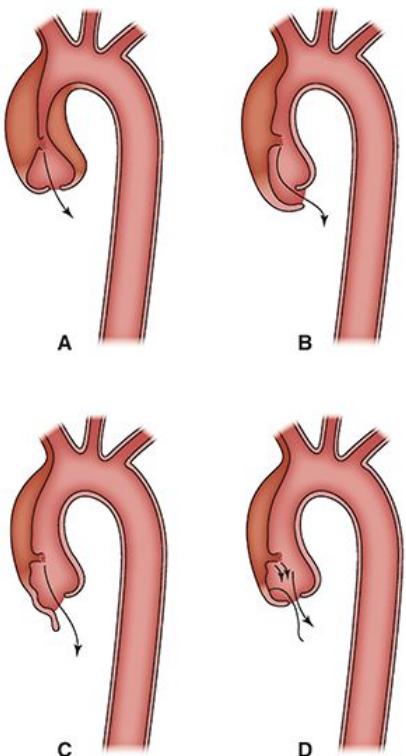

FIGURE 15.19 A-D, Mechanism of aortic regurgitation in proximal aortic dissection. Reprinted from Isselbacher EM, Eagle KA, Desanctis RW. Diseases of the aorta. In: Braunwald E, ed. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. Vol 2. 5th ed. Philadelphia, PA: Saunders Co.; 1997:1557. Figure 45-8. Copyright © 1997 Elsevier. With permission.

Chronic aortic insufficiency is characterized by volume and pressure overload of the left ventricle. Class I indications for surgery for severe aortic insufficiency include an ejection fraction of less than 50%, symptoms related to aortic insufficiency, and patients undergoing cardiac surgery for another reason.^{67,68} Patients with chronic aortic insufficiency often have a dilated LV cavity as a result of volume overload, and surgery is a reasonable consideration in asymptomatic patients with an LV end diastolic dimension of greater than 65 mm or an LV end systolic dimension of greater than 50 mm (class II recommendation).⁶⁸

Mitral Stenosis

Mitral stenosis is most often due to rheumatic heart disease, although it can be congenital or degenerative as well. With rheumatic mitral stenosis, thickening and fusion of the mitral commissures and leaflets and chordal thickening leads to a restricted orifice. Symptoms related to mitral stenosis are secondary to volume and pressure overload of the pulmonary circulation due to a fixed obstruction to LV filling. The LV end diastolic and ESVs are lower compared to a normal heart due to the left atrial-LV pressure gradient. Hemodynamic goals include avoiding tachycardia, which further decreases diastolic filling time. Any factors that further increase pulmonary hypertension should be avoided.

Mitral Regurgitation

Etiologies of mitral valve regurgitation include degenerative disorders; rheumatic disorders; congenital disorders; and disorders related to coronary artery disease, endocarditis, or trauma. Characterizing the mechanism of mitral regurgitation, when severe, helps decide whether repair or replacement is feasible.⁶⁹ Mitral regurgitation can be a result of annular dilation, excessive leaflet motion (prolapse or flail), or restricted leaflet motion. The Carpentier classification describes the mechanisms of various types of mitral regurgitation.⁷⁰ Carpentier class I refers to functional mitral regurgitation related to a dilated annulus, class II

refers to excessive leaflet motion in which the regurgitant jet is directed away from the degenerative leaflet, and class III refers to restricted leaflet motion in which the regurgitant jet is ipsilateral to the effected leaflet or central in the case of bileaflet restriction ([Figure 15.20](#)). Class IIIa is restricted leaflet motion involving the subvalvular apparatus (chordae and papillary muscles) seen in rheumatic heart disease. Class IIIb is restricted leaflet motion that often accompanies ischemic heart disease, in which the subvalvular apparatus is unaffected, although ventricular wall motion may be compromised. Traditionally, mitral repair with preservation of the chordal apparatus has been favored over replacement, with evidence of decreased mortality and improvement of ejection fraction, although some more recent studies have suggested otherwise.[71–74](#)

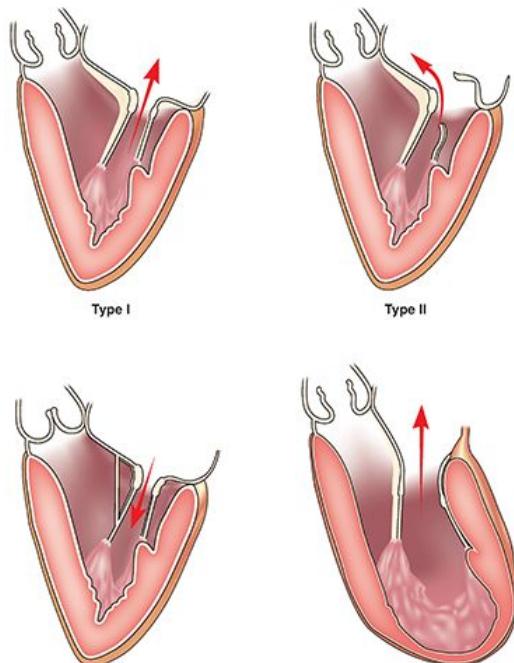

FIGURE 15.20 Carpentier classification of patients with mitral regurgitation (MR). Type I MR: normal leaflet length and motion but with annular dilation or leaflet perforation; type II MR: caused by leaflet prolapse, usually from myxomatous disease, papillary muscle rupture, or elongation; type IIIa MR: rheumatic disease with subvalvular involvement; type IIIb MR: caused by ischemic or idiopathic cardiomyopathy causing tethering or restriction of leaflets. Republished with permission of McGraw Hill LLC from Filsoufi F, Adams DH. *Surgical treatment of mitral valve endocarditis*. In: Cohn LH, Edmunds LH Jr, eds. *Cardiac Surgery in the Adult*. 2nd ed. New York, NY: McGraw-Hill, 2003:987-997; permission conveyed through Copyright Clearance Center, Inc.

Indications for surgical intervention in valvular heart disease include the following considerations: the presence of symptoms, the severity of the valvular lesion, the response of the ventricles to the volume and pressure overload, the effects of this overload on the pulmonary and systemic circulations, and the development of arrhythmias related to the lesions.[68](#) Patient comorbidities may make percutaneous procedures more favorable. The development and the transcatheter aortic valve implantation procedures, for example, offer an alternative to open heart surgery in those patients with severe aortic stenosis who are high-, intermediate-, and low-risk surgical candidates with improved survival and decreased risk of stroke.[75](#) Patients with endocarditis or bicuspid valves were excluded from these trials.[76–81](#)

Cardiac Dysrhythmias

During the perioperative period, changes may take place that trigger cardiac dysrhythmias. It is important to monitor for arrhythmias throughout this time, as they may cause hemodynamic instability and increase

morbidity and mortality. The incidence varies according to the type of surgery, morphology of arrhythmia, the form of monitoring (continuous vs intermittent), and the patient's history. A multicenter study with 17,201 patients undergoing a variety of procedures concluded that 70.2% had dysrhythmias (bradycardia, tachycardia, other arrhythmias) and 1.6% of these needed treatment.⁸² Bertrand et al⁸³ reported an incidence of 84% and noted that arrhythmias presented more often during the endotracheal intubation and extubation phases. Atlee⁸⁴ reported in patients undergoing cardiothoracic surgery, the incidence of some arrhythmia may exceed 90% with continuous monitoring. Melduni et al⁸⁵ reported it ranges from 4% to 20% for noncardiothoracic surgeries.

Etiology

Perioperative cardiac dysrhythmias are most likely to occur in patients with preexisting heart disease (coronary artery disease, valvular heart disease, or cardiomyopathies). Transient physiologic imbalances during the perioperative period make the heart more susceptible to abnormalities in the automaticity of pacemaker cells, the excitability of myocardial cells, and the conduction of the cardiac impulse.

Factors that may contribute to such imbalances include the following:

- Laryngoscopy, endotracheal intubation, ischemia, and release of catecholamines
- Electrolyte abnormalities, hypoxia, carbon dioxide levels, and pH changes
- Inhalation anesthetics, succinylcholine, anticholinesterase-anticholinergic combination reversal, most serotonin type 3 antagonists, droperidol, domperidone, and antiarrhythmics may prolong the QT interval and trigger arrhythmias.
- Extensive blockade of the sympathetic system by subarachnoid local anesthetics may produce bradyarrhythmias and prolong the QT interval.⁸⁶
- Ketamine due to its cardiovascular-stimulating properties
- Direct stimulation of the heart during cardiothoracic procedures and catheter insertion or stimulation of the autonomic nervous system (vagal response)

Mechanisms of Arrhythmia

Automaticity

Automaticity of the heart is its ability to spontaneously generate an electrical impulse to initiate contraction. Any cell of the cardiac conduction system can trigger its own action potential and act as a pacemaker, including cells in the SA node, the AV node, and specialized conducting fibers of the atria and ventricles. Normally, the highest rate of spontaneous depolarization occurs in the SA node, making it the dominant pacemaker in the heart. Abnormal automaticity of any part of the conduction system can lead to arrhythmias.

The resting membrane potential of the pacemaker cells is -60 to -70 mV, whereas in the cardiac muscle cells, it is -90 mV. When the membrane voltage reaches this threshold negative charge, reduction of the potassium efflux and slow influx of sodium (funny current) and calcium (T-type calcium channels) occur. This leads to the initiation of spontaneous depolarization during phase 4 of the cardiac action potential. Because this phase corresponds to diastole, it is also called **diastolic depolarization**. When the threshold potential is achieved (-40 mV), phase 0 is triggered mostly through activation of L-type calcium channels. Repolarization occurs during phase 3 when the potassium channels open and calcium channels close. Efflux of potassium causes the return to the resting membrane potential. Once a cell depolarizes, it is no longer excitable, being refractory to all stimuli. After this absolute refractory period, cardiac cells enter a relative refractory period during which only a greater than normal stimuli can cause cardiac cell membranes to depolarize ([Figure 15.21](#)).

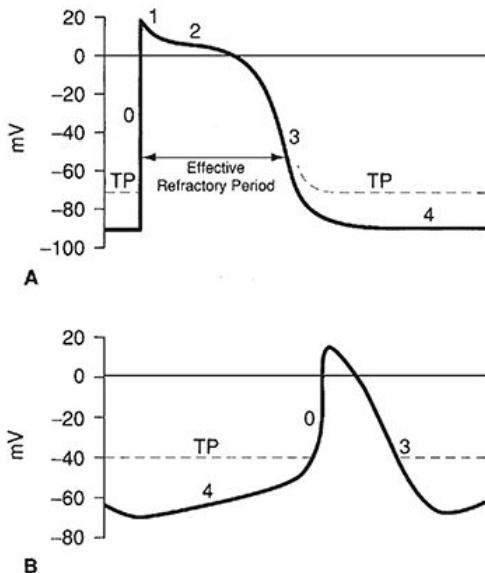

FIGURE 15.21 Cardiac action potential recorded from a ventricular contractile cell (A) or an atrial pacemaker cell (B). TP, threshold potential.

Excitability

Excitability is the ability of the cardiac cell to respond to a stimulus by depolarizing. A measure of excitability is the difference between the resting transmembrane potential and the threshold potential of the cell. The smaller the difference between these potentials, the more excitable or irritable is the cell. Therefore, enhanced automaticity occurs if the threshold potential becomes more negative or the resting membrane potential less negative. The opposite happens in hyperpolarization (Figure 15.22). Acetylcholine released from M_2 receptors during parasympathetic stimulation increases the conductance of the slow potassium channels (the outward flux of potassium). This causes hyperpolarization of the resting membrane potential and increases the membrane potential difference necessary to overcome in order to reach the threshold potential, decreasing excitability. Acetylcholine also decreases the conductance of the sodium channels (influx of sodium), which leads to slower depolarization and decreased automaticity.⁸⁷ Sympathetic stimulation through β_1 receptors increases the conductance of the sodium channels resulting in the depolarization threshold potential being reached more quickly and increased heart rate.

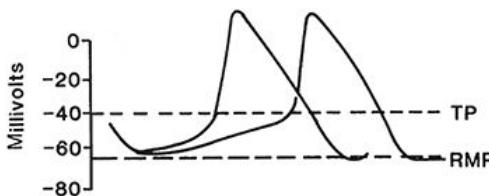

FIGURE 15.22 The rate of pacemaker discharge is dependent on the slope of spontaneous phase 4 depolarization, negativity of the threshold potential (TP), and negativity of the resting transmembrane potential (RMP).

Ectopic Pacemaker

An ectopic pacemaker (abnormal focus) manifests as a premature contraction of the heart that occurs between normal beats. A depolarization wave spreads outward from the ectopic pacemaker and initiates the premature contraction. The ectopic pacemaker may become persistent and assume the role of the dominant pacemaker in place of the SA node. The AV node and the bundle of His are the most common areas for the presence of

an ectopic pacemaker. Impulses generated outside the SA node follow a different pathway in the conduction system (usually slower) generating a change in the configuration of the QRS wave on the ECG.

Types of Dysrhythmias

A systematic approach in reading the ECG is essential for accurate diagnosis and correct treatment. It is important to determine the rate and rhythm, the appearance of the P waves and their relation to the QRS, and the morphology of the QRS complex ([Table 15.5](#)).

TABLE 15.5

Diagnosis of cardiac dysrhythmias from the electrocardiogram

- Are P waves present, and what is their relationship to the QRS complexes?
- Are the amplitudes, durations, and contours of the P waves, P-R intervals, QRS complexes, and Q-T intervals normal?
- During tachycardia, is the R-P long and P-R interval short (or vice versa)?
- What are the atrial and ventricular discharge rates (same or different)?
- Are the P-P and R-R intervals regular or irregular?

Heart Block

Heart block may occur at the SA node, the AV node, or the bundle branches. Causes of heart block include ischemia, age-related degeneration of the conduction system, drug-induced depression of the impulse propagation (digitalis, β -adrenergic antagonists), excessive parasympathetic nervous system stimulation, pressure on the conduction system by atherosclerotic plaques, or direct stimulation of heart by devices such as wires and catheters.

First-degree AV heart block is considered to be present when there is still one-to-one AV conduction but the P-R interval is longer than 0.2 second at a normal heart rate ([Figure 15.23](#)). Second-degree AV heart block is present when some AV conduction still is present but does not occur with every beat. It is classified as Mobitz type I (Wenckebach phenomenon) ([Figure 15.24](#)) or Mobitz type II heart block ([Figure 15.25](#)). Wenckebach phenomenon is characterized by a progressive beat-to-beat prolongation of the P-R interval until conduction of the cardiac impulse is completely interrupted and a P wave is recorded without a subsequent QRS complex. After this dropped beat, the cycle is repeated. Mobitz type II heart block is the occurrence of a nonconducted atrial impulse without a prior change in the P-R interval and is considered a higher degree of AV block than Mobitz type I.

FIGURE 15.23 First-degree atrioventricular block.

FIGURE 15.25 Mobitz type II. Republished with permission of McGraw Hill LLC from Patel AM. *Lange Instant Access EKGs and Cardiac Studies*. New York, NY: McGraw-Hill, 2010; permission conveyed through Copyright Clearance Center, Inc.

Third-degree AV heart block is present when there is no conduction of beats from the atria to the ventricles. The P waves are dissociated from the QRS complexes, and the heart rate depends on the intrinsic discharge rate of the ectopic pacemaker beyond the site of conduction block. If the ectopic pacemaker is near the AV node, the QRS complexes appear normal and the heart rate is typically 40 to 60 beats per minute ([Figure 15.26](#)). When the site of the block is infranodal, the escape ventricular pacemaker often has a discharge rate of less than 40 beats per minute and the QRS complexes are wide, resembling a bundle branch block ([Figure 15.27](#)).

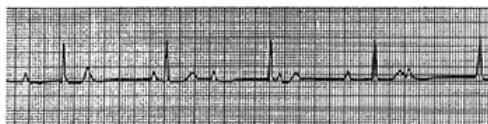

FIGURE 15.26 Third-degree atrioventricular heart block occurring at the level of the atrioventricular node (QRS complexes are narrow). There is no relation between the P waves and QRS complexes.

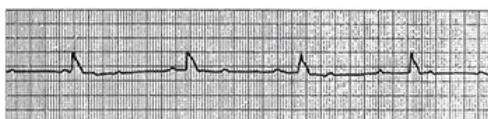

FIGURE 15.27 Third-degree atrioventricular heart block occurring at an infranodal level (QRS complexes are wide).

Patients may experience syncope (Stokes-Adams syndrome) at the onset of third-degree heart block, reflecting the 5- to 10-second period of asystole that may precede the initiation of an ectopic ventricular pacemaker. Occasionally, the interval of ventricular standstill at the onset of third-degree heart block is so long that death occurs. The treatment of patients with third-degree heart block usually requires insertion of a permanent artificial cardiac pacemaker. Temporary support may be provided with intravenous infusion of isoproterenol (chemical cardiac pacemaker) or a transvenous artificial cardiac pacemaker. The safe perioperative management of patients with implanted rhythm control devices such as pacemakers and implantable cardioverter-defibrillators (ICD) requires a basic understanding of the classification, function, and emergency management of these devices.^{[88,89](#)}

Bundle Branch Block

Blockage of the impulse conduction through the right or left bundle branches results in delay of activation of the corresponding ventricle, called **bundle branch block**, which may be complete or incomplete. Hemiblock or fascicular block refers to the blockade of either the anterior or posterior fascicle of the left bundle branch. Left bundle branch block is clinically significant and cardiac disease must be ruled out. Right bundle branch is commonly seen in healthy individuals but may be caused by right heart enlargement from conditions such as atrial septal defect, chronic lung disease, or pulmonary embolism.

Electrocardiographic criteria for complete right bundle branch block ([Figure 15.28](#)) include QRS duration longer than 120 milliseconds; “M-shaped” QRS complex in V₁ and V₂ (RSR'); and slurred S wave in I, aVL, and V₅ and V₆. Complete left bundle branch block ([Figure 15.29](#)) is characterized by QRS longer than 120 milliseconds, M-shaped QRS complex (RSR') in V₆, and QS or RS in V₁.

Reentry

A reentry circuit is the most likely mechanism for supraventricular tachycardia, atrial flutter, atrial fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. Reentry (circus movements) occurs when the same cardiac impulse returns to its site of initiation through a circuitous pathway and reexcites the cardiac tissue.⁹⁰ This contrasts with automaticity, where each beat is initiated by a new impulse. Reentry circuits can develop at any place in the heart where there is an imbalance between conduction and refractoriness creating a slow and fast pathway. Causes of this imbalance include elongation of the conduction pathway such as occurs in dilated hearts (especially a dilated left atrium associated with mitral stenosis), decreased velocity of conduction of cardiac impulses as occurs with myocardial ischemia or hyperkalemia, and a shortened refractory period of cardiac muscle as produced by epinephrine or electric shock from an alternating current. Each of these conditions creates a situation in which cardiac impulses

conducted by normal Purkinje fibers can return retrograde through abnormal Purkinje fibers that are not in a refractory state (a reentry circuit). Reentry circuits can be eliminated by speeding conduction through normal tissues so cardiac impulses reach their initial site of origin when the fibers are still refractory or by prolonging the refractory period of normal cells so the returning impulses cannot reenter.

Preexcitation Syndrome

A preexcitation syndrome is present when atrial impulses bypass the AV node through an abnormal conduction pathway to produce premature excitation of the ventricle. Normally, the ventricles are protected from rapid atrial rates by the refractory period of the AV node. The most common accessory conduction pathway producing a direct connection (anatomic loop) of the atrium to the ventricle is known as **Kent bundle** (usually left atrium to left ventricle) ([Table 15.6](#)).⁹¹ Conduction via this accessory pathway produces the Wolff-Parkinson-White syndrome, most often manifesting as intermittent bouts of supraventricular tachyarrhythmias. Electrocardiographic features include short P-R interval (<0.12 second), slurring of the QRS (δ wave), and widening of the QRS (>0.12 second). Patients with preexcitation syndrome who are asymptomatic or have no history of tachyarrhythmia usually do not require treatment. According to the American College of Cardiology, avoiding medications that block the conduction through the AV node is recommended, as this may lead to promote anterograde conduction through the accessory pathway.⁹² Medications that slow the conduction down the pathologic pathway (procainamide, flecainide) are preferred. Elimination of the pathologic conduction pathway can be achieved with radiofrequency catheter ablation.⁹³

Sinus Tachycardia

Sinus tachycardia is usually defined as a sinus rhythm with a resting heart rate of greater than 100 beats per minute ([Figure 15.30](#)). A common cause of sinus tachycardia is sympathetic nervous system stimulation such as may occur during a noxious stimulus in the presence of low concentrations of anesthetic drugs.

Hyperthermia increases heart rate approximately 18 beats per minute for every degree Celsius increase. Other important causes of sinus tachycardia include hypoxia, hypercarbia, hypovolemia, drugs, hormones, and intrinsic cardiac abnormalities.

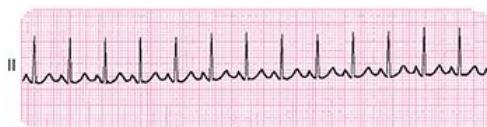

FIGURE 15.30 Sinus tachycardia. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Sinus Bradycardia

Sinus bradycardia is usually defined as a sinus rhythm with heart rate of less than 60 beats per minute ([Figure 15.31](#)) and may be caused by parasympathetic nervous system (vagal) stimulation of the heart. Other causes

may include hypoxia, medications, and cardiac conditions. Bradycardia that occurs in physically conditioned athletes reflects the ability of their hearts to eject a greater SV with each contraction compared with the less conditioned heart.

FIGURE 15.31 Sinus bradycardia. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Sinus Dysrhythmias

Sinus dysrhythmia, normal variation in the SA node rate, is present during normal breathing with heart rate (R-R intervals) varying approximately 5% during various phases of the resting breathing cycle ([Figure 15.32](#)). During inspiration, the heart rate increases, and during expiration, it decreases. This variation may increase to 30% during deep breathing. These variations in heart rate with breathing most likely reflect baroreceptor reflex activity and changes in the negative intrapleural pressures that elicit a waxing and waning Bainbridge reflex. Variation in heart rate that is not related to breathing (nonphasic sinus dysrhythmia) is abnormal and may be a result of SA node dysfunction, aging, or digitalis intoxication. In perioperative settings, sinus dysrhythmia is usually transient and often caused by autonomic nervous system imbalance as the result of an intervention (spinal or epidural anesthesia, laryngoscopy, surgical stimulation) or by the effects of drugs on the SA node.

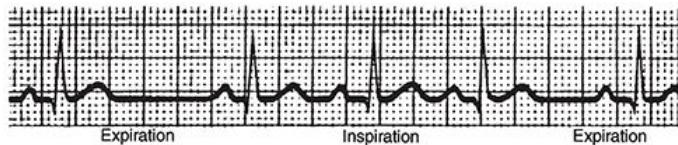

FIGURE 15.32 Sinus dysrhythmia reflecting changes in sinoatrial pacemaker activity with the breathing cycle.

Premature Atrial Contractions

Premature atrial contractions are recognized by an abnormal P wave and a shortened or prolonged P-R interval ([Figure 15.33](#)). The QRS complex of the premature atrial contraction has a normal configuration. The interval between the premature atrial contraction and the succeeding contraction is not an exact multiple of the normal P-P interval (noncompensatory pause) because the SA node is reset. Premature atrial contractions are usually benign and often occur in individuals without heart disease.

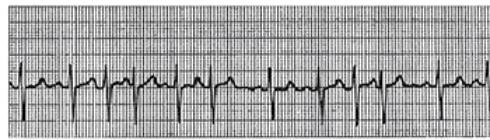

FIGURE 15.33 Premature atrial contractions resulting in an irregular rhythm.

Nodal (Junctional) Paroxysmal Tachycardia

Nodal paroxysmal tachycardia resembles atrial paroxysmal tachycardia except P waves may precede, follow, or be obscured by the QRS complex. It is common following heart surgery. Other causes include ischemia and digitalis intoxication.

Atrial Paroxysmal Tachycardia

Atrial paroxysmal tachycardia, which often occurs in otherwise healthy young individuals, is caused by rapid rhythmic discharges of impulses from an ectopic atrial pacemaker. The rhythm on the ECG is regular and the P waves are abnormal, often inverted, indicating a site of origin other than the SA node ([Figure 15.34](#)). The QRS complex is narrow. The rapid discharge rate of this ectopic focus causes it to become the pacemaker. Typically, the onset of atrial paroxysmal tachycardia is abrupt and may end just as suddenly with the pacemaker shifting back to the SA node. Atrial paroxysmal tachycardia may be terminated by parasympathetic nervous system stimulation of the heart with drugs or by carotid sinus massage. Drugs that increase refractoriness of the AV node (adenosine, calcium channel blockers, β -blockers) are preferred initial therapy for any narrow QRS paroxysmal supraventricular tachycardia.

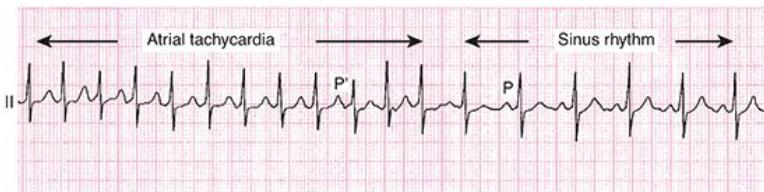

FIGURE 15.34 Atrial paroxysmal tachycardia. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. Clinical Anesthesia. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Atrial Fibrillation

Atrial fibrillation is characterized by normal QRS complexes occurring at a rapid and irregularly irregular rate in the absence of identifiable P waves ([Figure 15.35](#)). The irregular ventricular response reflects arrival of atrial impulses at the AV node at times that may or may not correspond to the refractory period of the node from a previous discharge. The SV is decreased during atrial fibrillation due to the loss of atrial contraction, which may contribute up to 30% to 40% in ventricular filling depending on the ventricular diastolic status and heart rate.

FIGURE 15.35 Atrial fibrillation. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. Clinical Anesthesia. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

A pulse deficit (heart rate by palpation is less than that of the ECG) reflects the inability of each ventricular contraction to eject a sufficient SV to produce a detectable peripheral pulse. Etiology of atrial fibrillation includes autonomic nervous system stimulation, ischemia, electrolyte imbalance, atrial dilation, infiltration or fibrosis, hyperthyroidism, hypertension, and sleep apnea. There is an estimated 5% annual risk of thromboembolism in patients with atrial fibrillation who are not treated with anticoagulants. Treatment includes rate control therapy, direct current cardioversion, pharmacologic cardioversion (flecainide, dofetilide, propafenone, ibutilide, and amiodarone), catheter ablation, and surgical Maze procedure. Patients with persistent atrial fibrillation should be considered for anticoagulation to prevent left atrial clot and thromboembolism.[94,95](#) The following medications are used for rate control: β -blockers, nondihydropyridine calcium channel antagonists (verapamil, diltiazem), digoxin, and amiodarone.

Atrial Flutter

Atrial flutter is a regular contraction of the atria at a rate of 250 to 300 beats per minute and on the ECG is characterized by 2:1, 3:1, or 4:1 conduction of atrial impulses to the ventricle ([Figure 15.36](#)). This occurs because the functional refractory period of Purkinje fibers and ventricular muscle is such that no more than 200 impulses per minute can be transmitted to the ventricles. The P waves have a characteristic saw-toothed appearance, especially in leads II, III, aVF, and V₁. Atrial flutter is seen commonly in patients with chronic pulmonary disease, dilated cardiomyopathy, myocarditis, ethanol intoxication, and thyrotoxicosis. This dysrhythmia may last minutes to hours before changing to sinus rhythm or atrial fibrillation. Treatment is similar to that of atrial fibrillation.

FIGURE 15.36 Atrial flutter. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Premature Ventricular Contractions

Premature ventricular contractions result from reentry or an ectopic pacemaker in the ventricles and are not preceded by a P wave. They are classified as unifocal or multifocal based on the morphology of the QRS depending on the number of sites of initiation. The QRS complex of the ECG is widened because the cardiac impulse is conducted through the slowly conducting muscle of the ventricle or an abnormal conduction pathway ([Figure 15.37](#)). The voltage of the QRS complex of the premature ventricular contraction is increased, reflecting the absence of the usual neutralization that occurs when a normal cardiac impulse passes through both ventricles simultaneously. The T wave of premature ventricular contractions usually has an electrical potential opposite that of the QRS complex. A compensatory pause after a premature ventricular contraction occurs because the next impulse from the SA node reaches the ventricle during its refractory period. When a premature ventricular contraction occurs, the ventricle may not have adequately filled to produce a detectable pulse. The subsequent pulse, however, may be increased due to added ventricular filling that occurs during the compensatory pause that typically follows a premature ventricular contraction.

FIGURE 15.37 Multifocal premature ventricular contractions. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Premature ventricular contractions often reflect significant cardiac disease. For example, myocardial ischemia may be responsible for initiation of premature ventricular contractions from an irritable site in poorly oxygenated ventricular muscle. Other causes include valvular heart disease, high-catecholamine state, hypoxia, hypercapnia, cocaine, alcohol, caffeine, electrolyte abnormalities, and medications. Treatment of premature ventricular contractions includes removal of trigger factors, β -blockers, calcium channel blockers, lidocaine, amiodarone, and radiofrequency ablation depending on the symptoms.

Ventricular Tachycardia

Ventricular tachycardia on the ECG resembles a series of ventricular premature contractions that occur at a rapid (200-300 beats per minute) and regular rate ([Figure 15.38](#)). It is classified as monomorphic or polymorphic and predisposes to ventricular fibrillation. Common causes of ventricular tachycardia are

myocardial ischemia, cardiomyopathies (dilated, hypertrophic, arrhythmogenic right ventricular cardiomyopathy), electrolyte abnormalities (potassium, magnesium, calcium), conditions that result in QT prolongation, drug toxicity, and congenital myocardial defects. The SV is often severely depressed during ventricular tachycardia because the ventricles have insufficient time for cardiac filling. Presentation may include palpitations, shortness of breath, chest pain, presyncope, syncope, and sudden cardiac arrest causing death.⁹⁶

FIGURE 15.38 Ventricular tachycardia. Reprinted with permission from Badescu GC, Sherman BM, Zaidan JR, et al. *Atlas of electrocardiography*. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. Clinical Anesthesia. 7th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013:1701-1720.

Nonsustained ventricular tachycardia may be defined as three or more consecutive ventricular beats at a rate greater than 100 beats per minute lasting less than 30 seconds and is usually asymptomatic.⁹⁷ Sustained ventricular tachycardia usually leads to hemodynamic instability and necessitates termination with electrical cardioversion. Therapies include correction of electrolyte abnormalities, ICD placement, β -blockers (sotalol, amiodarone), ablation, and revascularization.⁹⁶

Ventricular Fibrillation

Ventricular fibrillation is characterized on the ECG by an irregular wavy line with voltages that range from 0.25 to 0.5 mV (**Figure 15.39**). There is total absence of coordinated contractions with cessation of any effective pumping activity and disappearance of detectable pulse and systemic blood pressure. Ventricular fibrillation is usually initiated by a reentry mechanism. The only effective treatment of ventricular fibrillation is the delivery of direct electric current through the ventricles (defibrillation), which simultaneously depolarizes all ventricular muscle. This depolarization allows the initiation of a cardiac pacemaker remote from the irritable focus responsible for the ventricular fibrillation. Cardiopulmonary resuscitation must be initiated until a defibrillator becomes available. The survival rate of ventricular fibrillation may decrease by 7% to 10% for every minute that defibrillation is delayed, depending on the cardiopulmonary resuscitation quality. If defibrillation is delayed for more than 12 minutes, the survival rate is less than 5%.⁹⁸ It is important to identify the patients at risk for ventricular fibrillation and place a prophylactic ICD.⁹⁶
